8. **Fragile-X syndrome (see also page 1097). With the advent of new markers for the detailed structure of chromosomes, Lubs observed an unusual site of frequent breakage ("fragility") on the X chromosome and related it to a syndrome that includes mental retardation, flaring ears, elongated facies, slightly reduced cranial perimeter, normal stature, and enlarged testes. This chromosomal abnormality appears to be the most common inherited form of mental retardation (estimated to cause 1 case of retardation in every 1500 male births). Females, with their two X chromosomes, are affected about half as frequently, and then only to a slight degree. It is estimated that 10 percent of people older than 40 years have the fragile-X chromosome. In the female population, this figure seems correct. The fragile-X appears to be due to a heritable, CCG-unstable repeating sequence. Affected individuals have over 100 repeats and normal carriers have 40 to 200 repeats. The prolonged sequence inactivates a gene (FMR1) that codes for a RNA-binding protein. Rousseau and colleagues have described a simple and sensitive test, using DNA analysis, for the diagnosis of the syndrome both prenatally and after birth. Because the length of the triplet repeat relates to the degree of expression of retardation, the fragile-X alteration occasionally turns up in mentally normal males, and in some instances the male children of their daughters have the disease. In some of our cases, the intellectual deficit has been moderate in degree; the main abnormalities have taken the form of troublesome behavior, hyperactivity, an atypical type of gaze aversion, and asociality: These and other peculiar features of the syndrome and its unique pattern of inheritance (it is neither recessive nor dominant) have been discussed by Shapiro. At first, it was assumed that the fragile-X syndrome was only an example of the Renpenning syndrome (hereditary feeblemindedness in males with X-linked chromosomal disorder—see pages 635 and 1098), until it was pointed out that in this latter condition, stature was reduced, as was the cranial circumference, and that the X chromosomes of the Renpenning patients were not fragile.
In approximately 90 percent of patients with tuberous sclerosis, congenital hypomelanotic macules (formerly mistaken for “partial albinism” or “vitiligo”) appear before abnormalities.

Neurocutaneous diseases of this class. About half of all benign rhabdomyomas of the heart are associated with tuberous sclerosis, and, if located in the wall of the heart, may be found in the retina in or near the optic disc or at a distance from it. It is from this lesion, called a phakoma, that van der Hoeve derived the term that is applied to all phakomatoses (congenital ectodermoses). It is determined by a single autosomal dominant gene, the estimated prevalence of which is 1:50,000 to 1:300,000. The remaining cases are attributed to a gene mutation, the frequency of which is calculated to be 1:20,000 to 1:50,000. The disease involves many organs in addition to the skin and brain, and it may assume a diversity of forms, the least severe of which (i.e., the phakodeform) is difficult to diagnose; hence, one cannot be precise about the incidence of the disease. Tuberous sclerosis accounts for about 0.66 percent of the mentally retarded in institutions and 0.32 percent of the epileptics. The medical literature contains a number of reports of patients whose mentality is preserved and who have never had convulsions. It is likely that data drawn from mental hospital populations have exaggerated the overall frequency of mental retardation (Gomez).

**Etiology and Pathogenesis**

The abnormal gene has been localized to one of two sites—the long arm of chromosome 9, designated as TSC 1, and the short arm of chromosome 16, TSC 2. The former site is linked closely to the ABO blood group genes. The mutations are at loci of tumor-suppressor genes that are inactivated and this may, in part, explain the proclivity to develop various growths and hamartomas. Several hypotheses relating to neuronal migration or to the excessive secretion of growth factors have been proposed to link the inactivation of these genes with the pathogenesis of the characteristic lesions. The cellular elements within the lesions are abnormal in both number and size. The tumor-like growths in different organs may include cells of more than one type (e.g., fibroblasts, cardiac myoblasts, angioblasts, glioblasts, and neuroblasts), and their number is locally excessive. Something appears to have gone awry with the proliferative process during fetal life, for example. Whatever the initial symptom, the convulsive disorder and mental retardation become more prominent within 2 to 3 years. The facial cutaneous abnormality, the so-called adenoma sebaceum, appears later in childhood, usually between the fourth and tenth years, and is progressive thereafter.

**Clinical Manifestations**

The disease may be present at the time of birth (the diagnosis has been made by CT scan in neonates), but more often the infant is judged at birth to be normal. In approximately 75 percent of cases, attention is drawn to the disease initially by the occurrence of focal or generalized seizures or by retarded psychomotor development. As with any condition that leads to mental retardation, the first suspicion is raised by delay in reaching normal maturational milestones.

As the years pass, the seizures change pattern. In the first year or two they take the form of massive flexion spasms with hypersynchrony (irregular dysrhythmic bursts of high-voltage spikes and slow waves in the EEG). As many as 25 percent of our patients with these types of seizures have been found to have tuberous sclerosis. Later, the seizures change to more typical generalized motor and psychomotor attacks or atypical petit mal. Any one of the seizure types may be brief, especially if the patient is receiving anticonvulsant medication. Seizures are always the most reliable index of the cerebral lesions; focal neurologic abnormalities, which one might expect to occur from the size and location of the lesions, are distinctly uncommon.

Mental function continues to deteriorate slowly. Exceptionally there is a spastic weakness or mild choreoathetosis of the limbs and in a few cases an obstructive hydrocephalus. As in any state of severe mental retardation, a variety of nonspecific motor peculiarities—such as constant crying, muttering, stereotypical rocking and swaying movements, and digital mannerisms—may be observed. In nearly half of the cases, affective and behavioral derangements, often of hyperkinetic and aggressive type, are added to the intellectual deficiency.

The lack of parallelism in the severity of the epilepsy, mental deficit, and cutaneous abnormalities has been noted by all clinicians who have had a wide experience with this disease. Some patients are subject to recurrent seizures while retaining relatively normal mental function; in others, trivial skin lesions or a retinal phakoma may suggest the diagnosis in a mentally normal person with few seizures. In such cases, recognition may elude competent neurologists and dermatologists. As a general rule, early onset of seizures is predictive of mental retardation. Gomez and colleagues have suggested that the seizures damage the brain, a point with which we agree. However, it seems likely that both the epilepsy and mental retardation are the product of severe involvement of the brain by the lesions of tuberous sclerosis.

Limitation of space allows no more than a catalogue of other visceral abnormalities. In about half the cases, gray or yellow plaques (in reality gliomatous tumors) may be found in the retina or at a distance from it. It is from this lesion, called a phakoma, that van der Hoeve derived the term that is applied to all neurocutaneous diseases of this class. About half of all benign rhabdomyomas of the heart are associated with tuberous sclerosis, and, if located in the wall of the atrium, they may cause conduction defects. Other benign tumors of mixed cell type (angiomyolipomas) have been found in the kidneys, liver, lungs, thyroid, testes, and gastrointestinal tract. Cysts of the pleura or lungs, bone cysts in digits, and zones of marbling or densification in bones are some of the less common abnormalities.

In approximately 90 percent of patients with tuberous sclerosis, congenital hypomelanotic macules (formerly mistaken for “partial albinism” or “vitiligo”) appear before...
any of the other skin lesions (Fitzpatrick et al). They are arranged in linear fashion over the trunk or limbs and range in size from a few millimeters to several centimeters; their configuration is oval, with one end round and the other pointed, in the shape of an ash leaf. A Wood's lamp, which transmits only ultraviolet rays, facilitates the demonstration of the ash leaf lesions because of the absence of melanoblasts, which normally absorb light in the ultraviolet range (360-nm wavelength). These lesions become pink when rubbed and contain sweat glands; they are not usually present on the face or head. There is occasionally a white tuft of hair (poliosis). Electron microscopic examination shows a normal or reduced number of melanocytes, but their dopa reaction is reduced and melanosomes are small. Gold and Freeman as well as Fitzpatrick and colleagues have emphasized the frequency of these leukodermic lesions and their value in the diagnosis of tuberous sclerosis during infancy, before the appearance of other cutaneous lesions.

The well-developed facial lesions (adenomas of Pringle), pathognomonic of tuberous sclerosis, are present in 90 percent of patients over 4 years of age. Typically they are red to pink nodules with a smooth, glistening surface, and they tend to be limited to the nasolabial folds, cheeks, and chin; sometimes they also involve the forehead and scalp. Although called "adenoma sebaceum," these nodules are actually angiofibromas; the sebaceous glands are only passively involved (Fig. 38-5). The earliest manifestation of facial angiofibromatosis may be a mild erythema over the cheeks and forehead, intensified by crying. The occurrence of large plaques of connective tissue on the forehead is usually expressive of a severe form of the disease.

![Figure 38-5 Adenoma sebaceum of tuberous sclerosis.](image)

On the trunk, the diagnostic lesion is the "shagreen patch" (in reality a plaque of subepidermal fibrosis) found most often in the lumbosacral region. It appears as a flat, slightly elevated, flesh-colored area of skin 1 to 10 cm in diameter, with a "pigskin," "elephant hide," or "orange peel" appearance (Fig. 38-6). Another common site of fibromatous involvement is the nail bed; subungual fibromas usually appear at puberty and continue to develop with age. Other common skin changes, not in themselves diagnostic, include fibroepithelial tags (soft fibromas), café au lait spots, and port-wine hemangiomas.

![Figure 38-6 Shagreen patch on the skin of the lower back in a young patient with tuberous sclerosis.](image)

**Pathology** The brain exhibits a number of diagnostic anomalies. Broadening, unnatural whiteness, and firmness of parts of some of the cerebral convolutions are simulated by no other disease. These are the tubers after which the disease is named. On the surface of the brain, they range in width from 5 mm to 2 or 3 cm. Their cut surface reveals a lack of demarcation from cortex and white matter and the presence of white flecks of calcium; the latter, which are readily seen on CT scans and MRI, are called brain stones (see below). The walls of the lateral ventricles may be encrusted with white or pink-white masses resembling candle gutterings. When calcified, they appear in radiographs as curvilinear opacities that follow the outline of the ventricle. Rarely, nodules of abnormal tissue are observed in the basal ganglia, thalamus, cerebellum, brainstem, and spinal cord.

Under the microscope the tubers are seen to be composed of interlacing rows of plump, fibrous astrocytes (much like an astrocytoma, though lacking in glial fibrillar protein). In the cerebral cortex and ganglionic structures, derangements of architecture result from the presence of abnormal-appearing cells; greatly enlarged “monstrous” neurons and glial cells—often difficult to distinguish from one another, and displaced normal-sized neurons contribute to the chaotic histologic appearance. Gliomatous deposits may obstruct the foramina of Monro or the aqueduct or floor of the fourth ventricle, causing hydrocephalus. Neoplastic transformation of abnormal glial cells, a not infrequent occurrence, usually takes the form of a large-cell astrocytoma, less often of a glioblastoma or meningioma.

The phakomas of the retina are composed mainly of neuronal and glial components, but occasionally there is an admixture of fibrous tissue.

**Diagnosis** When the full combination of seizures and mental and dermal abnormalities are conjoined, the diagnosis is self-evident. It is the early stage of the disease and the forme fruste that give trouble, and here the experienced dermatologist can be of great help. Epilepsy—i.e., flexion spasms in infancy—and delay in psychomotor development are by no means diagnostic of tuberous sclerosis, since they occur in many diseases. It is in these cases and also in every sizable population of the epileptic or mentally retarded, especially when the family history is unrevealing, that a search for the dermal equivalents of the disease—the hypomelanotic ash-leaf spots, adenoma sebaceum, collagenous patch, phakoma of the retina, or subungual or gingival fibromas—is so rewarding. The finding of any of these one lesions provides confirmation of the partial and atypical case. Adenoma sebaceum may occasionally occur alone and is easily confused with acne vulgaris in the adolescent. The history of epilepsy and/or the demonstration of a dull mentality are helpful, but neither is a requisite for the diagnosis of tuberous sclerosis (Gomez).

The most useful laboratory measures for corroborating the disease are CT scanning and MRI (Fig. 38-7). The periventricular calcific lesions are particularly well shown on the CT scan, whereas MRI is more sensitive in detecting cortical lesions. A striking feature is an absence of edema in the surrounding tissue. An increasing number of cortical lesions demonstrated with MRI appears to correlate with an increased impairment of neurologic function (Rosch et al).
Neurofibromatosis of von Recklinghausen

Neurofibromatosis (NF) is a comparatively common hereditary disease in which the skin, nervous system, bones, endocrine glands, and sometimes other organs are involved in this proliferative process and the mechanism(s) by which it is accomplished are as unclear as in tuberous sclerosis.

The condition known as multiple idiopathic neuromas was the subject of a monograph by R. W. Smith in 1849; even at that time, he referred to examples recorded by other writers. It was von Recklinghausen, however, who in 1882 gave the definitive account of its clinical and pathologic features. The subsequent studies of the disease by Yaskov and Guthrie, Lichtenstein, Riccardi, and Martuza and Eldridge, and most recently by Créange et al and the comprehensive monographs of Crowe and Riccardi and their colleagues have provided a complete analysis of the clinical, pathologic, and genetic data pertaining to the disease.

Epidemiology Crowe and associates have calculated the prevalence of the disease to be 30 to 40 per 100,000 and expect one case in every 2500 to 3300 births. Approximately half of their cases had affected relatives, and in all instances the distribution of cases within a family was consistent with an autosomal dominant mode of inheritance. The disease has been observed in all races in different parts of the world, and males and females are about equally affected.

Cause and Pathogenesis The hereditary nature of NF has been appreciated for many years. More recently it has been established that NF comprises two distinct disorders, the genes for which are located on two separate chromosomes. The classic form of the disease, described below, has been shown by linkage analysis to be caused by a mutation located near the centromere on chromosome 17 (Barker et al). The second type, in which the main feature is bilateral acoustic nerve tumors, described further on, has been linked to a DNA marker on chromosome 22 (Rouleau et al). These two forms of NF have been loosely referred to as peripheral and central, respectively, but the terms neurofibromatosis type 1 and neurofibromatosis type 2 are less confusing (Martuza and Eldridge) and are used in the following discussion.

The pathogenesis remains obscure. Cellular elements derived from the neural crest (i.e., Schwann cells, melanocytes, and endoneurial fibroblasts, the natural components of skin and nerves) proliferate excessively in multiple foci, and the melanocytes function abnormally; but the hormones and growth factors that are involved in this proliferative process and the mechanism(s) by which it is accomplished are as unclear as in tuberous sclerosis.

Neurofibromatosis Type 1 (Classic, or Peripheral, NF) In the majority of patients, spots of hyperpigmentation and cutaneous and subcutaneous neurofibromatous tumors are the basis of clinical diagnosis. Pigmentary changes in the skin are nearly always present at birth, but neurofibromas are infrequent at that age. Both lesions increase in number and size during late childhood and adolescence. There may be a spurt of new lesions at puberty or during pregnancy. Exceptionally, a neurofibroma of a cranial nerve or a spinal root (sometimes with compression of the cord), disclosed during neurosurgical intervention, may be the initial manifestation of the disease. In the study of a large series of patients with neurofibromatosis (Crowe et al), approximately one-third were found to have the cutaneous manifestations while being examined for symptoms of some other disease; that is to say, the NF was asymptomatic. Usually these are the cases with the slightest degree of cutaneous abnormality. Of the remaining two-thirds, most consulted a physician because of the disfigurement produced by the tumors or because some of the neurofibromas were producing symptoms.

The patches of cutaneous pigmentations, appearing shortly after birth and occurring any place on the body, constitute the most striking clinical expression of the disease. They vary in size from a millimeter or two to many centimeters and in color from a light to dark brown (café au lait) and are rarely associated with any other pathologic state (Fig. 38-8). They do not appear to change in number as the patient ages but do become more pigmented. In a survey of pigmented spots in the skin, Crowe and associates found that 10 percent of the normal population had one or more spots of this type; however, anyone with more than six such spots, some exceeding 1.5 cm in diameter, nearly always proved to have von Recklinghausen disease. Of their 223 patients with NF, 95 percent had at least one spot, and 78 percent had more than six large ones. Freckle-like or diffuse pigmentations of the axillae and other intertriginous areas (groin, under breast), and small, round, whitish spots are characteristic and almost pathognomonic of the syndrome.

Figure 38-8 Typical large café au lait spot. The presence of six or more hyperpigmented lesions, each over 1.5 cm, is diagnostic of neurofibromatosis type 1.
When pressed, the soft tumors tend to invaginate through a small opening in the skin, giving the feeling of a seedless raisin or a scrotum without a testicle. This phenomenon, spoken of as "buttonholing," is useful in distinguishing the lesions of this disease from other tumors, e.g., multiple lipomas. A patient may have anywhere from a few of these dermal tumors to hundreds. The subcutaneous neural tumors, which are also multiple, take two forms: (1) firm, discrete nodules attached to a nerve or (2) an overgrowth of subcutaneous tissue, sometimes reaching enormous size. The latter, which are called plexiform neuromas (also pachydermatocele, elephantiasis neuromatosis, la tumeur royale), occur most often in the face, scalp, neck, and chest and may cause hideous disfigurement. When palpated, they feel like a bag of worms or strings; the bone underlying the tumor may thicken. Neurofibromas are easily distinguished from lipomas, which are soft, unattached to the skin or nerve, and not accompanied by any neurologic disorder. The only exceptions to this statement are rare cases of multiple symmetrical lipomatosis with axonal polyneuropathy (Launois-Beusaud disease). As a rule, congenital neurofibromas tend to be highly vascular and invasive and are especially prominent in the orbital, periorbital, and cervical regions. They are often accompanied by hypertrophy of a segment of the body. When the hypopigmentation overlies a plexiform neurofibroma and extends to the midline, one should suspect an intraspinal tumor at that level.

**Figure 38-9** Molluscum fibrosum non-neural skin tumors of von Recklinghausen disease.

Other abnormalities associated with type 1 (peripheral) NF include bone cysts, pathologic fractures (pseudoarthrosis), cranial bone defects with pulsating exophthalmos (sphenoid bone dysgenesis), bone hypertrophy, precocious puberty, pheochromocytoma, scoliosis, syringomyelia, nodules of abnormal gial cells in brain and spinal cord, and macrocephaly, rarely with obstructive hydrocephalus due to overgrowth of glial tissue around the sylvian aqueduct and fourth ventricle. Some degree of intellectual impairment is common (40 percent of Riccardi's series of 133 patients); but in our experience the figure is much less, and the impairment is usually not profound. Learning difficulty, developmental disorder, or hyperactivity have been more frequent abnormalities, occurring in almost 40 percent of patients. Rosman and Pearce have ascribed mental retardation in NF to congenital malformation of the cerebral cortex (cortical dysgenesis). The incidence of seizures is about 20 times higher than that in the general population. Headache, hydrocephalus, and tumors involving the optic pathways, meningiomas, gliomas, and malignant peripheral nerve tumors are common, even among adults, according to the survey of 158 patients by Créange and colleagues; also, pain was a common symptom in adults and often related to a malignant peripheral nerve sheath tumor.

Another unique finding is the Lisch nodule. This is a small whitish spot (hamartoma) in the iris (Fig. 38-10), present in 94 percent of Riccardi's type 1 cases but not found in patients with type 2 NF (bilateral acoustic neuromas) or in normal individuals (see below). Exceptionally, NF has been associated with peroneal muscular atrophy, congenital deafness, and partial albinism (Bradley et al.).

**Figure 38-10** Hamartomas of the iris (Lisch nodules), typical of neurofibromatosis, type 1.

In childhood, progressive blindness is a particularly troublesome complication. One or both optic nerves are involved in a tumor mass composed mainly of astrocytes. The diagnosis comes to mind at once in a child with any of the cutaneous manifestations of NF. Uncertainty as to its nature arises from the fact that the neuropathologist may be unable to decide between a benign hamartoma and a grade 1 astrocytoma. Enlargement in a succession of MRI scans may be needed to affirm its blastomatous nature.

**Neurofibromatosis Type 2 (Acoustic, or Central, NF)** In type 2 neurofibromatosis, as mentioned above, there is an absence or paucity of cutaneous lesions. Progressive deafness and the demonstration by enhanced CT or MRI of bilateral acoustic neuromas affords accurate diagnosis (Fig. 31-16). Other cranial or spinal neurofibromas, meningioma (sometimes multiple), and glioma may be added to the syndrome of deafness. This condition is considerably less frequent than type 1 NF.

**Pathology of NF1 and NF2** The cutaneous tumors are characterized by a rather thin epidermis whose basal layer may or may not be pigmented. The collagen and elastin of the dermis is replaced by a loose arrangement of elongated connective tissue cells. It lacks the compactness of the normal dermal collagen, which accounts for the palpable opening in the skin.

The pigmented (café au lait) lesions contain only the normal numbers of melanocytes; the dark color of the skin is due instead to an excess of melanosomes in the malpighian cells. Abnormally large melanosomes, measuring up to several microns in diameter, appear in some of the basal cells of the epidermis.

The nerve tumors are composed of a mixture of fibroblasts and Schwann cells (except the optic nerve tumors, which contain a combination of astrocytes and fibroblasts). Predominance of one or the other of these cells is the basis of the diagnosis of neurofibroma or schwannoma. Palisading of nuclei, sometimes encircling arrangements (Verocay bodies), is a feature of both. Occasionally, along spinal roots or sympathetic chains, one may find a tumor made up of partially or completely differentiated nerve cells (a typical ganglioneuroma). Clusters of abnormal glial cells may be found in the brain and spinal cord, and, according to Bielschowsky, they form a link with tuberous sclerosis. Clinically and genetically, however, the two diseases are quite independent.

Malignant degeneration of the tumors is found in 2 to 5 percent of cases; peripherally they become sarcomas, and centrally, astrocytomas or glioblastomas (Fig. 38-11).
Diagnosis If skin tumors and café au lait spots are numerous and Lisch nodules are present in the iris, the identification of the disease as type 1 neurofibromatosis offers no difficulty. A history of the illness in antecedent and collateral family members makes diagnosis even more certain. Uncertainty arises most frequently in patients with bilateral acoustic neuromas or other cranial or spinal neurofibromas or schwannomas with no skin lesions or only a few random ones although the tendency for these forms of NF to be accompanied by a paucity of skin lesions is well recognized. Plexiform neurofibromas with muscle weakness, due to nerve involvement, and abnormalities of underlying bone may be confused with other tumors, especially in young children, who tend to have few café au lait spots and few cutaneous neurofibromas. Hypertrophy of a limb, which may also occur, requires differentiation from other developmental anomalies.

As already mentioned, Crowe and coworkers believe that 80 percent of patients with von Recklinghausen disease can be diagnosed by the presence of more than six café au lait spots. Of those remaining 20 percent, those over 21 years of age will be found to have multiple cutaneous tumors, axillary freckling, and a few pigmented spots; in those under 21 with no dermal tumors and only a few café au lait patches, a positive family history and radiographic demonstration of bone cysts will be helpful in some instances. Café au lait spots and cutaneous tumors should always be sought, for they may help the neurologist diagnose an otherwise obscure progressive spinal syndrome, a cerebellar pontine angle syndrome, bilateral deafness, progressive blindness, and an occasional case of precocious puberty, hydrocephalus, or mental retardation.

Because of the many conditions that accompany classic neurofibromatosis and because they are potentially dangerous, the initial clinical evaluation should be supplemented by a number of ancillary investigations: measurement of IQ, EEG, slit-lamp examination of irides, radiography of optic foramen and internal auditory meatus, visual and auditory evoked responses, and CT scans or MRI of cranium and sometimes of spine and mediastinum. In the series of Duffner and colleagues, 72 percent of cases had abnormal signals in T2-weighted images of the basal ganglia, thalamus, hypothalamus, brainstem, and cerebellum. The EEG in their cases was abnormal in 25 percent. If there is suspicion of a pheochromocytoma, a 24-h urine should be tested for metabolites of epinephrine. Each of these tests not only is an aid to diagnosis but is essential to the intelligent management of the illness.

Treatment The skin tumors should not be excised unless they are cosmetically objectionable or show an increase in size, suggesting malignant change. The effects of radiotherapy are so insignificant that they do not justify the risk of exposure. Plexiform neurofibromas about the face offer especially difficult problems. Here one must resort to plastic surgery, but the results are not always satisfactory because the growth of tumors may involve cranial nerves superficially (with greater risk of paralysis after surgical excision) or alter the underlying bone, the latter being either eroded from pressure or hypertrophied from increased blood supply. Cranial and spinal neurofibromas are amenable to excision, and the glomas and meningo-angiofibromas usually demand surgical measures as well. Here the differentiation of hamartomas from gliomas of structures such as the optic nerves, hypothalamus, or pons may be difficult. Bilateral optic nerve gliomas are usually treated with radiation; unilateral ones are excised. Peripheral nerve tumors that have undergone malignant (sarcomatous) degeneration pose special surgical problems.

Affected individuals should be advised not to have children—a precaution that may not be necessary, because fertility, especially in males, seems to be reduced by the disease. Prognosis varies with the grade of severity, being most favorable in those with only a few lesions. But the disease is always progressive, and the patient should remain under continuous surveillance.

Cutaneous Angiomatosis with Abnormalities of the Central Nervous System

There are seven diseases in which a cutaneous or ocular vascular anomaly is associated with an abnormality of the nervous system: (1) meningio- or encephalofacial (encephalotrigeminal) angiomatosis with cerebral calcification (Sturge-Weber syndrome); (2) dermalomal hemangiomas and spinal vascular malformations (sometimes with limb hypertrophy, as in Klippel-Trenaunay-Weber syndrome); (3) the epidermal nevus (linear sebaceous neuromuscular syndrome); (4) familial telangiectasia (Osler-Rendu-Weber disease); (5) hemangioblastoma of cerebellum and retina (von Hippel-Lindau disease); (6) ataxia-telangiectasia (Louis-Bar disease); and (7) angiodysplasia corporis diffusum (Fabry disease). The last three disorders are considered elsewhere: ataxia-telangiectasia and Fabry disease with the inherited metabolic disorders (pages 1011 and 1037, respectively) and von Hippel-Lindau disease with intracranial neoplasms (page 705).

Meningo- or Encephalofacial Angiomatosis with Cerebral Calcification (Sturge-Weber Syndrome) A vascular nevus is observed at birth to cover a large part of the face and cranion on one side (in the territory of the ophthalmic division of the trigeminal nerve). In one-quarter of the cases the nevus is bilateral. The lesional variant in extent, the most limited being an involvement of only the upper eyelid and forehead and the most extensive being the entire head and even other parts of the body. The nevus is deep red (port-wine nevus), and its margins may be raised or flat; soft or firm papules, evidently composed of vessels, cause surface elevations and irregularities. Orbital tissue, especially the upper eyelid, is almost invariably involved; congenital buphthalmos may enlarge the eye before birth and glaucoma may develop later in that eye, causing blindness. The choroid is implicated in some cases. The increased cutaneous vascularity may result in an overgrowth of connective tissue and underlying bone, giving rise to a deformity like that of the Klippel-Trenaunay-Weber syndrome. Indicators of cerebral affection appear as early as the first year of life or later in childhood; the most frequent clinical manifestations are unilateral seizures followed by increasing degrees of spastic hemiparesis with smallness of the arm and leg, hemisensory defect, and homonymous hemianopia, all on the side contralateral to the trigeminal nerve. Skull films (usually normal just after birth) taken after the second year reveal a characteristic "tramline" calcification, which outlines the convolutions of the parieto-occipital cortex. CT scanning and MRI show the abnormalities of the involved cortex at an earlier age.

This condition is generally referred to as the Sturge-Weber syndrome, since it was W. Allen Sturge, in 1879, who originally described a child with sensorimotor seizures contralateral to a facial "port-wine mark," and Parkes Weber (1922, 1929), who gave the first radiographic demonstration of the atrophy and calcification of the cerebral hemisphere homolateral to the skin lesion. This eponym overlooks the important intervening contributions of Kalscher (1897, 1901), who first described the meningeval angioma in conjunction with the facial one; of Volland (1913), who demonstrated the intracranial calcific deposits; and of Dimitri (1923), who described the characteristic double-contoured radiographic shadows. Krabbe (1932, 1934) showed conclusively that the calcification lay not in the blood vessels (as Dimitri and many others had concluded) but in the second and third layers of the cortex (see Wohllin and Yakovlev for historical review and bibliography).

It must not be thought that all cranial hemangomas affect the cerebrum; facial nevi, especially the flat midline ones and the elevated strawberry nevi, are of no neurologic significance. And a cerebral meningeval angioma may be present without skin lesions. The involvement of the upper eyelid is of greatest importance; nearly all such cases are associated with cerebral lesions (Barlow). There seems to be a close correlation between the persistence or maldevelopment of the embryonic vascular plexus of the eyelid and forehead and that of the occipitoplatar parts of the brain. When the nevus lies entirely below the upper eyelid or on the scalp, a cerebral lesion is usually absent, although in a few instances such an angioma has been associated with a vascular malformation of the meninges overlying the brainstem and cerebellum. In angiograms, the abnormal meningeval vessels, which are largely veins, are not well seen; thus they can be distinguished from other hemorrhages. Meningeval vessels are rarely the source of subarachnoid or cerebral hemorrhage, and they do not enlarge to form a "mass lesion." The cortical lesion is destructive in type; lost neurons are replaced by glial tissue that calcifies. Possibly diversion of blood to the meninges during seizures causes the progressive ischemia of the cerebral cortex. Barlow believes the seizures to be responsible for the progressive neurologic deficits and that a special effort should be made to prevent them by carefully regulated medical therapy. Occasionally surgical excision of intractable discharging foci may be necessary, but often this may not be feasible in view of the magnitude of the cerebral lesion. Radiotherapy is unsuccessful in reducing the skin blemish; sensitive individuals usually try to hide it with cosmetics.

Although the encephalotrigeminal syndrome is of congenital origin, its cause and pathogenesis are unknown. Familial coincidence has been observed but is...
exceptional. No chromosomal abnormality has been demonstrated.

Dermatomal Hemangiomias with Spinal Vascular Malformations A hemangiomia of the spinal cord may rarely be accompanied by a vascular nevus in the corresponding dermatome, as first pointed out by Cobb. Such nevi are most frequent on the arm and trunk. When the cutaneous lesion involves an arm or leg, there may be enlargement of the entire limb or fingers in combination with underdevelopment of certain other parts of the body. Although symptoms are mild in some cases, a few have died of sudden massive hemorrhage into the brain. This is a closely related congenital neurocutaneous disorder in which a specific skin lesion (epidermal nevus or linear sebaceous nevus) is associated with a variety of hemianopic and neurologic abnormalities. The skull and brain abnormalities are ipsilateral to the nevus. One-sided thickening of the bone is characteristic. Mental retardation, seizures, and hemiparesis are the usual neurologic manifestations and have their basis in a wide variety of congenital abnormalities—unilateral cerebral atrophy, porencephalic cyst, leptomeningeal hemangioma, arteriovenous malformation, and atresia of cerebral arteries and veins. The somatic and neurologic abnormalities have been comprehensively reviewed by Solomon and Estes and by Baker and associates.

The Epidermal Nevus Syndrome This is a closely related congenital neurocutaneous disorder in which a specific skin lesion (epidermal nevus or linear sebaceous nevus) is associated with a variety of hemianopic and neurologic abnormalities. The skull and brain abnormalities are ipsilateral to the nevus. One-sided thickening of the bone is characteristic. Mental retardation, seizures, and hemiparesis are the usual neurologic manifestations and have their basis in a wide variety of congenital abnormalities—unilateral cerebral atrophy, porencephalic cyst, leptomeningeal hemangioma, arteriovenous malformation, and atresia of cerebral arteries and veins. The somatic and neurologic abnormalities have been comprehensively reviewed by Solomon and Estes and by Baker and associates.

Familial Telangiectasia (Osler-Rendu-Weber Disease) This, a vascular anomaly transmitted as an autosomal dominant trait, affects the skin, mucous membranes, gastrointestinal tract, and genitourinary tract, and occasionally the nervous system. The basic lesion is probably a defect in the vessel wall, and bleeding is thought to be due to the mechanical fragility of the vessel. The lesions range from the size of a pinhead to 3 mm or more; they are bright red or violaceous and blanch under pressure. Located sparsely in the skin of any part of the body, they first appear during childhood, enlarge during adolescence, and may assume spindle forms, resembling the cutaneous telangiectases of cirrhosis in late adult life. The significance of the lesions lies in their hemorrhagic tendency. During adult years they may give rise to epistaxis and intracranial hemorrhage as a result in an iron-deficient anemia. Pulmonary telangiectases may result in hemoptysis. An important feature of the generalized vascular dysplasia; patients with such lesions are particularly subject to brain abscesses and less so to bland embolic strokes.

The angomas of this disease may form in either the spinal cord or brain, where they produce apoplectic strokes; or as in one of our patients, an intermittently progressive focal thalamic syndrome resulting from enlargement of the vascular lesions (or possibly from a succession of small hemorrhages). An unexplained gastrointestinal, genitourinary, intracranial, or intraspinal hemorrhage warrants a search for small cutaneous lesions, which are easily overlooked. Caution eradicates a bleeding lesion, but satellite lesions tend to form.

Restricted Developmental Abnormalities of the Nervous System

In the course of clinical practice, one encounters a remarkable number of disorders of the nervous system, many of which are transmitted from generation to generation as mendelian dominant trait. Only a few of the more striking examples are described here. The reader may turn to books on genetics or terminology for an account of such oddities as hereditary unilateral piosis, hereditary Horner syndrome, pupillary inequalities, jaw wanking, absence of a particular muscle, etc.

Bifacial and Abducens Palsies (Möbius Syndrome) The syndrome of congenital facial diplegia with convergent strabismus is generally referred to as Möbius syndrome. It was first described by the Austrian Graefe. Its presence at birth is disclosed by the lack of facial movements and full eye closure. The most complete review of the subject in the English language is that of Horton. In his analysis of 61 cases of the congenital facial diplegia syndrome, there were 45 instances of abducens palsy, 15 of complete external ophthalmoplegia, 18 of lingual palsy, 17 of clubfeet, 13 of brachial disorders, 6 of mental defect, and 8 of an absent pectoral muscle. Thus the overlap with other neuromuscular and CNS abnormalities is evident. Early in life the mouth hangs open, the lower lip is everted, and there is difficulty in sucking. Usually this syndrome can be distinguished from the facial palsy of forceps or birth injury by its bilaterality and the other associated weaknesses. Occasionally more than one family member is affected (usually autosomal dominant inheritance). The cause of this peculiar condition is not known. The few adequate pathologic studies have shown a lack of nerve cells in the motor nuclei of the brainstem, changes that also characterize the Fazio-Londe syndrome (page 1162). Rarely, there may be an aplasia of facial muscles. The Möbius syndrome is also referred to on page 1531 in relation to restricted palsies of myopathic and neurologic origin.

Partial paralyses of facial muscles that dates from birth and cannot be attributed to obstetric trauma is not infrequent. In a common type, the lower lip on the involved side remains immobile when the child smiles or cries; the lip on the unaffected side is drawn downward and outward, resulting in a prominent asymmetry of the lower face. Often it is not appreciated that the side that droops during crying is the normal side (Nothelfer and Penny).

Congenital Lack of Lateral Gaze (Oculomotor Apraxia of Cogan; See page 278) Children with this congenital defect are unable to turn their eyes to either side volitionally or on command. Attempting to look to the right, the child turns the head to the right (there is no associated apraxia of head turning, as in the acquired condition), but the eyes lag and turn to the left. As a result, the patient has to overshoot the mark with the head in order to attain ocular fixation. Once the eyes fixate, the head returns to the primary position. To compensate for the deficiency of eye movements, the patient develops jerky thrusting movements of the head, which characterize all attempts at voluntary gaze. Caloric stimulation of the labyrinth causes tonic movement of the eyes but not nystagmus, as in the normal person. Also, optokinetic nystagmus cannot be induced. Vertical movements of the eyes are normal, however. A peculiar ocular movement may occur in conjunction with ataxia-telangiectasia and Gaucher disease. These children are slow to walk, and Ford observed one such child whose sibling had an absence of the vermis of the cerebellum. From this observation, the anatomic basis of this condition has not been studied.

CONGENITAL ABNORMALITIES OF MOTOR FUNCTION

Inheritance of congenital disorders, a major disturbance of motor function, usually nonprogressive, has been present since infancy or early childhood. The popular terms for some of these conditions have been infantile cerebral paralysis (Friedreich) and cerebral palsy. The latter name is not appropriate, nor is it useful from the physician's viewpoint, collocating, as it does, diseases of widely differing etiologic and anatomic types, wherein the hereditary and acquired and the intrauterine, natal, and postnatal diseases lose their identity. Unfortunately the name has been adopted as a slogan for fund-raising societies and for all manner of rehabilitation clinics throughout the United States, so that it will not soon disappear from medical terminology. The term often abbreviated "CFP" is still being used indiscriminately by laymen and physicians to designate every conceivable motor disorder of corticospinal, extrapyramidal, cerebellar, and even neuromuscular type in infants and children.

Etiology of the Congenital Cerebral Motor Disorders

Motor abnormalities that have had their onset early in life are numerous and diverse in their clinical manifestations. Marked prematurity is a determining factor in a large proportion of cases. Each year, about 50,000 infants weighing less than 1500 g are born in the United States. Approximately 85 percent survive, and of these, 5 to 15 percent have a motor disorder of cerebral origin and 25 to 30 percent are mentally impaired at school age (Volpe; see also Hack et al. To ascertain the etiologic and pathogenic factor(s), it is helpful to categorize a given case according to the extent and nature of the motor abnormality. A careful history of possible prenatal, perinatal, or postnatal insults to the developing nervous system must always be sought; certain correlations of these factors with the resulting pattern of neurologic deficit are outlined below. Most patients with these motor abnormalities of infancy and childhood reach adult years. Many of them have some degree of mental retardation and epilepsy in addition to the motor abnormalities, and there is an unavoidable overlapping in any consideration of the mechanisms of these three clinical states.

The following discussion of these problems is centered on three major etiologic syndromes—matrix hemorrhages in the immature infant, hypoxic-ischemic encephalopathy (Little disease), and certain developmental motor abnormalities.

Matrix (Subependymal) Hemorrhage in Premature Infants In low-weight immature infants (20 to 35 weeks gestational age), there often occurs, within a few days after birth, a catastrophic decline in cerebral function, usually preceded by respiratory distress (hyaline-membrane disease), with cyanosis and apneic spells. Also seen are failure of brainstem automatisms (sucking and swallowing), bulging of the fontanels, and appearance of sanguineous CSF. Once the infant becomes completely unresponsive, death usually ensues within a few days. Autopsy discloses a small lake of blood in each cerebral hemisphere (often asymmetrical), occupying the highly cellular (subependymal) germinal matrix, near the caudate nucleus at the level of the foramen of Monro. This region is supplied by the lenticulostriate, choroidal, and Heubner's recurrent arteries and is drained by deep veins, which enter the vein of Galen. In about 25 percent of cases, the blood remains localized in the matrix, while in the others it ruptures into the lateral ventricle or adjacent brain tissue. In a series of 914 consecutive autopsies in newborns, subependymal hemorrhage was found in 284 (31 percent); practically all of these neonates were of low birth weight (Banker and Bruce-Geggios)
lesions of lesser magnitude survive. Some rarely develop an obstructive hydrocephalus and require a ventricular shunt. In others, the hydrocephalus stabilizes and there is clinical improvement. Several series of surviving cases have now been followed for many years. Those in whom the hemorrhage was relatively more extensive are often left with motor and intellectual handicaps. In the Swedish series of Hagberg and Hagberg, 55 percent of the patients with spastic diplegia had preterm births and the neuropathologic basis was believed to be matrix hemorrhage, leukomalacia (see further on), or both. Congenital hemiplegia or quadriplegia are observed at lower frequency. In another series of 20 cases of posthemorrhagic hydrocephalus (Chapin et al.), 40 percent had significant motor deficits and over 60 percent had IQ scores of less than 85. In a personal experience with 12 less severe cases (mean birth weight 1.8 kg and gestational age of 32.3 weeks), only one had a residual spastic diplegia and 9 of the 12 had IQs in the low-normal or normal range. The average age of the children at the time of the last evaluation was 8.5 years.

Figure 38-12 Ultrasound demonstration of subependymal matrix hemorrhage in a premature infant (arrow).

The cause of this unique form of matrix hemorrhage is unsettled. In all probability it is related to greatly increased pressure in the thin-walled veins of the germinal matrix, coupled with a lack of adequate supporting tissue in these zones. The increased blood pressure or venous pressure is, in turn, manifestly related to the pulmonary disorders that occur in immature infants. These infants are also prone to the development of characteristic lesions of the cerebral white matter (periventricular leukomalacia, see below), and the residual neurologic deficits are the result of these lesions, added to the deficits due to the subependymal hemorrhage (mainly hydrocephalus). Acetazolamide and furosemide, which reduce the formation of spinal fluid and have been widely used in the treatment of posthemorrhagic ventricular dilatation, have been shown, in a large-scale controlled study, to be of little value in reducing the need for shunt placement (see International PHYD Drug Trial Group, in the References).

Periventricular Leukomalacia These are zones of necrosis of white matter in the deep watershed territories of cortical and central arteries. They lie lateral and posteroateral to the lateral ventricles, in a position to involve the occipital radiations and the sensorimotor fibers in the corona radiata (Banker and Larnroche; Shuman and Selednik). These white-matter lesions occur in about one-third of cases of subependymal hemorrhage, but they may develop independently in both premature and full-term infants who have suffered hypotension and apnea. In a study of 753 preterm infants, those born at 26 weeks gestation were at highest risk of this complication; the combination of intradural infection and premature rupture of membranes carried a 22 percent risk (Zupan et al.). Survivors often manifest cerebral diplegia and mental impairment. The motor disorder is usually more severe than the cognitive and language impairment.

Control of respiratory distress may reduce the incidence of matrix hemorrhages and periventricular leukomalacia. Claims have been made that the administration of indomethacin ethamsylate, a drug that reduces capillary bleeding, and the intramuscular injection of vitamin E for the first 3 days after birth and possibly the use of betamethasone reduce the incidence of periventricular hemorrhage (Benson et al.; Sinha et al.; see also Volpe for discussion of control of cerebral hemodynamics and effects of drugs in the neonatal period.)

Hypoxic-Ischemic Damage Little's conception of the hypoxic-ischemic form of "birth injury," enunciated in 1862, has been subjected to scrutiny over the years. While it is evident that many newborns suffer some degree of perinatal asphyxia, relatively few of them seem to manifest brain damage. Moreover, many infants with a variety of cerebral motor syndromes appear to have passed the parturitional (perinatal) period without mishap, indicating the greater importance of other prenatal and postnatal causative factors. Nonetheless, severe neonatal asphyxia of term or preterm babies is an important cause of spastic-dystonic-ataxic syndromes, often accompanied by seizures and mental subnormality.

One has the impression that the CNS tolerates hypoxia and reduced blood flow in the postnatal period better than at any other time in life. Indeed, animal experimentation supports this view. Not until the arterial O2 tension is reduced to 10 to 15 percent of normal does brain damage occur, and even then the impaired function of other organs contributes to the damage; nearly always there are irregularities of the heart and hypotension from myocardial damage as well as hepatic and renal failure. Thus it is more correct to think of the encephalopathy in terms of both hypoxia and ischemia, which usually occur in utero and are expressed postnatally by recognizable clinical syndromes.

As regards the cerebral syndromes that do follow an obviously difficult birth (reflected by low 5-min Apgar scores and the need of resuscitative measures), Fenichel finds it helpful to divide them into three groups, according to their severity: (1) In newborns with mild hypoxic-ischemic encephalopathy, the symptoms are maximal in the first 24 h and take the form of hyperalertness and tremulousness of the limbs and jaw (the "jittery baby") and a low threshold of the Moro reaction. The tone of the limbs is normal except for a mild increase in head lag during traction. The reflexes are brisk and there may be ankle clonus. The anterior fontanel is soft. The EEG is normal. Recovery is complete and the risk of handicap is extremely low. (2) Newborns with moderate hypoxic-ischemic encephalopathy are lethargic, obtunded, and hypotonic, with normal movements. After 48 to 72 h, the neonate may improve (having passed through a jittery hyperactive phase) or worsen, becoming less responsive in association with convulsions, cerebral edema, hypoventilation, and hyperammonemia from liver damage. The EEG is abnormal; Fenichel associates epileptiform activity and voltage suppression with an unfavorable outcome. Abnormal visual and auditory evoked potentials are other poor prognostic signs. (3) In neonates with severe hypoxic-ischemic encephalopathy, stupor or coma are present from birth; respirations are irregular, requiring mechanical ventilation. There are usually convulsions within the first 12 h. The limbs are hypotonic and motionless even in attempts to elicit the Moro response. Sucking and swallowing are depressed, but pupillary reactions and eye movements may at first be retained, only to be lost as the coma deepens.

It is in the second and third categories, i.e., the states of moderate to severe encephalopathy, where correction of the respiratory insufficiency and the metabolic abnormalities permits survival, that a number of motor abnormalities (corticospinal, extrapyramidal, and cerebellar) and mental retardation eventually emerge. Included in the category of severe hypoxic-ischemic encephalopathy are also newborns with a variety of developmental anomalies of the brain and other organs. In addition, they may have been exposed to certain prenatal risk factors (toxemia of pregnancy, antepartum uterine hemorrhage), or their growth may have been abnormal (small-for-date babies). Some are born at term; others are premature, and the birth process may or may not have been abnormal. One must then consider the possibility, originally pointed out by Sigmund Freud, that the abnormality of the birth process, instead of being causal, was actually the consequence of prenatal pathology. The latter might include preterm intraterine hypoxia-ischemia.

Other evidence of multifactorial etiology in the "causation" of cerebral palsy has been provided by Nelson and Ellenberg, who found that maternal mental retardation, birth weight below 2000 g, and fetal malformation were among the leading predictors. Breech presentation was another factor, and one-third of these cases also had a noncerebral malformation. Twenty-one percent of the 189 children in their series had also suffered some degree of asphyxia. Additional determinants were maternal seizures, a motor deficit in an older sibling, two or more prior fetal deaths, hyperthyroidism in the mother, pre-eclampsia, and eclampsia. In children with cerebral diplegia born at term, likely contributory factors that were operative in nearly half of them included toxemia of pregnancy, low birth weight for age (indicating undernutrition), placental infarction, and intraterine asphyxia.

The factors enumerated above are involved to different degrees in the outcome of pregnancies but are informative because they bring to light the significant proportion of cases of cerebral birth injury in which hypoxia-ischemia, matrix hemorrhages, and leukomalacia were not operative. In this last group, we would also include the symmetrical porencephalies and hydranencephalies (see also page 1053). The porencephalic cerebral defect, if unilateral, is usually in the frontal lobe and is a cause of congenital hemiplegia. If the defect is bilateral, there is bilateral hemiplegia as well as severe impairment of mental development. In hydranencephaly, the greater part of both cerebral hemispheres is replaced by a membrane. Only the inferior temporal and occipital lobes remain, along with the thalamus and basal ganglia. The cranium may be full-sized or enlarged. Such children survive for only a short time (weeks, months, or a few years), functioning...
Clinical Syndromes of Congenital Motor Disorders

With reference to the types of motor disorder evolving from the four major categories of cerebral disease—matrix hemorrhage, periventricular leukomalacia, hypoxic-ischemic encephalopathy, kernicterus (discussed further on)—the most frequent is spastic diplegia, i.e., motor disturbances are severe enough to involve the cord and medullary centers. In addition to diplegia, hypoxic-ischemic injury occurring in the term or preterm infant may take the form of a hemiplegia, double hemiplegia (quadruplegia), or a mixed pyramidal-extra-pyramidal or spastic-ataxic syndrome.

A second form of motor disorder is characterized by the development of severe spastic quadriparesis and mental retardation. The major insult is intrapartum asphyxia and perinatal hypoxia. Usually such infants will have had low 5-min Apgar scores, which in this circumstance have important predictive value. The pathologic lesions of the brain in this second group consist of hypoxic-ischemic infarction in distal fields of arterial flow, primarily in the cortex and white matter of parietal and posterior frontal lobes, leaving a ulcerative sclerotic cortex.

A third group, also discussed below, is characterized mainly by extrapyramidal abnormalities, combining athetosis, dystonia, and ataxia in various proportions. In summarizing several large series of congenital and neonatal motor disorders, spastic diplegia occurred in 10 to 33 percent of cases, spastic quadriparesis 19 to 43 percent, extrapyramidal forms in 10 to 22 percent, and mixed forms in 9 to 20 percent.

Spastic Diplegia (Cerebral Spastic Diplegia: 10 to Little Disease)
The pattern of paralysis is more variable than the term spastic diplegia implies; actually, several subtypes may be distinguished: the paraplegic, diplegic, quadriplegic, pseudobulbar, and generalized. Pure paraplegic and pseudobulbar types are relatively rare. Usually all four extremities are affected, but the legs may be more than the arms, which is the real meaning of diplegia. Hypotonia—retained tendon reflexes and hypotonic posture—is normally seen initially. Only after a few months do the tendon reflexes develop, which are often absent in the normal infant, here are clearly extensor, a finding that is pathologic at any later age. Also, still, awkward movements of the legs, which are maintained in an extended, adducted posture when the infant is lifted by the axillae, often do not attract attention until several weeks or months have passed. Seizures occur in approximately one-third of the cases, and it is not uncommon to observe a delay in all developmental sequences, especially those that depend on the motor system. Once walking is attempted, usually at a much later date than normal, the characteristic stance and gait become manifest. The slightly flexed legs are advanced stiffly in short steps, each describing usually an arc of a circle; addition of the thighs is often so strong that the legs may actually cross (scissors gait); the feet are flexed and turned in with the heels not touching the ground. In the adolescent and adult, the legs tend to be short and small, but the muscles are not markedly atrophic, as in spastic muscular atrophy. Passive manipulation of the limbs reveals spasticity in the extensors and adductors and slight shortening of the calf muscles. The arms may be affected only slightly or not at all, but there may be awkwardness and stiffness of the fingers and, in a few, pronounced weakness and spasticity. In reaching for an object, the hand may overpronate. Speech may be well articulated or noticeably slurred, and in some instances, a pure motor smile. The deep tendon reflexes are exaggerated, those in the legs more than the arms; the plantar reflexes are extensor in the majority of the cases. Scoliosis is frequent and may secondarily give rise to spinal cord and root compression and impaired respiratory function. As a rule, there is no disturbance of sphincteric function, though in acquiring voluntary control is usual. Athetotic movements of the face, tongue, and hands are present in some patients and may actually conceal the spastic weakness; ataxic and hypotonic forms also exist (see further on).

One subtype of spastic diplegia is associated with a relatively slight diminution in head size and intelligence. As indicated above, there is no unifying neuropathology; the condition occurs independently of matrix hemorrhages and periventricular leukomalacia as well as with them. The frequency of cerebral spastic diplegia, which is closely related to the degree of prematurity, has declined significantly since the introduction of neonatal intensive care facilities, and there is reason to believe that hereditary factors are of importance.

Infantile Hemiplegia, Paraplegia, and Quadriplegia

Hemiplegia is a common condition of infancy and early childhood. The functional difference between the two sides may not be noticed until weeks or months after birth, but the signs are usually present between the ages of 3 to 18 months, develops a massive hemiplegia, with or without aphasia, within hours. In the second group, the child is in excellent health for a year or longer before the abrupt onset of hemiplegia (see below). In hemiplegia that dates from earliest infancy—i.e., congenital hemiplegia—the parents first notice that movements of prehension and exploration are carried out with only one arm. A manifest hand preference at an early age should always raise the suspicion of a unilateral motor defect. The affection of the leg is usually recognized later, i.e., during the first attempts to stand and walk. Sitting and walking are usually normal during the first few months, in the classic cases, there is evident hyperreflexia of the tendon reflexes and usually a Babinski sign. The arm is held flexed, adducted, and pronated, and the foot assumes an equinovarus posture. Sensory and visual field defects are present in some patients. Mental defect may be associated with infantile hemiplegia but is less common and lesser in degree than with cerebral diplegia and much less common than with bilateral hemiplegia. There may also be speech delay, regardless of the side of the lesion; when this is present, one should look for mental retardation and expect to find a bilaterality of motor abnormality. Convulsions occur in 35 to 50 percent of children with congenital hemiplegia, and these may persist throughout life. They may be generalized but are frequently unilateral and limited to the hemiplegic side. Often, after a series of seizures, the weakness on the affected side will be increased for several hours or longer (Todd's paresis). Gastrointestinal and associates have described a hemiconvulsive-hemiplegic syndrome in which the progressive paralysis and cerebral atrophy are attributed to the convulsions. As months and years pass, the osseous and muscular growth of the hemiplegic limbs is retarded, leading to an obvious hemiatrophy.

With respect to the causation of congenital hemiplegia, it is generally agreed that perinatal asphyxia is only one of the possibilities. In the series of 681 children with “cerebral palsy” collected by Hesbergen and Hesbergen, there were 244 with hemiplegia. Of the latter, 189 were full-term babies and 55 preterm. Prenatal risk factors were identified in 47 percent, and they were mostly in the infants born prematurely. In nearly half of the cases, there was no clue as to the time in the intrauterine period when the cerebral lesion occurred.

In the second group—acquired infantile hemiplegia—a normal infant or young child, usually between the ages of 3 to 18 months, develops a massive hemiplegia, or with or without aphasia, within hours, within days. The disorder often begins with seizures, and the hemiplegia may not be recognized until the seizures have subsided. In Banker's autopsy series, there was arterial or venous thrombosis in some cases, but in many no occlusions were found. Some of the latter cases, in which arteriography had been negative, may have been embolic, possibly of cardiac origin. If the stroke occurs at an early age, the recovery of speech may be complete, though reduced speech delay may persist. The degree of the hemiplegia, both motor function and sensory, of course, varies. Often, as the deficit recedes, the arm becomes involved by athenetic, tremulous, or ataxic movements. There may be an interval of months or years between the hemiplegia and the athetosis.

Encephaloclastic (destructive) lesions underlie most of the cases of infantile hemiplegia and some cases of bilateral hemiplegia. The pathologic change is essentially that of ischemic necrosis. In many cases, the lesions must have been incurred in utero. (Prenatal delivery, fetal distress, and prematurity uterine hemorrhage may be indications of the process.) The lesions reflect not only the effects of anoxia but also those of circulatory insufficiency (ischemia), the result of hypotension or circulatory failure. The ischemia of circulatory failure tends to affect the tissues lying in arterial border zones, and there may also be venous stasis with congestion and attendant fetal distress. Usually such infants will have had low 5-min Apgar scores, which in this circumstance have important predictive value. In order to state the probable pathologic basis and future course of these illnesses, it is desirable to separate the extrapyramidal syndromes of prenatal-natal origin (which usually become manifest during the first year of life) from the acquired or hereditary postnatal syndromes, such as familial athetosis, Wilson disease, dystonia musculorum deformans, and the hereditary cerebellar ataxias, which become manifest later.

Double Athetosis

This is probably the most frequent of the congenital extrapyramidal disorders. In our clinical material and in reported series of cases, two types stand out—one that is due to hyperbilirubinemia or RH incompatibility (kernicterus, see below) and the other due to hypoxic-ischemic encephalopathy. With control of neonatal hyperbilirubinemia (by use of anti-Rh immune globulin, exchange transfusions, and phototherapy), kernicterus has almost disappeared, whereas the other,
more severe hypoxic-ischemic form regularly continues to be seen. Rarely, a congenital, nonhemolytic icterus or a glucose-6-phosphate dehydrogenase deficiency produces the same syndrome.

Like the spastic states, double athetosis may not be recognized at birth but only after several months or a year have elapsed. In some cases the appearance of changes progresses over several years, and it may seem to progress during adolescence and even early adult life. It must then be differentiated from some of the inherited metabolic and degenerative extrapyramidal diseases. Chorea and athetosis dominate the clinical picture, but bewildering combinations of involuntary movements—including dystonia, ataxic tremor, myoclonus, and even hemiballismus—may be found in a single case. At times, we have been unable to classify the movement disorder because of its complexity. It should be noted that practically all instances of double athetosis are also associated with a defect in voluntary movement.

Choreaathetosis in infants and children varies greatly in severity. In some, the abnormal movements are so mild as to be misinterpreted as restlessness or “the fidgets” in others, every attempted voluntary act provokes involuntary movements, leaving the patient nearly helpless. The clinical appearance of choreaathetosis and other involuntary movements is discussed in Chapter 4.

An early hypotonia, followed by retardation of motor development, is the rule in these cases. Erect posture and walking may be delayed until the age of 3 to 5 years and may never be attained in some patients. Tonic neck reflexes or fragments thereof tend to persist well beyond their usual time of disappearance. The plantar reflexes are usually flexor, though they may be difficult to interpret because of the continuous flexion and extension of the toes. Sensory abnormalities are not elicited. Because of the motor and speech impairment, patients are often erroneously thought to be mentally defective. In some, this conclusion is doubtless correct, but in others intellectual function is adequate, and a few can be educated to a high level.

A variety of rehabilitative measures have been tried: physiotherapy, surgery, sensory integrative therapy, progressive patterned movement, and neuromuscular facilitation. We agree with Hur, who has critically reviewed this subject, that properly controlled studies provide no proof of the success of any of these measures. Surely, with growth and development, new purposes and motor capacities are acquired. The less severely affected patients can even make successful occupational adjustments. The more severely affected ones rarely achieve a degree of motor control that permits them to live independently. One sees some of these unfortunate persons bobbing and twisting laboriously as they make their way in public places.

Imaging studies are seldom of diagnostic value. Mild cerebroatrophic loss of volume of the basal ganglia are seen in some cases, and cavitory lesions are present in some of the severe anoxic encephalopathies. The EEG is rarely helpful unless there are seizures.

The most frequent pathologic finding in the brain has been a whitish, marble-like appearance of the putamen, thalamus, and border zones of the cerebral cortex. These whorls of silver tend to be present in several cases. Tonic neck reflexes or fragments thereof tend to persist well beyond their usual time of disappearance. The plantar reflexes are usually flexor, though they may be difficult to interpret because of the continuous flexion and extension of the toes. Sensory abnormalities are not elicited. Because of the motor and speech impairment, patients are often erroneously thought to be mentally defective. In some, this conclusion is doubtless correct, but in others intellectual function is adequate, and a few can be educated to a high level.

Kernicterus This is now a rare cause of extrapyramidal motor disorder in children and adults. Such cases raise the broader question of the neuropathologic sequelae of early neonatal ischemia-fetals secondary to Rh and ABO blood incompatibilities or to a deficiency of the hepatic enzyme glucuronosyltransferase. The symptoms of kernicterus appear in the jaundiced neonate on the second or third postnatal day. The infant becomes listless, sucks poorly, develops respiratory difficulties as well as opisthotonos (head retraction), and becomes stuporous as jaundice intensifies. The serum bilirubin is usually greater than 25 mg/dL. In acidotic and hypoxic infants (e.g., those with low birth weight and hyaline membrane disease), the neurologic lesions develop with much lower levels of serum bilirubin.

The majority of infants with this disease die within the first two or week of life. Many of those who survive are mentally retarded, deaf, hypotonic, totally unable to sit, stand, or walk, and spend their lives in homes for the feebleminded. There are exceptional patients, however, obviously less damaged, who are mentally normal or at most only slightly backward. These are the children with a variety of persistent neuropsychologic sequelae. These are choreoathetosis, dysostosis, and rigidity of the limbs—a picture not too different from that of cerebral spastic diplegia with involuntary movements. Kernicterus should always be suspected if an extrapyramidal syndrome is accompanied by bilateral deafness and palsy of upward gaze. Later there may be a greenish pigmentation of the dental enamel.

Neonates who die in the acute stage of kernicterus show a unique yellow staining (icterus) of nuclear masses (Kern nuclei) in the basal ganglia, brainstem, and cerebellum. In surviving patients the pathologic changes consist of a symmetrically distributed nerve cell loss and gliosis in the subthalamic nucleus of Luys, the globus pallidus, the thalamus, and the oculomotor and cochlear nuclei; these lesions are the result of the hyperbilirubinemia. The immature cerebral cortex is usually spared. In the newborn, unconjugated bilirubin can pass through the poorly developed blood-brain barrier into these nuclei, where it is directly toxic. Acidosis and hypernatremia exacerbate the effect. Also in the newborn, the development of hyperbilirubinemia is enhanced by a transient deficiency of the enzyme glucuronosyltransferase, essential for the conjugation of bilirubin. Hereditary hyperbilirubinemia, due to lack of this enzyme (Crigler-Najjar syndrome), may have the same effect on the nervous system at a later period of infancy or childhood as hyperbilirubinemia due to Rh incompatibility.

Immunization, phototherapy, and exchange transfusions with female blood, designed to prevent high levels of unconjugated serum bilirubin, have been shown to protect the nervous system. If the blood bilirubin level can be held to less than 20 mg/dL (10 mg/dL in premature), the nervous system may escape damage. The effective use of these measures has practically eradicated this dreaded disease.

Both kernicterus and ichemic etat marbre must be differentiated clinically from hereditary choreoathetosis, the Lesch-Nyhan syndrome, and—later in life—from ataxia-telangiectasia and Friedrich ataxia.

Congenital and Neonatal Ataxias In these patients, difficulty in standing and walking cannot be attributed to spasticity or paralysis. Again, hypotonia and poverty of movement are the initial motor abnormalities; the cerebellar deficit becomes manifest at a later time, when the patient begins to sit, stand, and walk. There may or may not be a delay in reaching “motor milestones.” Attempts to attain sitting balance will first reveal an unsteadiness that is not soon overcome, even with practice. Reaching for a proffered toy is accompanied by jerky, incoordinated movements. The first steps are unsteady, as would be expected, with many tumbles, but the gait remains clumsy. Instability of the trunk may be accompanied by similar, more or less rhythmic movements of the head, so-called titubation. Despite the severity of the ataxia, the muscles of normal size, and voluntary movements, though weak in some patients, are possible in all the limbs. The tendon reflexes are present, and the plantar reflexes are either flexor or extensor. In some cases, the ataxia is associated with spasticity rather than hypotonia (spastic-ataxic diplegia). Relative improvement may be made in later years. In the older child, a cerebellar gait, ataxia of limb movements, nystagmus, and uneven articulation of words are readily distinguished from myoclonus, chorea, athetosis, dysostosis, and tremor.

In only a few cases have the pathologic changes been studied. Aplasia or hypoplasia of the cerebellum has been observed, but scoliotic lesions of the cerebellum are more common. The CT scan or MRI verifies the cerebellar atrophy. A cerebral and cerebellar lesion may coexist in patients with congenital ataxia, which is the reason for the term cerebrocerebellar diplegia.

Several risk factors have been identified in the congenital ataxias. A genetic factor is operative in some cases (Harding and Harding). Radiation of the maternal abdomen during the first trimester of pregnancy is said to have resulted in cerebellar hypoplasia. Mercury poisoning in utero is another cause of congenital ataxia. Most importantly, cerebellar ataxia may be the most prominent or sole effect of neonatal ischemia-hypoxia.

Pontocerebellar Hypoplasias Aside from the congenital ataxia described above, there are several rare familial forms in which a failure of cerebellar development is associated with mental retardation. Joubert reported a family in which there was dysgenesis of the vermis of the cerebellum, mental retardation, episodic hyperpnea, irregular, jerky eye movements, and unsteady gait. The syndrome appeared in 4 of 6 siblings. In other reports, chondroïd retinoblastomas, polydactyly, cryptorchidism, and prognathism have been mentioned. Detailed examination of the cerebrum of such cases is needed. In the Gillespie syndrome, a combination of achondroplasia, mental retardation, and basal ganglia anomalies. In the Paine syndrome, a familial disorder with developmental delay and mental retardation, there is microophalmy, optica hypoplasia, and myoclonic ataxia, the last presumably related to the cerebellar hypoplasia. These dysgeneses and the dissequilibrium syndromes reported from Sweden are brought together by the cerebellar ataxia; in the past, they fell into the group of ataxic cerebral paliesies. Imaging studies demonstrate the cerebellocerebral abnormality. Genetic factors are operative in some, but matters pertaining to etiology remain obscure (see Harding for details). A pure congenital cerebellar hypoplasia has been mapped to a gene locus on chromosome Xq (Barshishkin et al.). The ataxia was inherited as an X-linked recessive trait and was nonprogressive beyond early childhood.

Differential Diagnosis of the Congenital Ataxias The congenital ataxias must be distinguished from the progressive hereditary ataxias. The latter are likely to begin at a later age than the congenital ones. Some hereditary ataxias are intermittent or episodic. They are discussed in page 1010. Several forms of childhood ataxia are
neither congenital nor hereditary; they have an acute onset and may persist during childhood, adolescence, and adult life. Also to be distinguished from the ataxias of congenital and neonatal origin is an acute cerebellar ataxia of childhood, which can usually be traced to a viral infection or a postinfectious encephalitis, particularly after chickenpox. The opisthotonus-myoclonus ("dancing eyes") syndrome of Kinsbourne is another postinfectious disease peculiar to childhood (see pages 977 and 1097). The cerebellar ataxia in this disease may be overshadowed by polymyoclonus, which marks every attempted movement. With improvement, under the influence of corticosteroids, a cerebellar disorder of speech and movement becomes evident. A majority of the cases in which the disease becomes chronic (16 of the 26 cases followed by Marshall et al) were found later to be mentally backward. The cause of the disease has never been established. An occult neuroblastoma or other tumor is uncovered occasionally.

Yet another form of cerebellar ataxia, which is inherited as an autosomal dominant trait, occurs in discrete attacks. It usually begins in childhood and persists through adult life. In two of our patients, it began in mid-adult life; one form is improved by the administration of acetazolamide (see page 1022).

In the differential diagnosis of these acute forms of cerebellar ataxia, one must not overlook intoxication with phenytoin, barbiturates, or similar drugs.

The Flaccid Paralyses The cerebral form, first described by Foerster and called cerebral atonic diplegia, has already been mentioned. It can usually be distinguished from the paralysis of spinal and peripheral nerve origin and congenital muscular dystrophy by the retention of postural reflexes (flexion of the legs at the knees and hips when the infant is lifted by the axilla), preservation of tendon reflexes, and coincident failure of mental development.

The syndrome of infantile spinal muscular atrophy (Werdng-Hoffmann disease) is the leading example of flaccid paralysis of lower motor neuron type. Perceptive mothers may be aware of a paucity of fetal movements in utero, and in most cases the motor defect becomes evident soon after birth. The infant is born with arthropathies and deformities. Several other types of familial progressive muscular atrophy have been described in which the onset is in early or late childhood, adolescence, or early adult life. Weakness, atrophy, and reflex loss without sensory change are the main features and are discussed in detail in Chap. 39. A few patients suspected of having infantile or childhood muscular atrophy prove, with the passage of time, to be merely inactive "stack" children, whose motor development has proceeded at a slower rate than normal. Others may remain weak throughout life, with thin musculature. These and several other congenital myopathies—core, rod-body, nemaline, mitochondrial, myotubular, and fiber type disproportion and predominance—are described in Chap. 52. Unlike Werdning-Hoffmann disease, the effects of any of them tend to ameliorate as the natural growth of muscle proceeds. Rarely, polymyositis and acute idiopathic polymyositis manifest themselves as a syndrome of congenital hyoptonia.

Infantile muscular dystrophy and lipid and glycogen storage diseases may also produce a clinical picture of progressive atrophy and weakness of muscles. The diagnosis of glycojen storage disease (usually the Pompe form) should be suspected when progressive muscular atrophy is associated with enlargement of the tongue. The motor disturbance in this condition may be related in some way to the abnormal deposits of glycogen in skeletal muscles, though it is more likely due to degeneration of anterior horn cells that are also distended with glycogen and other substances. Certain forms of muscular dystrophy (myotonic dystrophy and several types of congenital dystrophy) may also be evident at birth or soon thereafter. The latter may have led to arthrogryposis and club foot (see page 1530). All of these disorders are described in detail in the chapters on muscle diseases.

Brachial plexus palsies, well-known complications of dystocia, usually result from forcible extraction of the fetus with traction on the shoulder in a breech presentation or from traction and tipping of the head in a shoulder presentation. The effects of such injuries are sometimes lifelong. Their neonatal onset is betrayed later by the small size and inadequate ouesous development of the affected limb. Either the upper brachial plexus (fifth and sixth cervical) or the lower brachial plexus (seventh and eighth cervical and first thoracic roots) suffer the brunt of the injury. Upper plexus injuries (Erb) are about 20 times more frequent than lower ones (Klumpke). Sometimes the entire plexus is involved (page 1427).

Facial paralysis, due to forces to the face to the neural nerve immediately distal to its exit from the stylomandibulorr, is another common (usually unilateral) peripheral nerve affection in the newborn. Failure of one eye to close and difficulty in sucking make this condition easy to recognize. It must be distinguished from the congenital facial diplegia that is often associated with abducens palsy, i.e., the Möbus syndrome discussed earlier in the chapter. In most cases of facial paralysis due to physical injury, function is recovered after a few weeks; in some, the paralysis is permanent and may account for lifelong facial asymmetry.

In summary, it can be said that all these forms of disabling motor abnormalities rank high as important issues in neuropaedics. Steps have been taken in most hospitals to identify and eliminate risk factors in attempts at prevention. Indeed, better prenatal care, reduction in premature births, and control of respiratory problems in critical care wards have reduced their incidence and prevalence. Physical and mental therapeutic measures appear to be helpful, but many of the methods have been difficult to evaluate in a nervous system undergoing maturation and change. The neurologist can contribute most by segregating groups of cases of different pattern and etiology and in differentiating the congenital groups of delayed expressivity from the treatable acquired diseases of this age period. Woefully lacking are critical neuropathologic studies.

INTRAUTERINE AND NEONATAL INFECTIONS Throughout the intrauterine period the embryo and fetus are subject to particular infections. Since the infective agent must reach the fetus through the placenta, it is evident that the permeability of the latter at different stages of gestation and the immune status of the maternal organism are determinative. We are including a discussion of these intrauterine infections here because some of them may lead to malformations of the brain and, later in life, must be distinguished from developmental abnormalities.

Until the third to fourth month of gestation, the large microbial organisms—such as bacteria, spirochetes, protozoa, and fungi—cannot invade the embryo, even though the mother harbors the infection. Viruses may do so, however—specifically rubella, cytomegalovirus (CMV), human immunodeficiency virus (HIV), and possibly others. The rubella virus enters embryonal tissues during the first trimester, Treponema pallidum during the third trimester, and Toxoplasma after that period. Bacterial meningitis (except for that due to Listeria monocytogenes, described below) is essentially a paranatal infection contracted during or immediately after parturition. Neonatal herpes simplex encephalitis, due to the type 2 (genital) virus, is also usually acquired by passage through an infected birth canal. Some cases of HIV infection may be acquired during delivery, but most are due to transplacental transmission.

The main neonatal infections—rubella, cytomegalovirus and herpes—are commonly designated by the acronym TORCH. With the persistence of Listeria, the rise of AIDS infections, and a marked reduction in rubella infections, the mnemonic LATCH, which includes Listeria and AIDS, might be more appropriate. Infants with all these infections share certain common features, such as low birth weight, prematurity, congenital heart disease, purpura, jaundice, anemia, microcephaly or hydropcephaly, cerebral calcifications, choreoathetosis, cataracts, microphthalmia, and pneumonitis; as a corollary, if any combination of these features is found, one should suspect one of these infections. In the majority of cases in which infections are all these clinical manifestations likely to be present, and in the cases of rubella and cytomegalovirus, only a small percentage of infected infants will show major systemic signs or symptoms... Nevertheless, on clinical grounds alone, certain of these infections can be identified and others excluded. For example, cerebral calcifications are present mainly in CMV encephalitis, but absent in herpes simplex encephalitis; in rubella, absent in HIV and CMV in CNS toxoplasmosis and rare in CMV encephalitis. In CMV, the calcifications are widely disseminated in toxoplasmic encephalitis and have a periventricular distribution in CMV infection. Cardiac lesions are present only with rubella, and deafness occurs only with CMV and rubella. Thus, there are clinical signposts to guide the clinician in selecting the appropriate diagnostic tests. Most importantly, in considering neonatal infections, one must also search for other, non-LATCH infections (see Chap. 32 and Chap. 33).

Added difficulty in the diagnosis of embryonal and fetal infections arises when the mother has been entirely asymptomatic. Isolation of the organism from fetal and neonatal tissues is possible in many cases, and from the placenta in the majority of instances. Cerebrospinal fluid, amniotic fluid, villous tissue, and skin biopsy are all commonly obtained. If the infection is recent, viral antigens or DNA are demonstrated by means of immunoassay, complement fixation, immunofluorescence, or polymerase chain reaction (PCR). Antibody titers are obtained during and after the passage of the antibody through the placenta, and the virus may be isolated from fetal or neonatal tissues.

Rovella Gregg, in 1941, first reported the association of maternal rubella and congenital cataracts in the neonate. His observations were quickly verified, and soon it became widely known that cataracts, deafness, congenital heart disease, and mental retardation constituted a kind of tetrad diagnostic of this disease. That a virus could affect so many tissues, causing in essence a noninflammatory developmental disorder of multiple organs, was a novel concept, and it raised the interesting prospect that other viruses might have similar effects. Surprisingly, however, only CMV and possibly herpes simplex viruses (HSV) have been incriminated in embryonal neuropathology. A large number of other viruses (e.g., influenza, Epstein-Barr, hepatitis) have been implicated in human teratogenesis, but in none is the relationship
It is now well established that most instances of congenital rubella infection occur in the first 10 weeks of gestation, and that the earlier the infection occurs, the greater the risk to the fetus. However, there is considerable risk beyond the first trimester, up to the 24th week (Hardy).

Following the massive rubella epidemics of 1964 and 1965, the congenital rubella syndrome has been expanded to include low birth weight; sensorineural deafness, sometimes unilateral (the most common complication); microphthalmia; pigmentary degeneration of the retina (salt-and-pepper chorioretinitis); glaucoma, cloudy corneas, and cataracts of special type (the latter two abnormalities usually cause visual impairment); hepatosplenomegaly, jaundice, and thrombocytopenic purpura; and a variety of defects due to ocular or intraventricular septal defect. There may be one, a few, or many of these abnormalities, in various combinations. The mental retardation is severe and may be accompanied by seizures and motor defects such as hemiplegia or spastic diplegia and rarely by seizures. Psychiatric symptoms, some resembling autism, are not infrequent.

Infection of the fetus after the first trimester results in a less impressive neonatal syndrome. The infant may seem lethargic and fail to thrive. The cranium is abnormally small. Only a cardiac abnormality, deafness, or chorioretinitis may provide clues to the diagnosis. The CSF shows an increase of mononuclear cells and an elevated protein. The infection may persist for a year or longer. Foci of calcification are rare and CT scanning and MRI are of little help in diagnosis. The maternal infection may be so mild that it is passed off as minor; but even when it is evident, the fetus is spared in about 50 percent of cases. Diagnosis can be verified in the neonate by demonstrating IgM antibodies to the virus or by the isolation of the virus from the throat, urine, stool, or CSF. Also, the virus has been obtained from cells in the amniotic fluid.

The neuropathology is of considerable interest. In the nervous system of abortuses (the abortion performed because of proven maternal rubella in the first trimester), R. D. Adams found no visible lesions by light microscopy, even though the virus had been isolated from the brain by Enders. At this period of development there is no inflammatory reaction because of the absence of polymorphonuclear leukocytes, lymphocytes, and other mononuclear cells in the fetus. At birth the brain is usually of normal size, and there may be no discernible lesions. In a few, a mild meningeal infiltration of lymphocytes as well as a few zones of necrosis and vasculitis with later calcification of vessels are seen, as are small hemorrhages, presumably related to the thrombocytopenia. Smallness of the brain and delay in myelination have been observed in children dying at 1 to 2 years of age. None of the brains in our series have been malformed. Rubella virus continues to be recoverable from the CSF for at least 18 months after birth. A delayed progressive rubella encephalitis in childhood has also been described (page 811).

Since there is no treatment for the active infection, the obvious approach to the problem of congenital rubella infection is to make sure that every woman has been vaccinated against rubella or has had the infection prior to pregnancy. The widespread use of rubella vaccine has reduced the chance of major outbreaks, but sporadic infections continue to be seen, and outbreaks of epidemic proportions continue to occur in developing countries.

Cytomegalovirus Infection

For many years it was accepted that, in the tissues of some infants who died in the first weeks and months of life, there were swollen cells containing intranuclear and cytoplasmic inclusions. This cytoplastic change seemed related to the fatalities. In 1956 and 1957, three different laboratories isolated what has now come to be called the human cytomegalovirus, or CMV (see Weller). This has proved to be the most frequent intrauterine viral infection.

Cytomegalovirus disease is caused by a DNA virus, a member of the herpes group, and is widespread in the general population. Although cervicitis is common, the virus is probably transmitted to the fetus transplacentally. Infection of the fetus usually occurs in the first trimester of pregnancy, sometimes later, by way of an inapparent maternal viremia and active infection of the placenta. The newborn can also be infected in the course of delivery or afterward by the mother's milk or by transfusions. However, only a small proportion of women known to harbor the virus give birth to infants with active infection. The likelihood of the fetus being infected is much greater if the seronegative mother becomes infected for the first time during pregnancy. Eighteen percent of infants born to such mothers were symptomatic at birth, and 25 percent became blind, deaf, or feebly minded within a few years (Fowler et al).

In mothers with recurrent CMV infection, the infants are asymptomatic at birth, and only a few of them developed serious sequelae. Evidently, the presence of maternal antibodies before conception protects against congenital CMV infection.

Early infection of the fetus may result in a malformation of the cerebrum; later, there is only inflammatory necrosis in parts of the normally formed brain. In the low-birth-weight or full-term infant, the clinical picture is one of jaundice, petechiae, hematemesis, menela, direct hyperbilirubinemia, thrombocytopenia, hepatosplenomegaly, microcephaly, mental defect, and convulsions. Cells in the urine may show cytoplastic changes. There is a pleocytosis and an increased protein in the CSF. Disseminated inflammatory foci involve the cerebrum, brainstem, and retinae. In the centers of aggregates of lymphocytes, mononuclear cells, and plasma cells are microglial cells containing inclusion bodies; some astrocytes are similarly affected. The granulomas later calcify, particularly in the periventricular regions. Often there is hydrocephalus.

Congenital CMV infections pose a much greater problem than rubella. There is no way of identifying the infected fetus prior to birth or to prevent inadvertent infections in the pregnant woman. As indicated above, if the pregnant woman has measurable titers of antibodies to CMV at the time of conception, her infant is relatively protected. Moreover, some infected infants (with viuria) may appear normal at birth but develop neural deafness and mental retardation several years later. Virus replication in infected organs continues after the first year and health workers are at risk. A second child may be infected.

There is no known treatment. The difficulties in prenatal diagnosis of maternal infection preclude planned abortion. Routine serologic testing should be done on every young woman of childbearing age. Until an effective vaccine becomes available, pregnancy should be avoided if a sexual partner is infected.

Childhood HIV Infection and AIDS

In the United States, about 10 percent of cases of acquired immunodeficiency syndrome (AIDS) have occurred in women, almost all of them of childbearing age, and the rate of new cases is increasing at a faster rate among them than among men. In children, practically all instances of AIDS come from an HIV-infected mother ("vertical transmission"). The infection may be acquired in utero, during delivery, or from breast feeding. The relative importance of each of these modes of transmission has not been settled.

It is estimated that HIV infection and AIDS occur in 15 to 30 percent of infants born to HIV-seropositive mothers (see Prober and Gerson). Infected infants present special difficulties in diagnosis, and the infection runs a more accelerated course in them than in adults. In the perinatal period, infected and noninfected infants can only rarely be distinguished clinically, and laboratory diagnosis is hampered by the presence of maternally derived antibody to HIV. The initial clinical signs usualy appear within a few months after birth; practically all infected infants become ill before their first birthday, and very few are asymptomatic beyond 3 years of age. Early signs consist of lymphadenopathy, splenomegaly, hepatomegaly, failure to thrive, oral candidiasis, and parotitis. In the European Collaborative Study, comprising 600 children born to HIV-infected mothers, 83 percent of infected children showed laboratory or clinical features of HIV infection by 6 months of age. By 12 months, 26 percent had AIDS and 17 percent had died of HIV-related diseases. Once AIDS is established in children, it does not differ materially from the syndrome in adults (Chap. 33).

With reference to the involvement of the nervous system, there is often a delay in the attainment of psychomotor milestones. In others, after a period of normal development, a psychomotor decline begins, with corticospinal or peripheral nerve signs, often with pleocytosis. The typical giant-cell AIDS encephalitis, neuritis, and myelitis is easily distinguished from CMV encephalitis and toxoplasmosis.

Infected children are also subject to a variety of opportunistic infections, including bacterial meningitis, toplasmosis, CMV encephalitis, fungal infections (cryptococcosis, aspergillosis, candidiasis, herpes simplex and zoster, and mycobacterial meningitis). There may also be vascular lesions, with infarction or hemorrhage and lymphoid neoplasia. These are discussed in Chap. 32 and Chap. 33. There is little to be done for these children, but this may be changing with the current use of three-drug antiretroviral therapy, as described in Chap. 33.

Toxoplasmosis

This tiny protozoan, Toxoplasma gondii, occurring freely or in pseudocyst form, is a frequent cause of meningencephalitis in utero or in the perinatal period of life. The disease exists in all parts of the United States but is more frequent in western European countries, particularly in hot, humid climates. The mother is most often infected by exposure to cat feces, handling uncooked infected mutton or other meat, or eating partially cooked meat, but she is nearly always asymptomatic or has
Granulomatous masses and zones of inflammatory necrosis abut the ependyma and meninges. The organisms, 6 to 7 mm in length and 2 to 4 mm in width, are visible in and near the lesions. Microcysts may also be found, lying free in the tissues without surrounding inflammatory reaction. The necrotic lesions calcify rapidly and, after several weeks or months, are readily visible in plain films of the skull. These appear in periventricular and other regions of the brain as multiple nodular densities.

In adults, mainly in patients with AIDS, the disease takes the form of a rapidly evolving meningoencephalitis in conjunction with myocarditis, hepatitis, and polymyositis. This syndrome is described on page 775, as are the diagnostic tests and treatment. In the infant, infections such as rubella, syphilis, CMV disease, and herpes simplex must be considered in the differential diagnosis. The most reliable means of diagnosis is the IgM indirect fluorescent antibody test, performed on umbilical cord blood. Passive transfer of IgG antibody from mother to fetus takes place, but its presence in the latter is not proof of active infection.

In women who develop antibodies in the first 2 or 3 months of pregnancy, treatment with spiramycin (Rovamyicin) prevents fetal infection. Once the fetus is infected, pyrimethamine and sulfadiazine must be used. A later second pregnancy is not affected.

### Congenital Neurosyphilis

The clinical syndromes and pathologic reactions of congenital neurosyphilis of the newborn are similar to those of the adult, as described on pages 762 to 768. Such differences as exist are determined principally by the immaturity of the nervous system at the time of spirochetal invasion.

The syphilitic infection may be transmitted to the fetus at any time from the fourth to the seventh months. The fetus may die, resulting in miscarriage or stillbirth, or may be liveborn only to be born with florid manifestations of secondary syphilis. The dissemination of the spirochotes throughout the body, the time of appearance of the secondary manifestations, and the time of formation of antisyphilitic antibodies (reagin) in the blood are all governed by the same biologic principles that apply to the adult.

At birth the spirochete may not have had time to cause syphilitic reagin or antibodies to appear; hence a negative Venereal Disease Research Laboratories (VDRL) reaction in umbilical cord blood does not exclude syphilis. In unselected groups of syphilitic mothers, 25 to 80 percent of fetuses are infected, and in 20 to 40 percent of those infected, the CNS is invaded, as judged by the finding of abnormal CSF. The types of congenital neurosyphilis (asymptomatic and symptomatic meningitis, meningovascular disease, hydrocephalus, general paresis, and tabes dorsalis) are the same as those in the adult except for the greater rarity of tabes dorsalis. The Hutchinson triad (dental deformities, interstitial keratitis, and bilateral deafness) is infrequently observed in complete form. The sequence of neurologic syndromes is also the same as in the adult, all stemming basically from a chronic spirochetal meningitis. The latter may become symptomatic in the first weeks and months of postnatal life, meningoencephalovascular lesions and hydrocephalus reaching maximal frequency during the 9-month to 6-year period; congenital paresis and tabes usually appear between the ninth to fifteenth years. The pathologic basis of each neurosyphilic syndrome is, respectively, meningitis (vascular syphilis), myoneuroencephalitis (general paresis), and meningoarachnitis (tabes dorsalis).

All neurologists have observed fewer and fewer cases of congenital neurosyphilis as the years pass, but there may be a recrudescence of the disease. If the syphilitic mother is treated before the fourth month of pregnancy, the fetus will not be infected. The infant may be normal or exhibit only mucocutaneous lesions, hepatosplenomegaly, lymphadenopathy, and anemia. There are in the neonatal period no signs of meningeal invasion, or there may be only an asymptomatic meningitis. If the latter is actively treated until the CSF is normal, vascular lesions of brain and spinal cord, hydrocephalus, general paresis, and tabes dorsalis will not develop. If cases of meningovascular syphilis, general paresis, and tabes dorsalis are treated for 3 to 4 weeks with penicillin until the CSF is rendered acellular and the protein reduced to normal, the neurologic disorder will be arrested and often there is functional improvement.

The various neurosyphilitic syndromes are described fully in Chap. 32, as mentioned above.

Congenital syphilis must be considered a potential albeit rare cause of epilepsy and mental retardation. Once the syphilitic infection has been treated in early life and rendered inactive (acellular CSF, normal protein), the occurrence of a congenital luetic infection can only be substantiated by an accurate history; the finding of the syphilitic stigmata in the eyes, teeth, and ears; or a positive serologic reaction in the CSF.

Treatment of syphilis in the child follows along the same lines as treatment of the syphilitic adult (page 767), with appropriate adjustment of dosage in accordance with the child's weight.

### Other Viral and Bacterial Infections

Several other infections of late fetal life or the neonatal period are only mentioned here, for to describe them all would be tedious and would elucidate no new neurologic principles. Meningitis due to the small gram-positive rod Listeria monocytogenes may be acquired in the usual way, at the time of passage through an infected birth canal or in utero, as a complication of maternal and fetal septicaemia due to this organism. In the latter case, it causes abortion or premature delivery. Neonatal meningitis is a particularly devastating and often fatal type of bacterial infection, not easily diagnosed unless the pediatrician is alert to the possibility of a silent meningitis in every case of congenital syphilis (page 740).

Herpes simplex virus (HSV) encephalitis may destroy large parts of the brain, particularly of the temporal lobes, and is frequently fatal. Coxsackie B, polioviruses, other enteroviruses, and arboviruses (western equine) seem to be able to cross the placental barrier late in pregnancy and cause encephalitis or encephalomyelitis in the fetus at term—indistinguishable from the disease in the very young infant.

Epstein-Barr virus is another and not infrequent cause of meningoencephalitis. In some instances it may present as an aseptic meningitis or a Guillain-Barré type of acute polyneuritis. This infection is more apt to affect the nervous system of children than that of adults. It is estimated that approximately 2 percent of children and adolescents with this infection have some type of neurologic dysfunction; rarely this will be the only manifestation of the disease. Sluiter Ford, chorea, and aseptic meningitis were the main neurologic findings in the case reported by Friedland and Yahr, and acute cerebellar ataxia and deafness in the case of Ezurum and associates (see also Chap. 32 and Chap. 33). Herpes zoster may occur in utero, leaving cutaneous scars and retarding development. Or zoster may appear soon after birth, the infection having been contracted from the mother. Later in childhood, varicella may induce an autoimmune pernicious demyelination and possibly a direct infection, affecting predominantly the cerebellum (pages 797 and 977), or the now rare Rey syndrome.

### EPILEPSIES OF INFANCY AND CHILDHOOD

The major types of seizure disorder have already been discussed in some detail in Chap. 16. In bringing them up again here, attention is drawn to the fact that epilepsy is mainly a disease of infancy and childhood. Approximately 75 percent of epilepsies fall into these age periods, and some of the most interesting and unique types of seizure are peculiar to these epochs of life. Epilepsies that are observed exclusively in infants and children are benign neonatal convulsions, benign myoclonic epilepsy of infancy, febrile seizures (both genetic and acquired), infantile spasms of West, absence seizures, the Lennox-Gastaut syndrome, rolandic and occipital paroxysms and other benign focal epilepsies, and the juvenile myoclonic epilepsies.

One principle that emerges is that the form taken by seizures in early life is in part age-linked. Neonatal seizures are predominantly partial or focal; infantile seizures take the form of myoclonic flexor (sometimes extensor) spasms; and the various forms of petit mal are essentially diseases of childhood (4 to 13 years). The motor phenomena of epilepsy in young children are often termed myoclonic, but this should not be confused with other, later-occurring epilepsies that are endowed with the
same name. Further, certain epileptic states tend to occur during certain epochs of life—one type of febrile seizures from 6 months to 6 years and generalized or temporal spike-wave activity with benign motor and complex partial seizures from 6 to 16 years, and juvenile myoclonic epilepsy in the mid- and late-adolescent years. In general, idiopathic epilepsy, so called because the cause cannot be determined, is predominantly a pediatric neurologic problem. This is not to say that seizures of unknown cause do not occur for the first time in adult life but rather that the onset of such seizures is far more frequent in childhood and tends to diminish once adulthood is reached.

The clinical characteristics of infantile and childhood seizures are fully described in Chap. 16.

MORE SEVERE FORMS OF MENTAL RETARDATION

The subject of mental retardation was introduced in Chap. 28, where it was pointed out that two major categories of this disorder have been delineated. In one, and by far the more common group, the mental retardation is relatively mild, allowing the individual to benefit from training and education; it is often familial (called subcultural) and is featured by a lack of definite neurologic abnormalities (except possibly a slightly higher incidence of seizures) and the absence of neuropsychiatric changes. A large part of this group, falling between 2 and 3 standard deviations from the normal mean IQ, probably are the lower end of the Gaussian curve of intelligence, the converse of which is genius. In the second group, the degree of mental retardation is usually more severe, most are nonfamilial, and a wide variety of neuropsychiatric changes are in evidence. The division is not absolute, for there are a few metabolic and developmental diseases in which mental retardation is profound, but with no somatic or neurologic abnormalities and no well-defined neuropsychiatric changes—e.g., Rett syndrome, autism, and the X-linked mental retardation syndromes such as the Renpenning and fragile-X types. In this chapter only these major types of severe mental retardation are described.

The overall frequency of severe mental retardation cannot be stated precisely. Rough estimates would place the figure at 0.2 to 0.4 percent of the general population and at about 10 percent of the retarded segment of society. It is important to emphasize that severe mental retardation in a large proportion of individuals can presently not be traced to particular congenital anomalies of development or to any of the disorders reviewed in the preceding pages. When groups of such severely retarded patients are studied clinically, a reasonably accurate etiologic determination of the underlying brain disease can be made in only slightly more than half of them. According to Penrose, chromosome abnormalities account for 15 percent, single-gene disorders for 7 percent, and environmental agents for 20 percent. Recent studies of the subtelomeric parts of chromosomes reportedly find abnormalities in another 7 percent of severely retarded children (Knight et al). No cause is found for the remaining cases. Males outnumber females 3:1. For purposes of comparison, our figures, obtained from a study of 1372 patients at the Walter E. Fernald School, are presented in Table 38-3.

From the neuropathologic standpoint, the examination of the brains of the severely retarded by conventional histopathologic methods discloses lesions in approximately 90 percent, and in fully three-quarters an etiologic diagnosis can be determined. Many of the remaining 10 percent of the "pathologically retarded" actually lack definite pathologic changes, but their brains are lighter in weight by 10 to 15 percent than age-matched normal brains. Interestingly, the proportion of vascular, hypoxic-ischemic, metabolic, and genetic lesions in this group of severely retarded is much the same as is found in a group selected on the basis of "cerebral palsy."

Here it is important to repeat a point made earlier and in Chap. 28, that a few of the severely disabled and a large majority of the mildly retarded do not have a recognizable cerebral pathology or exhibit any of the familiar and conventional signs of cerebral disease. Although the milder forms of mental retardation tend to be familial, this does not by itself separate them from the severe forms of mental retardation. There are several types of hereditary mental retardation, in which the retardation may be severe and in some of which there may be maldevelopment of the cerebral cortex. These are discussed further on.

Clinical Characteristics of the Severely Retarded

In one large group of severely retarded, designated the dysmorphic retardates, a variety of physical deformities, particularly microcephaly, is common. In a second group, multiple system retardation, the mental retardation is linked to nonskeletal abnormalities (hepatosplenomegaly as well as hematologic and skin disorders), which provide reliable clues to the underlying somatic disease. In a third group, the neurologic retardates, somatic abnormalities are lacking; the configuration of neurologic signs often leads to the diagnosis. And in a fourth and most difficult group, the uncomplicated retardates, there are no or minimal somatic, visceral, and neuropsychiatric abnormalities. One is then forced to turn to special features of the mental retardation itself for identification of the underlying disease. Table 38-4 elaborates our classification of the types of mental retardation.

Table 38-4 Types of severe mental retardation

The profoundly retarded infant with a virtually untestable IQ (dumb level in the older classifications) is identified early in life because he does not sit, stand, or walk. If any one of these motor activities is acquired, it appears to be late and is imperfectly performed. Language never develops; at most a few spoken words or phrases are remembered. Sphincteric control may never be attained, and if attained is precarious. If the mental defect is less severe than the one described above, falling into the IQ range of 20 to 45, or 45 to 70, there may still be somatic neurologic abnormalities; if specific motor defects do not coexist, then sitting, standing, and walking are achieved but not at the expected times. The existence of a mental defect is most clearly

Table 38-4 Types of severe mental retardation

The profoundly retarded infant with a virtually untestable IQ (dumb level in the older classifications) is identified early in life because he does not sit, stand, or walk. If any one of these motor activities is acquired, it appears to be late and is imperfectly performed. Language never develops; at most a few spoken words or phrases are remembered. Sphincteric control may never be attained, and if attained is precarious. If the mental defect is less severe than the one described above, falling into the IQ range of 20 to 45, or 45 to 70, there may still be somatic neurologic abnormalities; if specific motor defects do not coexist, then sitting, standing, and walking are achieved but not at the expected times. The existence of a mental defect is most clearly
evidenced by psychomotor delay and a failure to speak by the second or third postnatal year. The patient does not acquire the usual household and play activities as well as other children. However, delay in speech development must not, by itself, be taken as a mark of mental retardation, for in some children a unique delay in speech can be an isolated abnormality (see Chap. 28), with subsequent normal development of speech. Toilet training may be difficult to accomplish in the retarded child, but, again, bed wetting may be a problem in an otherwise normal child. Also, the deaf child may have to be considered separately; the problem becomes apparent by an indifference to noise and reduced vocalization (stereotypy of babbling).

More searching analyses of cognitive functions in the moderately retarded child have been undertaken by O'Connor and Hermelin, by Pulsifer, and by others. These authors have attempted to measure efficiency of visual and auditory perception, adequacy of communication, relations between language development and thought, construction of mental images, scanning, alertness, attention, and memory. It was concluded that none of these functions was specifically impaired. Instead, the retarded child could not properly encode new information because the memory systems and stock of assimilated knowledge were insufficient to provide a framework of items and categories with which new information could be integrated. Some also seem unable, perhaps because of this, to extract from perceived material selective features that can only be perceived by normal children. In an arrêt-on-facteur, the complexity of these operations, which the authors would reduce to a global failure of the normal processes of apperception and integration, has been called by Piaget a failure of assimilation and accommodation. This type of inadequacy is common to many different diseases, but in each one there are other subtle differences not yet fully analyzed by neuropsychologists.

Within the spectrum of mental retardation, apart from cognitive impairments, there are differences in behavior and personality, even in those with more or less the same IQ. Some moderately severe retardates are pleasant and amiable and achieve a rather satisfactory social adjustment. This is particularly notable in patients with Down and Williams syndromes. At the opposite end of the behavioral scale is the syndrome of autism, in which the individual fails to manifest normal interpersonal social contact, including communicative language. The phenylketonuric retardate is usually irritable, unaffectionate, and implacable, and the same is said of other retardates, such as those with the De Lange syndrome, discussed earlier in the section on retardation with dwarfism.

Regarding activity levels, many retarded individuals are slow, clumsy, and relatively akinetic. Others, as many as half of them, display an incessant hyperactivity characterized by a restless, seemingly inquisitive searching of the environment. When thwarted, they have a low frustration tolerance. They may be destructive and recklessly fearless and impervious to the risk of injury. Some exhibit a peculiar anhedonia that renders them indifferent to both punishment and reward. Other aberrant types of behavior, such as violent aggressiveness and self-mutilation, are common. Rhythmic rocking, head banging, incessant arm movements—so-called rhythms or movement stereotypes—are observed in the majority of severe retardates. They are maintained hour after hour without fatigue and may be accompanied by breathing sounds, squeals, and other exclamations. Self-stimulation, even hurtful—such as striking the forehead or ears or biting the fingers and forearms—seems compulsive or perhaps provides satisfaction. It is not that these rhythms are by themselves abnormal, for some of them occur for brief periods in normal babies, but that they persist. Some moderately retarded persons, when assigned to a simple task such as putting envelopes in a box, can continue this activity under supervision for several hours.

It is impossible to list all the varieties of mental retardation here; the point to be made is that all aspects of intellectual life, personality, and deportment are affected in varying degrees and that these effects have a neurologic basis. There is more than a hint that in particular diseases, because of their anatomy, the cognitive experience, affective life, and behavior, are abnormally affected. The group of moderately, and severely retarded, is divisible into groups with somatic systemic and neurologic abnormalities, though the proportions are not the same. There are fewer of the dysmorphic type and more of the nondysmorphic, nonneurologic group.

Etiology of Severe Mental Retardation From Table 38-3 it is obvious that many diseases can blight the development and maturation of the brain, leaving it in an arrested state. Some of them are acquired and some are congenital and hereditary. Some affect all parts of the organism, giving rise to associated dermal, skeletal, and visceral abnormalities, while others affect only the nervous system in particular patterns. With respect to the milder degrees of mental retardation, in all populations thus far studied, extreme low-birth-weight infants are more likely to have disabilities, brain abnormalities, and poorer language development and scholastic achievement. This correlates with lower social status, which must relate in some manner to biological factors (Scottish Low-Birth-Weight Study). Viral and spirochetal infections and parturitional accidents are common causes. They act acutely and are theoretically preventable. The factor of malnutrition during the fetal or infantile period of life as a cause of severe mental retardation has received considerable attention because it is worldwide. Animal experiments (by Winick and others) have demonstrated that severe undernutrition in early life leads to behavioral abnormalities and biochemical and morphologic changes in the brain, which may be permanent (see Chap. 41). Galler studied a group of infants in Barbados who were malnourished during the first year of life and then given an adequate diet. These children were followed to adulthood and compared with normally nourished siblings. Galler observed no effect on physical growth, but there were persistent attention deficits in 60 percent of the undernourished group and in only 15 percent of controls. The IQ scores of the former were also lower. Unfortunately, genetic factors were not completely controlled. In general, it may be said that the data showing mental retardation to be caused by malnutrition, while suggestive, are far from convincing.

Severe protein-calorie malnutrition in the first 8 months of life, which induces kwashiorkor, does seem to retard mental development. However, such patients are said to regain mental function when fed. The authors have been impressed with the ability of the nervous system to withstand the effects of nutritional deficiency, perhaps better than any other organ.

The action of exogenous toxins during pregnancy is another factor to be considered. Severe maternal alcoholism has been linked to a dysgenetic syndrome, including mental retardation, but the findings of several studies have not been consistent (see Chap. 43). Surprisingly, maternal addiction to opiates, while causing an opiate withdrawal in infants for weeks or even months (Wilson et al.), seems not to result in permanent injury to the nervous system. The exposure to small amounts of environmental lead is also controversial.

The effect of psychologic deprivation has been of interest. Following the observations that complete isolation of young female monkeys had a devastating effect on their later sexual and nurturing behavior, the idea became popular that sensory deprivation might cause faulty mental development in humans. Orphaned and neglected babies were found to be inactive, apathetic, and backward in comparison with those who were constantly stimulated by caring mothers. But surprisingly, while deprived properly at a later time, these babies soon caught up with their peers. The general idea of psychologic deprivation was the basis of many interesting head-start programs for poor and neglected children. To this day, however, it has not been proven that sensory, emotional, and psychologic deprivations are the causes of severe mental retardation or repeated scholastic failure. However, the problem is a complex one, and the arguments pro and con have been carefully elaborated by Hayward and Wacht. The controversies regarding the effects of prematurity, maternal hypotension, and eclampsia, which are often associated with retarded psychomotor development, were described earlier in this chapter.

The genetic types of severe mental retardation, including the novel type associated with subtelomeric abnormalities, have already been mentioned.

Differentiation of Types of Retardation: Clinical Approach

As a particular guide to the pediatrician and neurologist who must assume responsibility for the diagnosis and management of backward children harboring a wide array of structural and maldevelopments of the nervous system, the following clinical approach is suggested. First, as already described, there is an advantage in setting aside as one large group those who are only mildly retarded from those who have been severely delayed in psychomotor development since early life. With regard to the former group, having no obvious neurologic signs or physical stigmata, the only medical problems they present are in the spheres of behavioral, educational, and psychosocial adjustments. One should nevertheless initiate a search for the common metabolic, chromosomal, and infective diseases. In this large group one must be sure that the defect is a general and not one of hearing, poor sight, or the special language and attention deficits described in the retardates with somatic abnormalities.

For patients with the moderately severe and very severe deficits, one begins always with a careful physical examination, including a searching for somatic stigmata and neurologic signs. Abnormalities of eyes, nose, lips, ears, fingers, and toes are particularly important, as are a variety of neurologic abnormalities, as outlined in Table 38-4. Data so obtained allow classification into one of three categories, as follows.

In one group, those with somatic abnormalities (with or without obvious neurologic signs), one assumes the presence of a maldevelopment of the brain, possibly caused by a chromosomal abnormality. The psychomotor retardation is usually severe and often nongenetic and, as a rule, has a well-defined neuropathology. Diagnosis is determined by the gestalt of physical signs. The possible maldevelopments are numerous and diverse and have been summarized in Table 38-1 and Table 38-4; some of the main ones have been described earlier in the one group. One inevitably turns to the several atlases to delineate the syndromes (Hohens et al.; Jones).

In the second group, in which the abnormalities are confined to the nervous system, attention is focused on a larger number of diseases, many due to exogenous
factors such as perinatal hypoxia-ischemia, pre- or postnatal infections, trauma, and so on. There are usually conspicuous neurologic signs. The degree of mental retardation is variable, depending on the location and extent of a demonstrable neuropathology. Usually the family history is negative, but careful questioning of parents regarding the pregnancy, delivery, and early postnatal period, and examination of older hospital records may disclose the nature of the neurologic insult.

The third category of retardates is one in which neither somatic anomalies nor focal neurologic signs are present. The more severely retarded of this third group are represented by the following disease states: autism (Asperger-Kanner syndrome), the Rett and Williams syndromes, and the fragile-X and Renspenning syndromes. The last three have a genetic basis and are described together below.

The practical importance of this clinical approach is that it directs the intelligent use of laboratory procedures for confirmation of the diagnosis. CT scanning and MRI are useful in clarifying maldevelopment and neurologic diseases but are seldom helpful in the third group. EEG confirms seizure discharges when there is uncertainty as to the nature of episodic neural dysfunction. Karyotyping and genetic studies are useful in group 1 and rarely in group 2 patients.

The major pitfall to be avoided in this clinical approach is in mistaking a hereditary metabolic disease for a developmental one. Here one is helped by the fact that manifestations of the metabolic diseases are not usually present in the first days and weeks of life; they appear later and are progressive and often associated with visceral abnormalities. However, some metabolic diseases are those of slow progression that they appear stable, especially the late-onset ones, such as one type of metachromatic leukodystrophy, late-onset Krabbe leukodystrophy, adult adrenoleukodystrophy, and adult hexosaminidase deficiency (see Chap. 37).

Hereditary Mental Retardations

Fragile-X Syndrome There is now great interest in this syndrome, which some geneticists hold accountable, at least in part, for the preponderance of males among institutionalized retarded individuals. The subject is discussed earlier in this chapter, particularly as it relates to other chromosomal abnormalities (page 1067). A large kindred in which mental retardation was inherited in an X-linked pattern was first reported by Martin and Bell in 1943. It was in such a family, with X-linked mental retardation, that Lubs, in 1969, discovered a fragile site at the distal end of the long arm of the X chromosome; subsequently it was established that there is an unstable inherited CGG repeating sequence at this site, as discussed previously.

Fully 10 percent of mentally retarded males have this fragile X chromosomal abnormality. Females are sometimes affected, but their mental function is only slightly reduced. Affected males have only mild dysmorphic features (large ears, broad forehead, elongated face, and enlarged testes) that may not become obvious until puberty. Other behavioral problems of one sort or another are almost universal. Pulsifer, whose review of the psychosocial aspects of mental retardation is recommended, lists self-injurious, hyperactive, and impulsive behaviors as the most common. The hand flapping that is characteristic of autism may also be seen.

Renspenning Syndrome A similar type of hereditary, male sex-linked mental retardation has been described by Renspenning. The family comprised 21 males in two generations of Mennonites in western Canada whose IQs ranged from 30 to 40. As with the fragile-X syndrome, female siblings may show slight degrees of retardation. Affected members were small in stature and slightly microcephalic but otherwise free of somatic and neurologic abnormalities. They did not have the fragile-X abnormality.

Rett Syndrome This is yet another hereditary form of mental retardation, but affecting only girls. None of the cases reported by Hagberg and coworkers were male. Recently the responsible spontaneous mutation has been shown to be a dominant defect at chromosomal site Xq28. A fatal outcome in boys explains the expression of the syndrome only in girls, who are mosaic for the mutation. The involved gene, MECP2, is responsible for suppressing various other genes at critical stages of development.

The syndrome is characterized clinically by withdrawal behavior that simulates autism, dementia, ataxia, loss of purposeful hand movements, and respiratory irregularities, all of which appear and progress after a period of 6 to 18 months of normal development. Spasticity, muscle wasting, scoliosis, and lower limb deformities may become evident in late stages of the illness. Hand waving, hand wringing, and similar stereotypes are very characteristic features (and are subtly different from the hand flapping of autistic children).

Armstrong and Naidu, who have reviewed the neuropathology, have drawn attention to a number of subtle cortical abnormalities, most of which are consistent with disruption of the dynamic phase of brain development postnatally; however, not all cases showed these abnormalities. While most cases appear to be sporadic, there is a high familial incidence and concordance in twins. However, this is still a matter of contention.

Williams Syndrome This inherited form of mental retardation has also been mentioned earlier, on page 1068, in relation to the chromosomal abnormalities. It is characterized by only mild mental retardation but with striking retention and even precocity of musical aptitude, social amiability, and in some cases a retained interest because an index feature of these cases is a supravalvular aortic stenosis. It is not known whether there is a characteristic brain pathology, but a recent case of the disease only in girls, who are mosaic for the mutation. The involved gene, MEGP2, is responsible for suppressing various other genes at critical stages of development.

Autism (Kanner-Asperger Syndrome; Autistic Spectrum Disorders)

This condition was described almost simultaneously by Kanner in Baltimore (in 1943) and Asperger in Vienna (in 1944). Among the large group of retarded children, Kanner observed exceptional children who appeared to be associating, lack in communicative skills both verbal and nonverbal, and committed to repetitive ritualistic behaviors. At the same time certain intellectual capacities—such as retentive memory, skilled sensory and motor aptitudes, and capacity for visual spatial perception—were retained. In other words, the disorder did not pervade all aspects of mental development. It is the gestalt of negative and positive aptitudes that sets this syndrome apart from other types of retardation. Kanner incorrectly ascribed the condition to psychosocial factors—such as a cold, aloof parent—and regarded it as an autistic psychopathy. The implication that these children are literally “autistic”—i.e., that they have a rich inner psychic life or dream world out of relation to reality—is an assumption wholly without foundation. Asperger, whose observations included somewhat older children, less completely disabled, ascribed it to a special susceptibility to stresses, possibly related to hyperammonemia. Opinion varied as to the relationship between the severe Kanner syndrome and the less severe Asperger syndrome. The authors have taken the position that these forms of autism represent a single syndrome of varying severity, with similar pathologic underpinnings but possibly of multiple etiologies, including genetic.

For reasons mentioned above, the term autism, drawn from psychiatry, is inappropriate but is firmly embedded in the medical lexicon. Despite many claims to the contrary, there is absolutely no evidence of a psychosis. However, as Rapin points out, behavioral modification and special education are beneficial for the less severely affected. At one time the disorder was referred to as childhood schizophrenia, but the afflicted individuals do not resemble schizophrenics, even when they reach adulthood. The very early onset (preschool) onset of autism, the lack of delusional thinking, the correlation between behavioral problems of one sort or another are almost universal. Pulsifer, whose review of the psychosocial aspects of mental retardation is recommended, lists self-injurious, hyperactive, and impulsive behaviors as the most common. The hand flapping that is characteristic of autism may also be seen.

The major pitfall to be avoided in this clinical approach is in mistaking a hereditary metabolic disease for a developmental one. Here one is helped by the fact that manifestations of the metabolic diseases are not usually present in the first days and weeks of life; they appear later and are progressive and often associated with visceral abnormalities. However, some metabolic diseases are those of slow progression that they appear stable, especially the late-onset ones, such as one type of metachromatic leukodystrophy, late-onset Krabbe leukodystrophy, adult adrenoleukodystrophy, and adult hexosaminidase deficiency (see Chap. 37).

Clinical Features The autistic child is ostensibly normal at birth and may continue to be normal in achieving early behavioral sequences until 18 to 24 months of age.
Then an alarming regression occurs. In some instances, however, the abnormality appears even before the first birthday and is identified as different from normal by the mother; or, if there had been a previously autistic child, she recognizes the early behavioral characteristics. The level of activity is reduced or increased. There may be less crying and an apparent indifference to surroundings. Toys may be resisted. Motor developments, on the other hand, proceed normally and may even be precocious. Later there may be an unusual sensitivity to all modes of sensory stimulation. Occasionally the onset appears to have a relationship to an injury or an upsetting experience.

Regardless of the time of and rapidity of onset, the autistic child exhibits a disregard for other persons; this is typically quite striking but in milder cases is more subtle. Little or no eye contact is made, and the child is no more interested in another person than in an article of furniture. Preferred toys are manipulated cleverly, placed in varying lines, or rejected. Insistence on constancy of environment may be a point where the patient becomes distraught if even a single one of his possessions is moved from its original place and remains distraught until it is replaced. If speech develops at all, it is highly automatic (echolalic) and not used effectively to communicate. A repertoire of elaborate stereotyped movements—such as whirling of the body, manipulating an object, toe walking and particularly hand flapping are characteristic. Spinning toys or running water may have a strange fascination for these children.

It is important to point out, however, that in any sizable group of autistic children there is a wide range of deficits in sociability, drive, affect, and communicative (verbal and gestural behavior) ability, ranging from the averted negativistic, completely isolated state to one showing considerable language skill and some capacity for attachment to certain people and for scholastic achievement. In this higher-functioning group, taken to typify the Asperger syndrome, the child may be unusually adept in reading, calculating, drawing, or memorizing while still having difficulty in adjusting socially and emotionally to others. Many are clumsy and inept in athletic activities. The least degree of deficit allows success in a professional field but with handicap in the social sphere. We take the current emphasis on the term autistic syndrome to designate the concept that each of the core elements of the syndrome described by Asperger and by others may be in widely varying degrees of severity. This view permits a syndromic diagnosis of autism in patients with coexisting elements of other disorders, such as attention deficit disorder and manic-depressive or obsessive-compulsive disorders and expands the diagnosis to many children who are highly functional except for gaze aversion and other "soft signs" (Filipek).

Rapin, drawing on a large clinical experience with autism, has carefully documented its linguistic, cognitive, and behavioral features. She uses the term semantic-pragmatic disorder to designate the characteristic affective language and behavior and to distinguish it from other forms of developmental disorders and mental retardation.

Elements of autism, but not the whole syndrome with its positive and negative attributes, may appear in other diseases that interfere with brain development, specifically fragile-X and Rett syndromes, and fragmentary similarities are found in a few children with phenylketonuria, tuberous sclerosis, Angleman syndrome, and, rarely, Down syndrome—but these patients are easily distinguished from those with the far more common type of autism. Bolton and Griffiths have made the intriguing observation that autistic traits in patients with tuberous sclerosis correspond to the finding of tubers in the temporal lobe, and Delong and Heinz point out that patients with seizures from bilateral (but not unilateral) hippocampal sclerosis may fail to develop (or may lose) language ability as well as to acquire social skills after a period of normal development, in a manner similar to idiotic autism. The IQ of the majority is below 70.

Etiology and Pathology of Autism The basis of childhood autism is as much a mystery today as it was when Kanner and Asperger described it. Most of these children are physically normal except for a larger than average head size, but with no other somatic anomalies. The EEG is normal, as is CT or MRI. The significance of cerebellar vermal changes, reported originally by Courchesne et al., remains to be determined (Filipek).

In the few brains examined postmortem, no lesions of any of the conventional types were found. In five brains studied in serial sections by Bauman and Kemper, smallness of neurons and increased packing density were observed in the medial temporal areas (hippocampus, subiculum, entorhinal cortex), amygdala and septal nuclei, and mammillary bodies. In a subsequent review of the neuropathology, Kemper and Bauman concluded that three changes stand out: a curtailing of the normal development of neurons in the limbic system; a decrease in the number of Purkinje cells that appears to be congenital; and—in contrast to this—age-related changes in the size and number of the neurons in the diagonal band of Broca (located in the basal frontal septal region) as well as in the cerebellar nuclei and inferior olive. The age-related changes were inferred from studying the brains of autistic children who died at different ages, and they gave the appearance of a progressive or regressive process. These findings are in keeping with the concept of autism in social, language, cognitive, and behavioral domains may occur in widely varying degrees of severity. This view permits a syndromic diagnosis of autism in patients with coexisting elements of other disorders, such as attention deficit disorder and manic-depressive or obsessive-compulsive disorders and expands the diagnosis to many children who are highly functional except for gaze aversion and other "soft signs" (Filipek).

Course and Prognosis The disease is essentially nonprogressive, although some patients, as they grow older, begin to manifest additional visuospatial or auditory defects. The outcome is bleak, although a group of less affected children may show improvement in social relationships and schoolwork with the use of serotonin reuptake inhibitors, sometimes in very small doses (Delong; Filipek, personal communication). The peptide secretin has produced a number of anecdotal successes, but this outcome could not be reproduced in a controlled study (Sander et al.). According to Eisenberg, who reviewed many of Kanner's original cases and followed many other cases into adult life, one-third never spoke and remained social isolates, one-third acquired a rudimentary language devoid of communicative value, and the remainder were functional to various degrees with an affected, stilted, colorless speech. It is in the latter group, representing the mildest degrees of autism, that one finds the eccentricities, the nonsensical, flat personalities, unable to adapt socially and habitually avoiding eye contact but sometimes possessing certain unusual aptitudes in memory, mathematics, factual knowledge, history, and science. Rutter, who has written extensively on the subject, says that the degree of language impairment and lowered intelligence predicts outcome; those who do not speak by 5 years of age never learn to speak well.

Management of Mental Retardation Since there is little or no possibility of treating most of the diseases underlying mental retardation and there is no way of restoring function to a nervous system that is developmentally subnormal, the objective is to assist in planning for the patient's care, training, education, and social adjustment. The parents must be guided in forming realistic attitudes and expectations. Psychiatric and social counseling may help the family to maintain gentle but firm support of the patient so that he or she can acquire, to the fullest extent possible, good work habits and a congenial personality.

Most individuals with an IQ above 60 and no other handicaps can be trained to live an independent life; special schooling may enable them to learn skills useful in a vocation. Social factors that contribute to underachievement must be sought and eliminated if possible. If the IQ is below 20, institutionalization is almost inevitable, for few families can provide the long-term custodial care that is needed. Well-run institutions are usually more humane and more successful in this type of care than are institutions for mental retardation.

Chapter 39

DEGENERATIVE DISEASES OF THE NERVOUS SYSTEM

General Clinical Characteristics

General Pathologic Features
Classification
Diseases Characterized Mainly by Progressive Dementia
Alzheimer Disease
Leber Atrophy (Pick Disease)
Frontotemporal Dementia
Other Degenerative Dementias

Diseases in Which Dementia is Associated with Other Neurologic Abnormalities
Huntington Chorea
Acanthocytosis with Chorea

Syndromes of Progressive Ataxia
Familial Ataxia with Severe Encephalopathy
Adul Polyneuronic Body Disease

Diseases Characterized by Abnormalities of Posture and Movement
Dystonic Disorders

Syndrome of Progressive Deafness
Encephalomyelitis with Multifocal Ataxias (Predominantly Spinal)

Syndrome of Progressive Blindness
Syndrome of Signs of Cerebellar Atrophy

Syndrome of Muscular Weakness and Wasting Without Sensory Changes
Radiculopathy Disease
Hereditary Forms of Progressive Muscular Atrophy and Spastic Paraparesis

Chapter References

The adjective degenerative has no great appeal to the modern neurologist. For one thing, it has an unpleasant non-medical connotation, referring as it does to a state of moral turpitude or deviant behavior as the consequence of a sociopathic tendency. More important, it is not a satisfactory term medically, since it implies an inexplicable decline from a previous level of normalcy to a lower level of function—an ambiguous conceptualization of disease that satisfies neither theoretician nor scientist.

It is becoming increasingly evident that many of the diseases included in this category depend on genetic factors, or at least they appear in more than one member of the same family, in which case they are more properly designated as heredodegenerative. Even more diseases, not differing in any fundamental way from the heredodegenerative ones, occur sporadically, i.e., as isolated instances in given families. For diseases of this type, Gowers in 1902 suggested the term atrophy, by which he meant a lack of "vital endurance" of the affected neurons, resulting in their premature death. This concept embodies an untested, unproven hypothesis—that aging and degenerative changes of cells are based on the same process. Understandably, contemporary neuropathologists are reluctant to attribute to simple aging the diverse processes of cellular diseases that are constantly being revealed by ultrastructural and molecular genetic techniques.

The reader may be perplexed by the inconsistent use of the terms atrophy and degeneration, both of which are applied to diseases of this category. Spatz argued that on purely histopathologic grounds they are different. Atrophy specifies a gradual wasting and loss of a system of neurons, leaving in their wake no degradative products and only a sparsely cellular, fibrous gliosis. Degeneration refers to a more rapid process of neuronal, myelin, or tissue breakdown, the degradative products of which evoke a more vigorous reaction of phagocytosis and cellular gliosis. The difference lies in both the speed and the type of breakdown. It is of some interest that many of the diseases that are characterized by degeneration, in Spatz's sense of the term, are now known to be of metabolic origin, while very few of the purely atrophic ones have been shown to have a metabolic basis.

The new and fashionable pathologic term for the wasting and dissolution of neurons, in both the system atrophies and the degenerative diseases, is apoptosis. This term has been borrowed from embryology, where it refers to the naturally occurring cell death in the central nervous system during development and probably involves the expression of genes that cause a dissolution of neurons over a short period of time ("programmed" cell death), leaving no trace of a pathologic reaction. The process of neuronal degeneration is quite different; it refers to a series of changes in mature neurons, occurring over a relatively protracted period of time and leaving a discrete glial scar.

There are also, within recent memory, several examples of diseases that were formerly classed as degenerative but are now known to have a metabolic, toxic, or nutritional basis or to be caused by a "slow virus" or by a nonviral transmissible agent. It seems reasonable to expect that with increasing knowledge, more and more diseases whose causes are now unknown will find their way into these categories. Until such time as the causation of all neurologic diseases is known, there must be a name and a place for a group of diseases that have no known cause and are united only by the common attribute of gradually progressive disintegration of part or parts of the nervous system. In deference to traditional practice, they are collected here under the rubric degenerative diseases.

General Clinical Characteristics

The diseases included in the degenerative category begin insidiously, after a long period of normal nervous system function, and pursue a gradually progressive course that may continue for many years, often a decade or longer. In this respect they differ from most of the metabolic diseases. Frequently it is impossible to assign a date of onset. Sometimes, the patient or the patient's family gives a history of abrupt appearance or developmental delay, or other memorable event coincided with the initial symptoms. Often a skilfully taken history will reveal that the patient or family had been aware of a pre-existent condition, the subtle symptoms of which had been present for some time but had attracted little attention. Whether trauma or other stress can actually evoke or aggravate a degenerative disease is a question that cannot be answered with absolute certainty, but it seems highly improbable. Anyone who states that a neurologic disease has "tainted" the family. Furthermore, it may not be realized that an illness is hereditary if other members of the family have a much more or much less severe form of the disorder than the patient. Sometimes, in the latter case, only the careful examination of other family members will disclose the presence of a hereditary disease. It should be remembered, however, that familial occurrence of a disease does not necessarily mean that it is inherited but may indicate instead that more than one member of a family had been exposed to the same infectious or toxic agent.

As a rule, the degenerative diseases of the nervous system run a ceaselessly progressive course and with few exceptions are uninfluenced by any medical or surgical measures, so that dealing with a patient with this type of illness may be an anguishing experience for all concerned. However, some of these diseases are
characterized by long periods of stability; moreover, some symptoms (e.g., those of Parkinson disease) can be alleviated by skillful management, and the physician’s interest and advice may be of great help.

The bilateral symmetry of the clinical manifestations and lesions is another noteworthy feature of the degenerative diseases; it alone may distinguish members of this group from many other diseases of the nervous system. Again, this principle requires qualification, for in the earliest stages of some degenerative diseases (e.g., Parkinson disease, amyotrophic lateral sclerosis) there may be greater involvement of one limb or one side of the body. Sooner or later, however, despite the asymmetrical beginning, the inherently symmetrical nature of the process asserts itself.

General Pathologic Features

Many of the degenerative diseases are characterized by the selective involvement of anatomically and physiologically related systems of neurons. This feature is exemplified by amyotrophic lateral sclerosis, in which the pathologic process is limited to motor neurons of the cerebral cortex, brainstem, and spinal cord, and by certain forms of progressive ataxia, in which only the Purkinje cells of the cerebellum are affected. Many other examples could be cited (e.g., Friedrich ataxia) in which several discrete neuronal systems disintegrate, leaving others unscathed. These degenerative diseases have therefore been called system atrophies or systemic neuronal atrophies, and many of them turn out to be strongly hereditary. The selective vulnerability of certain systems of neurons is not an exclusive property of the degenerative diseases, however; several disease processes of known cause have similarly circumscribed effects on the nervous system. Ophtheria toxin, for instance, selectively affects the myelin of the peripheral nerves near the spinal ganglia, and triorthocresyl phosphate affects both the corticospinal tracts of the spinal cord and the spinal motor neurons. Other examples are the special vulnerability of the Purkinje cells to hyperthermia, the cerebellar granule cells to methyl mercury compounds, the basal ganglionic neurons to manganese, and the hippocampal neurons to anoxia. Conversely, in Alzheimer disease and most other degenerative diseases, the pathologic changes are somewhat less selective and eventually more diffuse.

As one would expect of any pathologic process that is based on the slow wasting and loss of neurons, not only the cell bodies but also their dendrites, axons, and myelin sheaths disappear—unaccompanied by an intense tissue reaction or cellular response. The cerebrospinal fluid (CSF), therefore, shows little if any change—at most a slight increase in protein content. Moreover, since these diseases invariably result in tissue loss (rather than in new tissue formation, as occurs with neoplasms or inflammations), radiologic examination shows either no change or a volumetric reduction (atrophy) with a corresponding enlargement of the CSF compartments. These radiologic findings help distinguish the neuronal atrophies from other large classes of progressive disease of the nervous system—namely, tumors, infections, and other processes of inflammatory type.

CLASSIFICATION

Since grouping of the degenerative diseases in terms of etiology is not possible (except that in many a hereditary, or genetic, factor can be recognized), we resort, for practical purposes, to a division based on the presenting clinical syndromes and their pathologic anatomy. Although this is the most elementary mode of classification of naturally occurring phenomena, it is a necessary prelude to diagnosis and scientific study and preferable to a haphazard listing of diseases by the names of the neurologists or neuropathologists who first described them.

I. Syndrome of progressive dementia, other neurologic signs being absent or inconspicuous

A. Diffuse cerebral atrophy
   1. Alzheimer disease
   2. Diffuse cerebral cortical atrophy of non-Alzheimer type
   3. Some cases of Lewy body dementia

B. Circumscribed cerebral atrophy
   1. Pick disease (lobar sclerosis)
   2. Frontotemporal dementia
   3. Thalamic degeneration

II. Syndrome of progressive dementia in combination with other neurologic abnormalities

A. Huntington chorea
B. Other (nonhuntingtonian) types of chorea and dementia
C. Cortical- striatal-spinal degeneration (Jakob) and the dementia-Parkinson-amyotrophic lateral sclerosis complex (Guamanian and others)
D. Dentatorubropallidoluysian degeneration (DRPLA)
E. Cerebrocerebellar degeneration
F. Familial dementia with spastic paraparesis, amyotrophy, or myoclonus
G. Lewy body disease
H. Some cases of Parkinson disease
I. Corticobasal ganglionic degeneration
J. Polygicincus body disease

III. Syndrome of disordered posture and movement

A. Parkinson disease (paralysis agitans)
B. Striatostral degeneration with or without autonomic failure (Shy-Drager syndrome and olivopontocerebellar atrophy (multiple system atrophy)
C. Progressive supranuclear palsy (Steele-Richardson-Olszewski)
D. Dystonia musculorum deformans (torticollis deformans)
E. Dystonia musculorum deformans (familial type)
F. Hallervorden-Spatz disease
G. Corticobasal ganglionic degeneration
H. Restricted dystonias, including spasmodic torticollis and Meige syndrome
H. Familial tremors
I. Multiple tic disease (Gilles de la Tourette syndrome)
J. Acanthocytic chorea

IV. Syndrome of progressive ataxia

A. Spinocerebellar ataxias (early onset)
   1. Friedreich ataxia
   2. Non-Friedreich, early-onset ataxia (with retained reflexes, hypogonadism, myoclonus, and other disorders)
B. Cerebellar cortical ataxias
   1. Holmes type of familial pure cerebellar-olivary atrophy
   2. Late-onset cerebellar atrophy of Marie, Foix, and Alajouanine
C. Complicated cerebellar ataxia (later-onset ataxia with brainstem and other neurologic disorders)
   1. Olivopontocerebellar degenerations (OPCA)
      a. Clinically pure (Déjerine-Thomas type)
      b. With extrapyramidal and autonomic degeneration (multiple system atrophy)
      c. Conjoined with spino-cerebellar degeneration (Menzel type)
   2. Dentatorubral degeneration (Ramsay Hunt type)
   3. Dentatorubropallidoluysian atrophy
   4. Machado-Joseph-Azorean disease
   5. Other complicated late-onset, autosomal dominant ataxias (including Harding’s types 1, 2, and 3) with pigmentary retinopathy, ophthalmoplegia, slow eye movements (Werdet), neuropolysis, optic atrophy, deafness, extrapyramidal features, and dementia

V. Syndrome of slowly developing muscular weakness and atrophy (nuclear amyotrophy)

A. Motor disorders with amyotrophy: motor system disease
   1. Amyotrophic lateral sclerosis
   2. Progressive spinal muscular atrophy
   3. Progressive bulbar palsy
   4. Hereditary forms of progressive muscular atrophy and spastic paraplegia
B. Spastic paraplegia without amyotrophy
   1. Primary lateral sclerosis
   2. Hereditary spastic paraplegia
VI. Sensory and sensorimotor disorders (neuropathies)

A. Hereditary sensorimotor neuropathies—peroneal muscular atrophy (Charcot-Marie-Tooth); hypotrophic interstitial polyneuropathy (Déjerine-Sottas); Refsum disease, etc.

VII. Syndrome of progressive blindness or ophthalmoplegia with or without other neurologic disorders

A. Optic atrophy (Leber)
B. Pigmentary degeneration of retina (retinitis pigmentosa)
C. Stargardt disease

VIII. Syndromes characterized by neurosensory deafness

A. Pure neurosensory deafness
B. Hereditary hearing loss with retinal diseases
C. Hereditary hearing loss with system atrophies of the nervous system

DISEASES CHARACTERIZED MAINLY BY PROGRESSIVE DEMENTIA

Alzheimer Disease

This is the most common and important degenerative disease of the brain, incurring to an increasing degree an immense societal impact. Some aspects of the intellectual deterioration that characterizes this disease have already been described in Chap. 21, under “The Neurology of Dementia,” and the relationship of this disease to Alzheimer's disease has fully discussed. The process has been of shrinkage in size and weight of the brain, i.e., “atrophy,” is an inevitable accompanying of advancing age, but that these changes alone are of slight clinical significance and their structural basis is uncertain (e.g. slight loss of brain weight or simple depletion of neurons). By contrast, severe degrees of diffuse cerebral atrophy that evolve over a few years are invariably associated with the underlying pathologic changes in these cases most often prove to be those of Alzheimer disease. For this reason it is usual to speak of the clinical syndrome as dementia of the Alzheimer type (DAT) or probable Alzheimer disease, if the diagnosis is uncertain. The traditional practice of giving Alzheimer disease and senile dementia the status of separate diseases was probably attributable to the relatively young age (51 years) of the patient originally studied by Alois Alzheimer in 1907. Such a division is illogical, since the two age of onset, are clinically and pathologically indistinguishable. There is a smooth, exponential, age-dependent increase in incidence after 40 years of age.

Epidemiology

Although Alzheimer disease has been described at every period of adult life, the majority of patients are in their sixties or older; a relatively small number have been in their late fifties or younger. It is one of the most frequent mental illnesses, making up some 20 percent of all patients in psychiatric hospitals and an even larger proportion in nursing homes in the United States, in 17 series comprising 15,000 persons over the age of 60 years, the mean incidence of moderate to severe dementia was calculated to be 4.8 percent (Wang). In Rochester, Minnesota, the incidence rate for dementia in general is 187 cases per 100,000 population per year, and for Alzheimer disease, 123 cases per 100,000 annually (Shoenberg et al).

These staggering statistics may be viewed from another perspective. The incidence rate of clinically diagnosed Alzheimer disease is similar throughout the world, and it increases comparably with age, approximating 3 new cases yearly per 100,000 persons below age 60 and 125 new cases per 100,000 of those over 60. The prevalence of the disease per 100,000 population is near 300 in the group aged 60 to 69; it is 3200 in the 70 to 79 group and 10,800 in those over age 80. In the year 2000, there will be 2.5 million patients with Alzheimer disease in the United States. Prevalence rates, which depend also on overall mortality, are three times higher in women, although it does appear that the incidence of new cases is only slightly disproportionate in women. The survival of patients with Alzheimer disease is reduced to half of the expected rate, most of the deaths occurring ultimately from respiratory and cardiovascular causes.

Several putative epidemiologic risk factors for Alzheimer disease—such as birth order, mother's age at birth, family history of Down syndrome, or head injury—seem marginal at best and in some instances may be due to selection bias. Whether low educational attainment is a risk factor for the development of Alzheimer disease or, conversely, whether cognitively demanding occupations protect against dementia has not been settled (Katzman; Cobb et al).

The familial occurrence of Alzheimer disease, viewed as less than 1 percent of all cases, has been well established, most of the pedigrees being consistent with an autosomal dominant inheritance (Nee et al; Goidsmith et al; see further on, in the section on pathogenesis). Reports of a substantial familial aggregation of dementia without a specific pattern of inheritance also suggest the operation of more than one genetic factor. Several studies have documented a significant increase in the risk of apparently sporadic Alzheimer disease among first-degree relatives of patients with this disorder. Again, this risk is disproportionately greater in females, adding to the evidence that women in general are at slightly higher risk for Alzheimer disease (Silverman et al). Li and coworkers have provided evidence that patients with an earlier age of onset of Alzheimer disease (before age 70) are more likely to have relatives with the disease than are patients with later onset. Genetic studies are difficult because the disease does not appear at the same age in a given proband. Even in identical twins, it may develop at the age of 60 years in one of the pair and at 80 years in the other. Death from other diseases may prevent its detection.

Clinical Features

The onset of mental changes is usually so insidious that neither the family nor the patient can date the time of its beginning. Occasionally, however, it is brought to attention by an unusual degree of confusion in relation to a fellible illness, an operation, mild head injury, or the taking of medication. Other patients may present with complaints of dizziness, nondescript headaches, or other vaguely expressed and changeable somatic symptoms.

The gradual development of forgetfulness is the major symptom. Small day-to-day happenings are not remembered. Seldom-used names are particularly elusive. Little is forgotten from an earlier period of life also tend to be lost. Appointments are forgotten and possessions misplaced. Questions are repeated again and again, the patient having forgotten what was just discussed. It is said that remote memories are preserved and recent ones lost (Ribot's law of memory), but this is only relatively true; it is difficult to check the accuracy of ancient memories. Albert and associates, who tested the patient's recognition of dated political events and pictures of prominent people past and present, found that some degree of memory loss extends to all decades of life (specific neuropsychological testing is discussed further on).

Once the memory disorder has become pronounced, other failures in pronouncing certain words in normal conversation become increasingly apparent. The patient's speech is halting because of failure to recall the needed word. The same difficulty interrupts writing. Vocabulary becomes restricted, and expressive language stereotyped and inflexible. Comprehension of spoken words seems at first to be preserved, until it is observed that the patient does not carry out a complicated request; even then it is uncertain whether the request was not understood because of inattention or was forgotten. Almost immediate is first, these disturbances of language become more apparent as the disease progresses. Finally, there is a failure to speak in full sentences; the finding of words requires a continuous search; and little that is said or written is fully comprehended. There is a tendency to repeat a question before answering it, and later there may be a rather dramatic repetition of every spoken phrase (echolalia). The deterioration of verbal skills has been then progressed beyond a groping for names and common nouns to an obvious anomic aphasia. Other elements of receptive and executive aphasia are later added, but discrete aphasia of the Broca or Wernicke type are characteristically lacking.

Skill in arithmetic suffers a similar deterioration. Faults in balancing the checkbook, mistakes in figuring the price of items and in making the correct change—all these activities. In some patients, visuospatial orientation becomes defective. The car cannot be parked; the arms do not find the correct sleeves of the dressing gown; the corners of the tablecloth cannot be oriented with the corners of the table; the patient turns in the wrong direction on the way home or becomes lost. The route from one place to another cannot be described, nor can given directions be understood. As this state worsens, the simplest of geometric forms and patterns cannot be copied.

In some patients, ideomotor apraxia, or apraxia of inalienable, the term cannot be used correctly, the patient at first seems unchanged in overall motility, behavior, temperament, and conduct. Social graces, whatever they were, are retained in the initial phase of the illness, but troublesome alterations gradually appear in this sphere as well. Improvident business deals may be made. Restlessness and agitation or their opposites—inertia and placidity—become evident. Dressing, shaving, and bathing are neglected. Anxieties and phobias, particularly fear of being left alone, may emerge. A disturbance of the normal day and night sleep patterns is prominent in some patients. A poorly organized paranoid delusional state, sometimes with hallucinations, may become manifest. The patient may suspect his elderly wife of having an...
illicit relationship or his children of stealing his possessions. A stable marriage may be disrupted by the patient's infatuation with a younger person or by sexual indiscretions, which may astonish the community. The patient's affect coarsens; he is more egocentric and indifferent to the feelings and reactions of others. A gluttonous appetite sometimes develops, but more often eating is neglected, with gradual weight loss. Later, grasping and sucking reflexes and other signs of frontal lobe disorder are readily elicited (Heary et al), sphenicteric continence fails, and the patient sinks into a state of relative akinnesia and mutism, as described in Chap. 21.

Difficulty in locomotion, a kind of unsteadiness with shortened steps but with only slight motor weakness and rigidity, frequently supervenes. Elements of parkinsonism akinnesia and rigidity and a finer tremor can be perceived in patients with advanced motor disability. Ultimatey the patient loses the ability to stand and walk, being forced to lie inert in bed and having to be fed and bathed, and the legs may curl into a fixed posture of paraplegia in flexion (persistent vegetative state; page 369).

The symptomatic course of this tragic illness usually extends over a period of 5 or more years but, judging from studies of Down cases, the pathologic course has a much longer asymptomatic duration. This concept is supported by the delayed studies of Linn and colleagues, who found that a lengthy "preclinical" period (7 years or more) of stepwise decline in memory and attention span preceded the clinical diagnosis. Surprisingly, throughout this period, corticospinal and corticorex sensory functions, visual acuity, ocular movements, and visual fields remain relatively intact. If there is ocular movement, hemianopsia, hemianopia, etc., either the diagnosis of Alzheimer disease is incorrect or the disease has been complicated by a stroke, tumor, or subdural hematoma. Exceptions to this statement are rare. The tendon reflexes are little altered and the plantar reflexes almost always remain flexor. There is no true sensory or cerebellar ataxia. Convulsions are rare until late in the illness, when up to 5 percent of patients reportedly have infrequent seizures. Occasionally, widespread myoclonic jerks or mild choreoathetotic movements are observed late in the illness. Eventually, with the patient in a bedfast state, an intercurrent infection such as aspiration pneumonia or some other disease mercifully terminates life.

The sequence of neurologic dysfunctions may not follow this described order, and one or another deficit may take precedence, presumably because the disease process, after becoming manifest in the memory cortex of the temporal lobes, may affect one particular part of the associative cortex earlier or more severely in one patient than in another. This allows a relatively restricted deficit to become the source of early medical complaint long before the full syndrome of dementia has declared itself. We have observed four limited deficits of this type, as follows:

1. Korsakoff amnesic state. The early stages of Alzheimer disease may be dominated by a disproportionate failure of retentive memory, with integrity of other cognitive abilities. In such patients, immediate memory (essentially a measure of attention), tested by the capacity to repeat a series of numbers or words, is essentially intact; it is the short- and long-term (retentive) memory that fails. Retentive memory may become impaired to the point where the patient can recall nothing of what he had learned a minute or two previously. Yet as a business executive, for example, he may continue to make acceptable decisions if the work utilizes long-established habit patterns and practices. In such cases, the temporal horns tend to be enlarged more than the rest of the ventricular system, indicating atrophy of the inferomedial temporal lobe.

2. Dysnomia. The forgetting of words, especially proper names, may first bring the patient to a neurologist. Later the disorder involves common nouns and progresses to the point where fluency of speech is seriously impaired. Every sentence is reduced to a pause and search for the wanted word; if this is not found, a circumlocution is substituted or the sentence is left unfinished. When the patient is given a choice of words, including the one that was missed, there may be a failure of repetition. Repetition of the spoken word brings out a lesser degree of the same difficulty. A useful test for the failure to find names (dysnomia), which is probably the most common abnormality of language in this disease, is the category-fluency test. The patient is given 1 min to name as many items as possible in each of four categories—vegetables, vehicles, tools, and clothing. Alzheimer patients fall below a score of 50 items. The naming deficit, evident with everyday words, is less than that of the patient used to generate a list of farm animals—a test that may elicit only three or four responses. Other components of language may be relatively intact, but before long it is evident that the patient does not understand all that he hears or reads. In contrast, nonverbal memory and the ability to calculate and make simple judgments may still be preserved. Duplicating our own experience, Mesulam and Chawluk and their colleagues have described patients in whom an aphasic disorder began with anomia and eventually affected reading, writing, and comprehension without the additional intellectual and behavioral disturbances of dementia. In our own observation of such patients, if observed for a sufficiently long period, develop a more general dementia, sometimes as long as 5 years or more after the onset of aphasia. Rarely, this syndrome represents a focal degenerative disorder (lobar atrophy of Pick or frontotemporal dementia), distinct from Alzheimer disease (Jipa et al, Kirnsh et al). Usually the electroencephalogram (EEG) is normal or shows only a mild degree of slowing, but magnetic resonance imaging (MRI) may disclose a focal atrophy of the language areas (Caselli et al).

3. Visuospatial disorientation. Partially-occipital functions are sometimes altered in the course of Alzheimer disease and may fail while other functions are relatively preserved. As remarked above and in Chap. 22, prosopagnosia, losing one's way in familiar surroundings or inability to interpret a road map, to distinguish the left from the right, or to park or get out of a parked car, are early signs. In addition, difficulty in setting the table or dressing are all manifestations of a special failure to orient the schema of one's body with that of surrounding space. Exceptionally there is a neglect of stimuli in one visual field.

4. Paranoia and other personality changes. Frequently, at some point in the development of senile dementia, the most prominent event is the occurrence of paranoia or bizarre behavior. The patient becomes convinced that relatives are stealing his possessions or that an elderly and even infirm spouse is guilty of infidelity. He may hide his belongings, even relatively worthless ones, and go about spying on family members. Hostilities arise, and wills may be altered irrationally. Many of these patients are constantly worried, tense, and agitated. Of course, paranoid delusions may be part of a depressive psychosis and of other dementias, but most of the senile patients in whom paranoia is the presenting problem seem not to be depressed, and their cognitive functions are for a time relatively well preserved. It is tempting to think that a very early senile encephalitis of the limbic cortices has exposed a lifelong trait of suspiciousness, but this is purely hypothetical.

Sometimes other disorders of behavior will announce the oncoming dementia. Social indiscretions, rejection of an old friend, embarking on an imprudent financial venture, or an amorous pursuit that is out of character are examples of these types of behavioral change.

Some clinicians attempt to subdivide the Alzheimer–senile dementia syndrome into subtypes. Amnesic defect without lexical-semantic abnormalities represents more than 50 percent of the cases and concerns the more prevalent, more predictable, and more frequent pattern of Clinical language disorder. It is more prevalent in a younger age group and more likely to progress to the point where fluency of speech is seriously impaired. Every sentence is reduced to a pause and search for the wanted word; if this is not found, a circumlocution is substituted or the sentence is left unfinished. When the patient is given a choice of words, including the one that was missed, there may be a failure of repetition. Repetition of the spoken word brings out a lesser degree of the same difficulty. A useful test for the failure to find names (dysnomia), which is probably the most common abnormality of language in this disease, is the category-fluency test. The patient is given 1 min to name as many items as possible in each of four categories—vegetables, vehicles, tools, and clothing. Alzheimer patients fall below a score of 50 items. The naming deficit, evident with everyday words, is less than that of the patient used to generate a list of farm animals—a test that may elicit only three or four responses. Other components of language may be relatively intact, but before long it is evident that the patient does not understand all that he hears or reads. In contrast, nonverbal memory and the ability to calculate and make simple judgments may still be preserved. Duplicating our own experience, Mesulam and Chawluk and their colleagues have described patients in whom an aphasic disorder began with anomia and eventually affected reading, writing, and comprehension without the additional intellectual and behavioral disturbances of dementia. In our own observation of such patients, if observed for a sufficiently long period, develop a more general dementia, sometimes as long as 5 years or more after the onset of aphasia. Rarely, this syndrome represents a focal degenerative disorder (lobar atrophy of Pick or frontotemporal dementia), distinct from Alzheimer disease (Jipa et al, Kirnsh et al). Usually the electroencephalogram (EEG) is normal or shows only a mild degree of slowing, but magnetic resonance imaging (MRI) may disclose a focal atrophy of the language areas (Caselli et al).

It has been our impression that each of the restricted cerebral disorders described above is only relatively pure. Careful testing of mental function—and this is of diagnostic importance—frequently discloses subtle abnormalities in several cognitive spheres. Initially, most patients have a disproportionate affection of the temporoparietal cortices, hence the earlier impairment on the performance parts of the Wechsler Adult Intelligence Scale. Within several months to a year or two, the more general aspects of mental deterioration become apparent, and this aphasia-aprosog-aspasic aspects of the syndrome become increasingly prominent. If one of the foregoing explained deficits remained and sulci were widened over a period of years, one is justified in suspecting a cause other than Alzheimer disease, such as Binswanger disease, hydrocephalus, frontotemporal dementia (see further on), or embolic infarction of one part of the temporal or parietal lobe (pages 451 and 878).

Also, as stated earlier, a hemispheric visual field defect, cortical sensory loss, or hemiparesis is seldom if ever due to Alzheimer disease alone. However, more complete involvement of vision, of perception, of visual orientation, of visual perception (object agnosia) or faces (prosopagnosia), visual scanning, color identification, stereocare, separation of figures from background, and hand-eye coordination, are frequent in the more advanced stages (Mendes et al). Rarely there is a partial or even a complete Balint syndrome (page 491).

It is true that while most patients with Alzheimer disease walk normally until relatively late in their illness, infrequently a short-stepped gait and imbalance draw attention to the disease and worsen slowly for several years before cognitive manifestations become evident.

For research purposes and to establish certain inclusive and exclusive criteria for the diagnosis of Alzheimer disease, a work group of the National Institute of Neurological and Communication Disorders and Stroke (NINCDS) and the Alzheimer’s Disease and Related Diseases Association (ADRA) have proposed the following diagnostic criteria: (1) dementia defined by clinical examination, the Mini-Mental Scale, the Blessed Dementia Scale, or similar mental status examination; (2) age of patient (over 40 years); (3) deficits in two or more areas of cognitive and progressive worsening of memory and other cognitive functions—such as language, speech, object recognition, praxis and motor skills (praxis); and (4) absence of other brain diseases (McKhann et al; Tatemoko et al).

Using these criteria, the correct diagnosis is achieved in more than 85 percent of patients.

Pathology. In the advanced stages of the disease, the brain presents a diffusely atrophied appearance and brain weight is usually reduced by 20 percent or more (Fig. 39-1). Cerebral convolutions are narrowed and sulci are widened to a varying degree. The third and lateral ventricles are symmetrically enlarged to a varying degree. Usually the atrophic process involves the frontal, temporal, and parietal lobes, but cases vary considerably. The extreme atrophy of the hippocampus—the most prominent finding, visible on coronal MRI—is believed to be diagnostic. Microscopically, there is widespread loss of nerve cells, most marked in the cerebral cortex. In addition to pronounced neuronal loss in the hippocampus, adjacent parts of the medial temporal cortex—namely, the entorhinal cortex, parahippocampal gyr, and subiculum—are affected. The anterior nuclei of the thalamus, septal nuclei and diagonal band of Broca, the amygdala, and particular brainstem parts of the
In addition, three microscopic changes give this disease its distinctive character: (1) the presence within the nerve cell cytoplasm of thick, fiber-like strands of silver-staining material, often in the form of loops, coils, or tangled masses (Alzheimer neurofibrillary change, or “tangles”). The strands are composed of a hyperphosphorylated form of the microtubular protein “tau” and appear as pairs of helical filaments when studied ultrastructurally; (2) spherical deposits of amorphous material scattered throughout the cerebral cortex and most easily seen with periodic acid–Shiff (PAS) and silver-staining methods; the core of the aggregates is the protein amyloid, surrounded by degenerating nerve terminals (senile or neuritic plaques). Amyloid is also scattered throughout the cerebral cortex in a nascent “diffuse” form, without organization or core formation and appreciated mainly by immunohistochemical methods, as well as in the walls of small blood vessels near the plaques—so-called congophilic angiopathy; (3) granulovacular degeneration of neurons, most evident in the pyramidal layer of the hippocampus.

Neuritic plaques and neurofibrillary changes are found in all the association areas of the cerebral cortex, but it is the neurofibrillary tangles and neuronal alterations and loss, not the plaques, that correlate best with the severity of the dementia (Araujo et al.). If any part of the brain is disproportionately affected, it is the hippocampus, particularly the CA1 and CA2 zones (of Lorente de Nó) and the entorhinal cortex, subiculum, and amygdala. These parts have abundant connections with other parts of the temporal lobes cortex and dentate nucleus of the hippocampus and undoubtedly account for the amnesic component of the dementia. The plaques themselves are not seen in the parenchyma favored site. Only a few tangles and plaques are found in the hypothalamus, thalamus, periaqueductal region, pontine tegmentum, and granule-cell layer of the cerebellum.

Experienced neuropathologists recognize a form of Alzheimer disease, particularly in older patients (>75 years), in which there are senile plaques but few if any neurofibrillary tangles (20 percent of 150 cases reported by Joachim et al.). [In general, senile (neuritic) plaques are found to be more diffusely distributed than the fibrillary changes.] Another problem for the neuropathologist is to distinguish between the normal aged brain and that of Alzheimer disease. It is not unusual to find a scattering of senile plaques in individuals who were thought to be mentally normal during life. Henderson and Hubbard studied 27 demented individuals aged 64 to 92 years and 20 age-matched, nondemented controls. In the former, 3 to 38 percent of the hippocampal neurons contained neurofibrillary tangles; in all but 2 of the controls, the number of hippocampal neurons with tangles fell below 2.5 percent. Hence, the difference between plaques and tangles in the aging brain and in Alzheimer disease is largely quantitative.

Of interest also is the observation of Joachim and associates that 18 percent of their Alzheimer cases had sufficient neuronal loss and Lewy bodies in the substantia nigra to justify a diagnosis of Parkinson disease. Leverenz and Sumi found that 25 percent of their Alzheimer patients showed the pathologic (and clinical) changes of Parkinson disease—a much higher incidence than can be attributed to chance. Also, of 11 patients with progressive supranuclear palsy reported by Gearing and coworkers, 10 were demented and 5 had Alzheimer disease. These mixed cases, including those with Pick disease, present problems not only of classification, but also in understanding the neurobiology of these degenerative diseases. This subject is discussed further on in the section on Parkinson disease.

It is of historical interest that Alzheimer was not the first to describe plaque formation. One of the hallmarks of this pathologic state. These military lesions (“Hendrich”) had been observed in senile brains by Blocq and Marinsco in 1892 and were named senile plaques by Simchowicz in 1910. In 1907, Alzheimer described the case of a 51-year-old woman who died after a 5-year illness characterized by progressive dementia. Throughout the cerebral cortex he found the characteristic lesions, but he also noted—that thanks to the use of Blieschowsky’s silver impregnation method—a clumping and distortion of fibrils in the neuronal cytoplasm, the neurofibrillary change which now, appropriately, carries Alzheimer’s name.

Pathogenesis Careful analyses of the senile plaques and neuronal fibrillary changes have been made in recent years in an attempt to elucidate the mechanism of Alzheimer disease. Several new histologic techniques have been devised and put to service in this endeavor—refinements of the silver impregnation method, which stains both amyloid and its main constituent (amyloid b protein, or Ab); immunoreactive methods, using antibodies raised to rabbit thymus (ubiquitin), to demonstrate neuronal tau protein and amyloid b protein; and thioflavine S and Congo red with ultraviolet and polarized light to identify amyloid b protein and amyloid. Tau is a discrete cytoskeletal protein that is thought to promote the assembly of microtubules and to stabilize their structure as well as to participate in synaptic plasticity in a yet to be defined manner. In the pathologic circumstances of Alzheimer disease, progressive supranuclear palsy, and frontotemporal dementia (see further on), tau is hyperphosphorylated and aggregates, resulting in an overloading of the perikarya and neurites with paired helical filaments which constitute neurofibrillary tangles. Electrophoretically, tau moves with the beta globulins and is thought to function as a transferrin, i.e., it binds iron and delivers it to the cell. Tau can be measured in the CSF and serum.

The Ab protein is a small portion of a set of amino acids collectively referred to as the amyloid b protein precursor (APP), which is normally bound to neuronal membranes. The Ab protein is cleaved from the APP by the action of proteases termed a, b, and d secretase. A current hypothesis, favored by Selkoe, focuses on the manner in which APP is cleaved by these enzymes to give rise to different-length residues of Ab, normally secreted as a 40–amino acid product, Ab40, and as a longer 42–amino acid form, Ab42. The latter assumes a nonfibrillar amorphous form, the main ingredient in the diffuse plaque, and in theory is believed to be toxic to neurons. It may be the d form of secretase that is largely responsible for creating the longer Ab42 fragment. This might allow a potential method of treatment by blocking the activity this enzyme.

Several pieces of evidence favor this hypothesis. It appears that the diffuse deposition of Ab42 precedes the formation of neurofibrils and plaques. The fact that the gene coding for APP is located on chromosome 21, one of the regions linked to familial Alzheimer disease, and that this chromosome is the one duplicated in the Down syndrome (see further on), suggests a causative connection between the overproduction of amyloid and all its Ab residues and the disease. Another suggestive connection between these mechanisms has been the finding that the gene errors in several forms of familial Alzheimer disease code for a category of endosomal proteins termed presenilins, which interact with, or may indeed be, the d secretase enzyme that produces Ab42. Transgenic mice with mutations for APP or for human presenilins develop plaques with Ab42 but not neurofibrillary tangles. Also, there is a provocative relationship between certain circulating proteins, particularly lipoproteins, and amyloid; this is discussed further on. It should be noted in this regard that mutations of the APP gene, detailed below, are associated with fewer than 0.1 percent of Alzheimer patients (Terry).
to have no useful purpose in the organism and conceivably could be reduced in quantity without harm.

Vascular changes do not have an important role in the pathogenesis of Alzheimer disease. It is definite that Alzheimer disease is not related to any of the usual types of arteriosclerosis. There are, however, small-vessel changes, accounting for the reduced cerebral blood flow reported by many investigators. This small-vessel change is not limited to the cerebral arteries, since a less degree of arteriosclerosis in the cerebral vascular bed is found in mentally intact old individuals. Probably the deposition of amyloid in cerebral vessels is a secondary phenomenon as well. The initial reports of the transmissibility of Alzheimer disease (Gouras et al) have not been corroborated.

No relationship to premortem personality traits or to the level of cognitive functioning earlier in life has been established, but an intriguing finding from what has become known as the "run study" suggests that poor linguistic ability early in life corresponds to the later development of Alzheimer disease (DA Skowton et al). In this study, the autobiographies of 93 nuns, written in their twenties, were rated for linguistic and ideational complexity. Of 14 sisters who died in late life, deterioration of cognitive function and neuropathological criteria proven Alzheimer disease occurred in 7 who had low "idea density" in their writings and in none of which their writings were more clinically evident infarcts. The dementia of normal-pressure hydrocephalus may also be confused with Alzheimer dementia. The differential diagnosis of these diseases is described in (Gouras et al) and might reduce its frequency (Tang et al). Carefully constructed, prospective studies are needed to test this idea and the long-term safety of the drug.

Neurotransmitter Abnormalities Considerable interest was created in the late 1970s by the finding of a marked reduction in choline acetyltransferase (ChAT) and acetylcholine in the hippocampus and neocortex of patients with Alzheimer disease. This loss of cholinergic synaptic capacity was attributed to the loss of cells in the basal forebrain nuclei (nucleus basalis of Meynert), from which the major portion of neocortical cholinergic terminals originate (Whitehouse et al). As is often true in medical science, the early enthusiasm for the cholinergic hypothesis proved less justified in the light of subsequent research. A 50 percent reduction in ChAT activity has been found in regions such as the caudate nucleus, which show neither plaques nor tangles (see review of Selko). The specificity of the nucleus basalis of Meynert, which is the cholinergic major winner of Alzheimer brain shows that this cholinergic measure may be more sensitive to deficiencies in cholinergic ones and a diminution of noradrenergic, GABAergic, and serotonergic functions in the affected neocortex. The concentration of amino acid transmitters, particularly of glutamate, is reduced in cortical and subcortical areas (Sakai et al). The Alzheimer cortex shows a decreased concentration of several neurotransmitter substances—particularly substance P, somatostatin, and cholecystokinin—but it has not been determined whether any of the aforementioned biochemical abnormalities, including the cholinergic ones, are primary or are secondary to heterogeneous neuronal loss. Finally, the administration of cholinomimetics—whether they be acetylcholine precursors (e.g., choline or lecithin), degradation inhibitors (e.g., physostigmine), or muscarinic agonists that act directly on postsynaptic receptors—has not had a sustained therapeutic effect.

Chase and associates have demonstrated a 30 percent reduction in cerebral glucose metabolism in Alzheimer disease, greatest in the parietal lobes, but again the meaning of this, whether it is due to loss or to hypofunction of neurons, remains to be decided. The significance of aluminum in the genesis of neurofibrillary tangles, however, has never been determined. Recently it has been suggested that the use of estrogen by postmenopausal women delays the onset of the disease and might reduce its frequency (Tang et al). Carefully constructed, prospective studies are needed to test this idea and the long-term safety of the drug.

Genetic Aspects of Alzheimer Disease Of great interest and potential importance was the discovery, in patients with the clearly inherited form of Alzheimer disease, of a defective gene localized to a region of chromosome 21, near the b-amylloid gene that codes for an errant amyloid precursor protein (APP) (St George-Hyslop et al). This also provided a possible explanation for the Alzheimer changes that characterize practically all patients with the trisomy 21 defect (Down syndrome) after their 20th year, but the gene defect on chromosome 21, as already noted, is responsible for only a tiny percentage of proved familial cases. Other kindreds with familial Alzheimer disease have been linked to gene mutations of chromosome 14 (Sherfington et al., accounting for up to 50 percent of familial cases, and on chromosome 19) is associated with a tripling of the risk of developing sporadic Alzheimer disease (Rosas, Stittmatter et al., and Pivovak et al.). (This is the same allele that contributes to an elevated low-density lipoprotein fraction in the serum). Possession of two e4 alleles virtually assures the development of disease in those who die at an earlier age. The e4 allele also modifies the age of onset of some of the familial forms of the disease. In contrast, the e2 allele is underrepresented among Alzheimer patients. For these reasons it has been proposed that apolipoprotein E, by interacting with APP or tau protein in some way, modifies the formation of plaques.

These findings have led to interest in using the e4 genotype as a marker for the risk of Alzheimer disease, but it must be pointed out that these are statistical relationships that do not invariably connect the allele to the disease in a particular individual. Therefore the results of such testing must be interpreted with caution. The e4 allele does not act as a mendelian trait but as a susceptibility (risk) factor. It follows that many individuals without the allele also develop Alzheimer disease.

Studies of the molecular genetics of Alzheimer disease are yielding new information at such an astonishing rate that much of the foregoing text will soon be outdated. Useful basic reviews of this subject are those of Martin and of Selkoe, listed in the references.

Differential Diagnosis The most important ancillary tests in routine use are CT scanning and MRI (Fig. 39-1). In patients with advanced Alzheimer disease, the lateral and third ventricles are enlarged to twice normal size and the cerebral sulci are narrowed. As stated previously, fine-section coronal MRI of the medial temporal lobes shows atrophy of the hippocampus, and the lateral ventricles are larger than normal. Early in the course of disease, however, the changes do not exceed those found in many mentally intact old persons. For this reason, one cannot rely on imaging procedures alone for diagnosis. They are most valuable in excluding brain tumor, subdural hematoma, multi-infarct dementia, and obstructive hydrocephalus. The EEG undergoes a diffuse slowing, to the theta and delta range, but only late in the course of the illness. The CSF is also normal, though occasionally the total protein is slightly elevated. Using the constellation of clinical data, CT scanning, and MRI—along with the age of the patient and time course of the disease—the diagnosis of senile dementia of Alzheimer type is being made correctly in 85 to 90 percent of cases.

Neuropsychological tests show a deterioration in memory and verbal access skills. Testing is particularly useful when there is a serial decline in ability. The use of these examinations is described in Chapter 21. Certain aspects of attention and executive function in Alzheimer disease have recently been reviewed by Perry and Hodges.

There is no available biologic marker of Alzheimer disease with the exception of an imprecise association with the disease-modifying e4 apolipoprotein allele, as mentioned earlier. The specificity of certain pupillary reactions has been suggested. Interest in this subject followed a report that Alzheimer patients show an enhanced pupillary sensitivity to instillation of tropicamide eyedrops. Subsequent studies have failed to replicate these observations. The measurement of amyloid protein and its derivatives in the spinal fluid and blood are being investigated as diagnostic tests. The most difficult problem in differential diagnosis, in the authors' experience, has been the distinction between a late-life depression and a dementia, especially when some degree of both is present. Multi-infarct dementia may be difficult to separate from Alzheimer dementia, since patients with the latter illness may have had one or more clinically invalident inferences. The dementia of normal-pressure hydrocephalus may also be confused with Alzheimer dementia. The differential diagnosis of these
several treatable conditions is discussed in Chap. 21, Chap. 30, Chap. 34, and Chap. 49. From time to time, we have been confident on clinical grounds that a patient had Alzheimer disease, only to have revealed at autopsy that progressive supranuclear palsy. Lewy body disease, Pick disease or another non-Alzheimer degeneration of the frontal lobes, or cortical-basal ganglionic degeneration was the cause. All of these are discussed later in this chapter.

**Treatment**

There is no certain evidence that any of the proposed forms of therapy for Alzheimer disease—cerebral vasodilators, stimulants, l-dopa, massive doses of vitamins B, C, and E, and many others—has any salutary effect. Trials of oral physostigmine, choline, and lecithin have yielded mostly negative or uninterpretable results, and the same can be said for currently popular cholinergic precursors and agonists and acetylcholinesterase inhibitors, such as tacrine and donepezil, although there is some evidence of mild effect. The use of trazodone, haloperidol, thioridazine, risperidone, and related drugs may suppress some of the aberrant behavior and hallucinations when these are problems, making life more comfortable for both patient and family. Small doses of diazepines, such as lorazepam, are useful when sleep is severely disturbed.

The general management of the demented patient should proceed along the lines outlined in Chap. 21, keeping in mind that the physician's counsel is often the family's main resource for medical and social issues.

**Associated Pathologic States**

As indicated earlier, the histologic changes of Alzheimer disease have a number of interesting associations. The changes are far more pronounced in the brains of patients with Parkinson disease than in the brains of age-matched controls (Hokfelt and Mathiesen). As a corollary, large numbers of Lewy bodies (a characteristic feature of Parkinson disease) have been found in 10 percent of patients who had been diagnosed as having Alzheimer disease (Woodard). These findings at least partly explain the high incidence of dementia in patients with Parkinson disease (see further on, in the sections regarding Parkinson disease and Lewy body dementia), yet not more than 20 to 30 percent of patients with Parkinson disease have plaques and tangles. Another association between the two diseases is apparent in the Guamanian Parkinson-dementia complex, which is also discussed below. In this entity, the symptoms of dementia and parkinsonism are related to neurofibrillary changes in the cerebral cortex and substantia nigra, respectively; senile plaques and Lewy bodies are unusual findings.

There are rare instances, such as those reported by Malamud and Lowenberg and by Loken and Cxivan, in which dementia begins in late childhood, with the finding at postmortem examination of the typical Alzheimer lesions in the cerebral cortex and basal ganglia. The clinical picture in these juvenile and early adult cases has been more varied than in the older ones. In some, paucity of speech, mutism, tremor, stooped posture, marked grasp and suck reflexes, and pyramidal and cerebellar signs leading to inability to stand or walk have appeared at various stages of the disease.

The finding of neurofibrillary changes (and to a lesser extent of plaques) in boxers (“punch-drunk syndrome,” or “dementia pugilistica”) is another interesting ramification of the Alzheimer disease process (page 944). Hydrocephalus is present also, but there is insufficient information to determine whether it is a normal-pressure tension hydrocephalus from multiple subarachnoid hemorrhages or a hydrocephalus ex vacuo from cerebral atrophy.

**Lobar Atrophy (Pick Disease)**

In 1892, Arnold Pick of Prague first described a special form of cerebral degeneration in which the atrophy is circumscribed (most often in the frontal and/or temporal lobes), with involvement of both gray and white matter—hence the term lobar rather than cortical sclerosis. In 1911, Alzheimer presented the first careful study of the microscopic changes. The most complete analyses of the pathologic changes are those of Spatz, van Mansvelt, Morris and coworkers, and Tissot and associates.

Since the recognition of Pick disease rests more on pathologic than on clinical criteria, they are described first.

In contrast to Alzheimer disease, in which the atrophy is relatively mild and diffuse, the pathologic change in lobar atrophy is much more circumscribed and sometimes asymmetrical. The atrophy may extend to the island of Reil and the amygdaloid-hippocampal structures. The parietal lobes are involved less frequently than the frontal and temporal lobes. The affected gyrri become paper-thin; these parts of the brain resemble the kernel of a dried walnut. The cut surface reveals not only a markedly thinned cortical ribbon but a grayish appearance and reduced volume of the white matter. The corpus callosum and anterior commissure share in the atrophy. The overlying pia-arachnoid is thickened, and the ventricles are enlarged. The pre- and postsuperior, central temporal, and occipital convolutions are relatively unaffected and stand out in striking contrast to the wasted parts. Pick insisted that the disease essentially involves the association areas of Flechsig.

In some instances, atrophy of the caudate nuclei has been pronounced, almost to the degree seen in Huntington chorea. The thalamus, subthalamic nucleus, substantia nigra, and globus pallidus may also be affected, but only to a slight degree.

The salient histologic feature of Pick disease is a loss of neurons, most marked in the first three cortical layers. Surviving neurons are often swollen, and some of them contain argyrophilic (Pick) bodies within the cytoplasm. Ultrastructurally, the Pick bodies are made up of straight fibrils, thus differing from the paired helical filaments that characterize Alzheimer disease. These bodies predominate in the medial parts of the temporal lobes, especially in the atrophic hippocampi. "Ballooning" of cortical neurons is found mainly in the frontal cortex; in such cases, according to Tissot and others, atrophy of the basal ganglia and substantia nigra is especially frequent. A degeneration of myelinated fibers in the white matter beneath the atrophic cortex (a heavy strio-recipient lesion) is seen in both the cortex and subcortical white matter. Most neuropathologists consider the loss of myelinated fibers to be consequent to neuronal loss. Senile plaques and Alzheimer neurofibrillary changes are seen in the atrophic zones in some of the cases (mixed Alzheimer and Pick disease), alluded to earlier, and there is granulovacuolar degeneration of neurons in the hippocampus, but not to the degree seen in Alzheimer disease.

The striking lobar cortical atrophy and changes in the white matter are readily visualized by CT scanning and MRI.

**Clinical Features**

Whether the diagnosis of Pick disease can be made on purely clinical grounds is doubtful. Our predictions as to the existence of the pathologic changes and their differentiation from those of Alzheimer disease and the recently defined entity of "frontotemporal dementia" (described below) have been erratic, although we should improve with the use of stricter clinical criteria, CT scanning, and MRI. In our experience, the gradual onset of mental confusion with respect to place and time, amnesia, slowness of comprehension, inability to cope with unaccustomed problems, loss of tact, deterioration of work habits, neglect of personal hygiene and grooming, apathy, and alteration of personality and behavior have been prominent features. In addition to personality change, behavior and hallucinations when these are problems, making life more comfortable for both patient and family. Small doses of diazepines, such as lorazepam, are useful when sleep is severely disturbed.

The cause of Pick disease is unknown. Sjögren and associates concluded from a genetic survey of the cases in Stockholm that Pick disease was probably transmitted as a dominant trait with polygenic modification. A Dutch family with almost 100 percent penetrance over several generations has been reported by Schenk. Women seem to be affected more often than men. No chemical, vascular, traumatic, or other factor of possible causal importance has been identified.
The course of the illness is usually 2 to 5 years, occasionally longer, and nothing can be done therapeutically except to postpone the end by careful nursing.

Frontotemporal Dementia

This descriptive term has long been used by neurologists and neuropathologists to refer to any dementia that is associated with degeneration of the frontal and temporal lobes. Most such instances have proved to be examples of Alzheimer disease and, in lesser numbers, to Pick disease, as noted above. Also for many years, neurologists have been aware of instances of dementia that are identical clinically and in their gross pathology (gyral atrophy) to the Alzheimer and Pick types but do not show the characteristic histological types of either of these diseases. These also, however, exhibit tau immunostaining material in neurones of the affected regions. One source of abnormal (i.e., hyperphosphorylated) tau is from a mutation of the tau gene on chromosome 17; indeed, an abnormality of this gene is associated with such a frontotemporal dementia (Basun et al.). But abnormal aggregates of tau have been identified in practically all neurodegenerative diseases and form the main constituent of the paired helical filaments (neurofibrillary tangles) of Alzheimer disease.

It appears from the observations of Brun and Neary and their associates that pure tau-reactive cases actually outnumber Pick disease as strictly defined by the Pick inclusion, but the distinctions between the two have not always been clear from writings on the subject. Some of the clinical aspects are discussed in Chap. 21, but, broadly speaking, the patients under discussion present the personality and behavioral abnormalities that would be expected from frontal and anterior temporal lobe disease. These cases are characteristically disorganized, poor in judgment, and distractible, and, in a general disengagement of affect, and a large number of perseverative errors. Some cases show marked confusion and greatly worsening parkinsonism or the development of the neuroleptic malignant syndrome.

In recent writings on this subject, the term frontotemporal dementia has come to be used in a highly restricted sense, being arbitrarily assigned to cases that show only tau-staining material in neurons. More such cases are sporadic, but an inherited variety linked to chromosome 17 has been described, in which parkinsonism is prominent; it is in these cases that the intraneuronal deposition of tau is most striking, in both the frontotemporal cortex and the substantia nigra.

Noteworthy also is the observation that a dementia identical to that of the tau-reactive cases occurs without any tau staining of neurons. Also, some of the frontally predominant cases have shown only marked vacuolation (micravacuolation) of the affected cortex; cases of the latter type have been described in patients with amyotrophic lateral sclerosis (where tau staining has reportedly been found in the anterior horn cells).

The relationship between Pick disease and frontotemporal dementia is still uncertain. The clinical and gross pathologic findings—a regional frontotemporal atrophy of the cortex, a butterfly-like configuration of Pick bodies, or tau-staining material in neurones of the affected regions and greater affection of the white matter in Pick disease. If indeed the Pick and tau inclusions are shown in the future to be clearly distinctive biological changes, they can be considered to represent separate diseases, but many reported cases of sporadic lobar atrophy demonstrate both types of change, or what is even more confusing, neither type—in which making it impossible at this time to be certain of the purity of each type.

Other Degenerative Dementias

Diffuse Cerebral Atrophy of Non-Alzheimer Type

There are other forms of progressive, diffuse brain atrophy leading to dementia that show none of the pathological features of either Alzheimer or Pick disease or any of the other diseases that are sometimes associated with a dementing illness (Parkinson or Lewy body disease, amyotrophic lateral sclerosis, progressive supranuclear palsy, etc.).

In Sweden, for example, Sjögren has found familial cases of this type, as have Schaumburg and Suzuki in this country, and we have seen occasional sporadic examples. The clinical picture in these cases has been indistinguishable or has varied slightly from that of Alzheimer disease, and autopsy has disclosed widespread cerebral atrophy, most pronounced in the frontal lobes. Microscopically these cases are characterized by a diffuse neuronal loss, slight glial proliferation, and secondary demyelination of the white matter, like that observed with the frontal lobe atrophy of Pick disease. Other instances of sporadic and familial presenile dementia have shown subcortical gliosis or non-specific cellular changes (atrophy of nerve cells and nuclei, loss of Nissl substance). A number of the latter type have in the past been described under the rubric of “Kraepelin disease” and more recently as “dementia lacking distinctive histologic features” (Knoopman et al.). Perhaps some or all of these cases will turn out to be a variant of the “tau” form of frontotemporal dementia, as discussed above.

Lewy Body Disease

Another syndrome in which the dementia may be clinically indistinguishable from Alzheimer disease is one in which the cortical neurons contain Lewy bodies and in which neurofibrillary changes or senile plaques are less conspicuous or absent. Reports of Lewy body dementia have been increasing steadily since the original communication by Okazaki and others in 1961; many of these have been from Japan (see Kosaka’s review). To some extent this is due to improved histologic techniques, particularly the immunoreactive ubiquitin and, more recently, synuclein stains, which enable one to visualize Lewy bodies in the cerebral cortex more clearly than before (see the discussion of Parkinson disease, which follows). The fact that aggregated a-synuclein makes up most of the Lewy body will undoubtedly prove important in relation to both Parkinson and Lewy body disease. Next to Alzheimer disease and diffuse (non-Alzheimer) cerebral atrophy, diffuse Lewy body disease is thought to be the most common form of diffuse cerebral cortical atrophy with dementia.

Burkhardt and colleagues, in an analysis of 34 cases of diffuse Lewy body disease, found that the most characteristic syndrome was one of progressive dementia in an elderly patient with late onset of parkinsonian signs in some cases. For this reason, the disease also properly belongs in the category of dementias that are associated with degeneration of the frontal and temporal lobes. Most such instances have proved to be examples of Alzheimer disease and, in lesser numbers, to Pick disease, as noted above. Also for many years, neurologists have been aware of instances of dementia that are identical clinically and in their gross pathology (gyral atrophy) to the Alzheimer and Pick types but do not show the characteristic histological types of either of these diseases. These also, however, exhibit tau immunostaining material in neurones of the affected regions. One source of abnormal (i.e., hyperphosphorylated) tau is from a mutation of the tau gene on chromosome 17; indeed, an abnormality of this gene is associated with such a frontotemporal dementia (Basun et al.). But abnormal aggregates of tau have been identified in practically all neurodegenerative diseases and form the main constituent of the paired helical filaments (neurofibrillary tangles) of Alzheimer disease.

The relationship between Pick disease and frontotemporal dementia is still uncertain. The clinical and gross pathologic findings—a regional frontotemporal atrophy of the cortex, a butterfly-like configuration of Pick bodies, or tau-staining material in neurones of the affected regions and greater affection of the white matter in Pick disease. If indeed the Pick and tau inclusions are shown in the future to be clearly distinctive biological changes, they can be considered to represent separate diseases, but many reported cases of sporadic lobar atrophy demonstrate both types of change, or what is even more confusing, neither type—in which making it impossible at this time to be certain of the purity of each type.

Lewy Body Disease

Another syndrome in which the dementia may be clinically indistinguishable from Alzheimer disease is one in which the cortical neurons contain Lewy bodies and in which neurofibrillary changes or senile plaques are less conspicuous or absent. Reports of Lewy body dementia have been increasing steadily since the original communication by Okazaki and others in 1961; many of these have been from Japan (see Kosaka’s review). To some extent this is due to improved histologic techniques, particularly the immunoreactive ubiquitin and, more recently, synuclein stains, which enable one to visualize Lewy bodies in the cerebral cortex more clearly than before (see the discussion of Parkinson disease, which follows). The fact that aggregated a-synuclein makes up most of the Lewy body will undoubtedly prove important in relation to both Parkinson and Lewy body disease. Next to Alzheimer disease and diffuse (non-Alzheimer) cerebral atrophy, diffuse Lewy body disease is thought to be the most common form of diffuse cerebral cortical atrophy with dementia.

Burkhardt and colleagues, in an analysis of 34 cases of diffuse Lewy body disease, found that the most characteristic syndrome was one of progressive dementia in an elderly patient with late onset of parkinsonian signs in some cases. For this reason, the disease also properly belongs in the category of dementias that are associated with degeneration of the frontal and temporal lobes. Most such instances have proved to be examples of Alzheimer disease and, in lesser numbers, to Pick disease, as noted above. Also for many years, neurologists have been aware of instances of dementia that are identical clinically and in their gross pathology (gyral atrophy) to the Alzheimer and Pick types but do not show the characteristic histological types of either of these diseases. These also, however, exhibit tau immunostaining material in neurones of the affected regions. One source of abnormal (i.e., hyperphosphorylated) tau is from a mutation of the tau gene on chromosome 17; indeed, an abnormality of this gene is associated with such a frontotemporal dementia (Basun et al.). But abnormal aggregates of tau have been identified in practically all neurodegenerative diseases and form the main constituent of the paired helical filaments (neurofibrillary tangles) of Alzheimer disease.

Byrne and associates noted that episodic increases in confusion, hallucinations, and paranoid delusions were a feature of the Lewy body dementia; these psychotic features are generally uncharacteristic of Alzheimer and lobar dementias. In Lennox’s review, one-third of patients with Lewy body dementia had these swings in behavior, as well as the illness advanced, the amynesia, dyscalculia, visuospatial disorientation, aphasia, and apraxia did not differ from those of Alzheimer disease. In the cases of Fearnley and coworkers, there was a supranuclear gaze palsy simulating that of progressive supranuclear palsy. In our limited experience with Lewy body disease, the parkinsonian symptoms have been more prominent than in progressive supranuclear palsy; the most characteristic feature besides the movement disorder has indeed been intermittent psychotic or delirious behavior. Others have commented on an extreme sensitivity to neuroleptic drugs, including increased confusion and greatly worsening parkinsonism or the development of the neuroleptic malignant syndrome.

Thalamic Dementia

A relatively pure degeneration of thalamic neurons has been described in relation to a progressive dementia (Sten; Schulman). The dementia in these cases evolved relatively rapidly (several months) and was associated with choreoathetosis. Garcia and colleagues described five cases of subacutely evolving thalamic dementia; the clinical presentation was also very similar to that of Creutzfeldt-Jakob disease; however, the thalamic neuronal loss and gliosis of the thalamus. A large kindred of such cases, characterized by subacute dementia and myoclonus and inherited as an autosomal trait, has been reported by Little and coworkers. In members of this family, the clinical presentation was also very similar to that of Creutzfeldt-Jakob disease; however, the pathologic changes were confined to the thalamus, particularly to the mediodorsal and other medial thalamic nuclei. Transmission of the disease to primates was unsuccessful.

In the diagnosis of this large category of chronic dementias, one must consider several nondegenerative disorders in which dementia may predominate and focal neurologic abnormalities may be minimal. Several of the treatable ones are listed in the discussion of Alzheimer disease, above, and a larger group is reviewed in Chap. 21. Also to be considered, particularly in dementias with onset at one age, are the inherited metabolic dis-eases discussed in Chap. 37, the chief among which are the leukodystrophies—metachromatic, adrenal, globoid body (Krabbe disease)—and the poliodystrophies—neuronal ceroid lipofuscinosis (Kuf disease), GD I and II (McAuliffe and Wilson disease (see page 1005). Each of these displays characteristic neurologic features, but each may present in the early stages with a decline in intellectual function and a behavioral disorder.

Finally, a brief comment is required regarding the group of diseases called “vascular dementia,” listed in many classifications as the second most common cause of mental decline after Alzheimer disease. As discussed in Chap. 34, multiple cortical strokes may cause increasing deficits that cumulatively qualify as a dementia, but each element of focal cerebral disease that contributes to the cognitive decline can be identified, and a stepwise decline that corresponds to the abrupt onset of each
stroke is evident. A more difficult problem arises in a limited number of patients who have a multitude of deep lacunar infarctions. Their mental capacities may appear to decline slowly, although memory is not involved disproportionately, and usually a pseudobulbar state or one of the other characteristic lacunar stroke syndromes can be identified, so there is little trouble in differentiation from the degenerative dementias. The subcortical white matter change ofBinswanger disease causes similar diagnostic problems, as discussed on pages 451 and 878. Beyond these vascular diseases and the familial CADASIL disease (cerebral autosomal dominant arteriopathy with subcortical infarcts, page 876), which is of uncertain cause, the authors are dubious of the category of vascular dementia. Most cases turn out to be Alzheimer disease with one or more visible infarctions.

**DISEASES IN WHICH DEMENTIA IS ASSOCIATED WITH OTHER NEUROLOGIC ABNORMALITIES**

**Huntington Chorea**

This disease, distinguished by the triad of dominant inheritance, choreoathetosis, and dementia, commemorates the name of George Huntington, a medical practitioner of Pomeroy, Ohio. In 1872, in a paper read before the Meigs and Mason Academy of Medicine and published later that year in the Medical and Surgical Reporter of Philadelphia, Huntington gave a succinct and graphic account of the disease, based on observations of patients that his father and grandfather had made in the course of their practice in East Hampton, Long Island. Reports of this disease had appeared previously (see De Jong, in the References, for historical background), but they lacked the accuracy and completeness of Huntington's description. Vesse, in 1932, was able to show that practically all the patients with this disease in France could be traced to about six individuals who had emigrated in 1630 from the tiny East Anglian village of Bures, in Suffolk, England. One remarkable family was traced for 300 years through 12 generations, in each of which the disease had expressed itself.

To quote Huntington, the rule has been that “When either or both of the parents have shown manifestations of the disease . . . one or more of the offspring invariably suffer of the disease, if they live to adult life. But if by any chance these children go through life without it, the thread is broken and the grandchildren and great-grandchildren of the original shakers may rest assured that they are free from disease.” Davenport, in a review of 962 patients with Huntington chorea, found only 5 who had descended from unaffected parents. Possibly, in these latter patients, a parent had the trait, but in very mild form. Or, one or more of these patients represented rare sporadic instances of Huntington chorea, i.e., individuals in whom a mutation had occurred from a normal gene to the mutant, disease-producing form.

In university hospital centers, this is one of the most frequently observed types of hereditary nervous system disease. Its overall frequency is estimated at 4 to 5 per million, and 30 to 70 per million among whites of northern European ancestry. The usual age of onset is in the fourth and fifth decades, but 3 to 5 percent begin before the 15th year and some even in childhood. In about 30 percent, symptoms become apparent by 50 years. The progression of the disease is slower in older patients. Once begun, the disease progresses relentlessly, until only a restricted existence in a nursing home or psychiatric hospital is possible and some other disease terminates life.

Exhaustive genealogic documentation has established the cause to be an autosomal dominant gene with complete penetrance (see below). Martin has made the observation that young patients usually inherit the disease from their fathers and older patients from their mothers. It has been observed beginning at almost the same age in identical twins.

Until recently, it had not been possible to foretell which of the children of a patient will be stricken with the disease. Caudate glucose metabolism—measured by positron emission tomography (PET) in earlier studies—even if reduced in most presymptomatic patients, proved not to be a sufficiently reliable indicator of persons at risk for Huntington disease. The most important achievement in respect to the presymptomatic detection of Huntington disease was the discovery, by Gusella and colleagues, of a marker linked to the Huntington gene, localized to the short arm of chromosome 4. Subsequently these investigators and others identified the gene abnormality as an excessively long repeat of trinucleotides (CAG), the length of which determines not only the presence of the disease but also the age of onset. This discovery has made possible the development of a test for the detection of the defective gene in asymptomatic individuals. In view of the fact that there is no treatment for the disease, testing raises certain ethical considerations that need to be resolved before its widespread utilization.

**Clinical Features**

The mental disorder assumes several subtle forms long before the more obvious deterioration of cognitive functions becomes evident. In appraising the half the cases, slight and often annoying alterations of character are the first to appear. Patients begin to find fault with everything, to complain continuously, and to nag other members of the family; they may be suspicious, irritable, impulsive, eccentric, untidy, or excessively religious, or they may exhibit a false sense of superiority. Poor self-control may be reflected in outbursts of temper, fits of despoticness, alcoholism, or sexual promiscuity. Disturbances of mood, particularly depression, are common (almost half of the patients in some series) and may constitute the most prominent symptoms early in the disease. Invariably, sooner or later, the intellect begins to fail. The patient becomes less communicative and more socially withdrawn. These emotional disturbances and changes in personality may reach such proportions as to constitute a virtual psychosis (with persecutory delusions or hallucinations).

Diminished work performance, inability to manage household responsibilities, and disturbances of sleep may prompt medical consultation. There is difficulty in maintaining attention, in concentration, and in assimilating new material. Mental flexibility lessens. There is loss of fine manual skills (see further on). The performance parts of the Wechsler Adult Intelligence Scale show greater loss than the verbal parts. Memory is relatively spared. This gradual dilapidation of intellectual function has been characterized as a “subcortical dementia” (page 450); i.e., elements of aphasia, agnosia, and apraxia are observed only rarely and memory loss is not profound. Often the process is so slow that some degree of intellectual capacity is retained for many years.

The abnormality of movement is at first slight and most evident in the hands and face; often the patient is merely considered to be fidgety, restless, or “nervous.” Slowness of movement of the fingers and hands, a reduced rate of finger tapping, and difficulty in performing a sequence of hand movements are early motor signs. Gradually these abnormalities become more pronounced until the entire musculature is implicated. The frequency of blinking is increased (the opposite of parkinsonism), and voluntary protrusion of the tongue is constantly interrupted by unwanted darting movements. In the advanced stage of the disease, the patient is seldom still for more than a few seconds. The movements are slower than the brusque jerks and postural lapses of Sydenham chorea, and they involve many more muscles. They tend to recur in stereotyped patterns yet are not as stereotyped astics. In more advanced cases, they acquire an astatic or dystonic quality. Muscle tone is usually decreased until late in the illness, when there may also be some degree of rigidity, tremor, and bradykinesia, elements suggestive of Parkinson disease (Westphal or “rigid” variant, which is more common with a childhood onset). Tendon reflexes are exaggerated in one-third of patients, but only a few have Babinski signs. Voluntary movements are initiated and executed more slowly than normal, but there is no weakness and no real ataxia, although speech, which becomes dysarthric and explosive due to incoordination between tongue and diaphragm, may convey the impression of a cerebellar disorder. There is poor control of effort or of the synergies that are required to perform movements. In the advanced stage of the disease, the patient is unable to maintain attention, in concentration, and in assimilating new material. The performance parts of the Wechsler Adult Intelligence Scale show greater loss than the verbal parts. Memory is relatively spared. This gradual dilapidation of intellectual function has been characterized as a “subcortical dementia” (page 450); i.e., elements of aphasia, agnosia, and apraxia are observed only rarely and memory loss is not profound. Often the process is so slow that some degree of intellectual capacity is retained for many years.

As Wilson stated, the relation of the choreic to the mental symptoms “abides by no general rule.” Most often the mental symptoms precede the chorea, but they may accompany or follow it, sometimes by many years. In our own material, with two exceptions of late onset with rigidity rather than chorea, once the movement disorder was fully established, there was nearly always some degree, perhaps slight, of cognitive abnormality. Exceptional cases have been reported, in which the movement disorder has been the first to appear for 30 to 35 years without mental changes in patients with the gene abnormality of Huntington disease (Britton et al). After 10 to 15 years, most patients deteriorate to a vegetative state, unable to stand or walk and eating little; in this late stage, a mild amyotrophy may appear. Noteworthy is the high suicide rate in Huntingtonians, as pointed out by Huntington (Schoenfeld et al). Also, there is a high incidence of trauma; chronic subdural hematoma is a common finding at autopsy.

The first signs of the disease may appear in childhood, but this is rare (even under the age of 4). beyond this, several series of such cases have been described (Farrell and Connolly; van Dijk et al). Mental deterioration at this early age is more often accompanied by cerebellar ataxia, behavior problems, seizures, bradykinesia, rigidity, and chorea than by chorea (Byrns et al). However, this rigid form of the disease (Westphal variant) is known also to occur occasionally in adults, as mentioned above. For the eastern United States, the rigid form is distinctly more common in the children than in adults (Youn et al).

Earlier onset in successive generations (anticipation) is well described in the early writings on the subject and is now known to be attributable to increasing lengths of the CAG repeat sequence, as already pointed out. The dementia is generally more severe in cases of early onset (15 to 40 years) than in those of later onset (55 to 60 years).
At the gene locus implicated in Huntington disease there are normally 11 to 34 (median 19) consecutive repetitions of the CAG triplet that codes for glutamine; individuals with more than 35 to 39 triplets may have the disease and those with more than 42 invariably acquire the signs of disease if they live long enough. As already noted, the CAG repeat length correlates with disease severity, the early-onset cases having the largest number of repeats. Furthermore, in adult patients with early onset of the disease, the emotional disturbance tends to be initially prominent and precedes the chorea and intellectual loss by many years; with older age of onset, choreiform movements and progressive dementia are more often the initial components and have their onset at nearly the same age.

**Pathology and Pathogenesis** Gross atrophy of the head of the caudate nucleus and putamen bilaterally is the characteristic abnormality, usually accompanied by a moderate degree of gyral atrophy in the frontal and temporal regions. The caudatal atrophy alters the configuration of the frontal horns of the lateral ventricles; the inferolateral borders do not show the usual bulge formed by the head of the caudate nucleus; in addition, the ventricles are diffusely enlarged (Fig. 39-2). In CT scans, the bicaudate-cranial ratio is increased in the majority of patients. This finding corroborates the clinical diagnosis in the moderately advanced case.

The early articles of Alzheimer and Dunlap and the more recent one of Vonsattel and DiFiglia contain the most authoritative descriptions of the microscopic changes. The latter authors have graded the disease into early, moderately advanced, and far advanced stages. In five genetically verified early cases, no striatal lesion was found, which suggests that the first clinical manifestations are based on a biochemical disorder without visible structural change, at least by light microscopy. This view is supported by the observation that Huntington patients studied with PET show a characteristic decrease in glucose metabolism, which appears early in the disease and precedes the loss of tissue (Hayden et al.). The striatal degeneration begins in the medial part of the caudate nucleus and spreads, tending to spare the nucleus accumbens. Of the six cell types in the striatum (differentiation based on size, dendritic arborizations, spines, and axon trajectories), the smaller cells are affected before the larger ones. Loss of dendrites of the small spiny neurons has been an early finding. The large cells are relatively preserved and exhibit no special alterations. The lost cells are replaced by fibrous astrocytes. With neuronal loss, the myelinated fibers also disappear. The anterior parts of the putamen and caudatum are more affected than the posterior parts. In our own cases we have not been impressed with changes in the globus pallidus, subthalamic nucleus, red nucleus, or cerebellum, but others have observed slight changes in these parts and in the pars reticulata of the substantia nigra. In the cerebral cortex, there is said to be slight neuronal loss in layers 3, 5, and 6, with replacement gliosis. Cases are reported with typical striatal lesions but normal cortices, in which only chorea had been present during late life. In our early to moderately advanced cases, even quantitative analyses of the cortex have not disclosed a significant loss of neurons. Several neuropathologists have observed marked cell loss and gliosis in the subthalamic nuclei in children or young adults with chorea and behavior disorders.

The biochemical defects in Huntington chorea are only beginning to be understood. The impaired glucose metabolism in the caudate nucleus, preceding visible atrophy, has already been mentioned. Since at least a partial explanation for L-dopa–induced involuntary movements is an excess of dopamine (in contrast to Parkinson disease, in which there is a decrease), it has been postulated that the abnormal movements of Huntington chorea represent a heightened sensitivity of striatal dopamine receptors. There are disturbances in the metabolism of other putative neurotransmitters (norepinephrine, glutamic acid decarboxylase, choline acetyltransferase, GABA, acetylcholine, and somatostatin), but the significance of these biochemical disturbances is unknown.

The product of the Huntington disease gene has been termed huntingtin and its mutated form contains an excessive number of glutamine residues as a result of the excess copies of the CAG nucleotide. Although the function of the protein is not known, an excess of huntingtin accumulates in the nuclei of neurons in human disease and in transgenic mice with an increased number of CAG repeats. Moreover, the protein accumulates in cells of the striatum and parts of the cortex affected in Huntington disease.

**Diagnostic Problems** Once the disease has been observed in its fully developed form, its recognition requires no great clinical acumen. The main difficulty arises with patients who lack a family history but in whom the progressive chorea, emotional disturbance, and dementia with onset in adult life are typical. This difficulty has been largely overcome since the mutation causing Huntington disease is identified. It is now possible to confirm or exclude the diagnosis by analysis of DNA from a blood sample, the presence of greater than 39 to 42 CAG triplets at the Huntington locus essentially confirming its presence, lesser numbers leaving room for equivocation. Sometimes it is learned later that the family history was incomplete or falsified or that an illness in a parent had been misinterpreted. Chorea that begins in late life, with only mild or questionable intellectual impairment and without a family history of similar disease, is another source of difficulty; referring to it as senile chorea does not solve the problem. Indeed, senile chorea may have more than one cause. We have seen it appear with infections, drug therapy, and thyrotoxicosis, only to disappear after a few weeks. Chorea in early adult life always raises the question of a late form of Sydenham chorea or of lupus erythematosus with antiphospholipid antibodies, but neither familial occurrence nor mental deterioration is part of these diseases. Other progressive neurologic disorders that are inherited as autosomal dominant traits and begin in adolescence or adult life (e.g., polymyoclonus with or without ataxia, acanthocytosis with progressive chorea, and especially dentatorubropallidoluysian degeneration) can closely mimic Huntington disease, as described further on, and sometimes only the pathologic picture settles the matter.

Other problems in differential diagnosis include bilateral thalamic degeneration with dementia and chorea, referred to earlier; paroxysmal choreoathetosis (page 83); Wilson disease (page 1026); acquired hepatocerebral degeneration (page 1195); and, most often, schizophrenia or manic-depressive psychosis complicated by tardive dyskinesia (page 1264). Many drugs in addition to L-dopa occasionally cause chorea (amphetamine, tricyclic antidepressants, lithium, isoniazid).

**Therapy** The dopamine antagonist haloperidol, in daily doses of 2 to 10 mg, is probably the most effective agent in suppressing the movement disorder. Because of the danger of superimposing tardive dyskinesia on the chronic disorder, the chorea should be treated only if it is functionally disabling, using the smallest possible dosages and providing numerous drug holidays. Haloperidol may also help alleviate abnormalities of behavior or emotional lability, but it does not alter the progress of the disease. The authors have not been impressed with the therapeutic effectiveness of other currently available drugs. Levodopa and other dopamine agonists make the chorea worse and, in the rigid form of the disease, evoke chorea. Drugs that deplete dopamine or block dopamine receptors—such as reserpine, clozapine, and tetrabenazine—suppress the chorea to some degree, but their side effects (drowsiness, akathisia, and tardive dyskinesia) outweigh their desired effects. The juvenile (rigid) form of the disease is probably best treated with antiparkinsonian drugs. Huntington disease pursues a steadily progressive course and death occurs, on an average, 15 to 20 years after onset, sometimes much earlier or later. The psychologic and social consequences of the disease require supportive therapy, and genetic counseling is essential.

**Acanthocytosis with Choreea** A few reports of a slowly progressive familial chorea and dementia in association with an abnormality of erythrocytes have appeared in English, American, and Japanese journals. The disease has the following characteristics: (1) onset in adolescence or early adult life of generalized involuntary movements (described as chorea but including dystonia and tics); usually beginning as an orofacial dyskinesia and spreading to other parts of the body; (2) mild to moderate mental deterioration in some but not all of the cases; (3) decreased or absent tendon reflexes and evidence of chronic axonal neuropathy and denervation atrophy of muscles; (4) atrophy and gliosis of the caudate nuclei and putamens but no neuronal loss in the cerebral cortex or other parts of the brain; and (5) acanthocytosis (thorny or spiky appearance of erythrocytes). The last change, according to Sakai and coworkers, is due to an abnormal composition of covalently (lightly) bound fatty acids in erythrocyte membrane proteins (palmitic and docosahexanoic acids increased and stearic acid decreased). The pattern of inheritance has been autosomal
recessive but was dominant in one New England family. The acanthocytosis may be overlooked when it is mild but can be detected by scanning electron microscopy. In the series of 19 cases reported by Hardie and colleagues, the manifestations included dystonia, tics, vocalizations, rigidity, and lip and tongue biting; more than half had cognitive impairment or psychiatric features. The average age of onset was 32 years; 7 of the 19 cases were sporadic. The disease has been linked in almost all families to chromosome 9q. The so-called McLeod phenotype differs hematologically in that there is an abnormal expression of Kell surface antigens on the erythrocyte.

Several other rare degenerative disorders with chorea, some of which have already been mentioned, fall into this category. Midlife progressive chorea without dementia (after more than 25 years follow-up) has been reported. There was no abnormality of chromosome 4. Dentatorubropallidoluysian atrophy, diagnosed clinically as Huntington chorea, was found in four European families by Warner and associates and is described further on in the section on cerebellar degenerations. The extrapyramidal manifestations included chorea, myoclonus, and rigidity. Adult-onset chorea and dementia have been described with propionic acidemia; propionic acid was elevated in the plasma, urine, and CSF. This disorder must be added to other metabolic diseases described in Chap. 37 as causes of chorea and dyskinesia—such as glutaric acidemia, keratin sulfaturia, calcification of basal ganglia, and Hallervorden-Spatz disease (Hagberg et al).

Corticostriatospinal Degenerations

Included in this category are a number of degenerative diseases in which the symptoms of dementia, parkinsonism, and myotonic lateral sclerosis present in various combinations. Some of the diseases that make up this group have not been sharply delineated and are difficult to separate from one another (see also page 1140).

Under the title “spastic pseudosclerosis,” Jakob, in 1921, described a chronic disease of middle to late adult life, characterized by abnormalities of behavior and intellect; weakness, ataxia, and spasticity of the limbs (chiefly the legs); extrapyramidal symptoms such as rigidity, slowness of movement, tremors, athetotic postures, and hesitant, dysarthric speech; and normal spinal fluid. The pathologic changes were diffuse and consisted mainly of an outfall of neurons in the frontal, temporal, and central motor gyri, corpus striatum, ventromedial thalamus, and bulbner motor nuclei. In one of Jakob’s cases, there were also prominent changes in the anterior horns and corticospinal tracts in the spinal cord like those of amyotrophic lateral sclerosis (ALS). The latter finding gave rise to Wilson’s concept of the disease as a corticostriatospinal degeneration. A degenerative and probably familial disorder that had been described earlier by Creutzfeldt-Jakob was considered by Spiltemeyer to be sufficiently similar to the one of Jakob to warrant the designation Creutzfeldt-Jakob disease.

As discussed in Chap. 33, the disorder described by Creutzfeldt and Jakob has been a source of endless controversy because of its indeterminate character. On the one hand, it has been confused with the subacute evolving myoclonic dementia, “subacute spongiform encephalopathy,” which is now known to be an infection due to an unconventional transmissible agent (prion). The authors believe that the latter disease, which is described on page 814, bears at best only a superficial resemblance to the one described by Creutzfeldt and Jakob, and that the two disorders should be clearly separated. Unfortunately, the eponym is so entrenched in medical usage that any attempt to remove it stands little chance of success. On the other hand, sporadic and familial cases that are not transmissible and lack a prominent spongiform change merge with a rather heterogeneous but overlapping group of degenerative disorders, all rare, including progressive dementia and spastic paraplegia, progressive dementia and ALS, the Parkinson-dementia-ALS complex of Guarn and the corticopallidospinal degeneration of Davison.

Other variants of this category of disease continue to appear. The authors have observed several patients in whom extreme rigidity, corticospinal signs, and evidence of ALS have developed over a period of several years. In the later stages of the disease, the patient, while alert, is totally helpless—unable to speak, swallow, or move the limbs. Only eye movements are retained, and even these are hampered by supranuclear gaze palsy in advanced cases. Intellectual functioning appears to be better preserved than movement but is difficult to assess. Other bodily functions are intact. The course is slowly progressive and ends fatally in 5 to 10 years. There is no family history of similar disease, and there are no clues as to causation. Gilbert and colleagues have described similar cases with signs of Parkinson disease, motor neuron disease, and dementia; in their cases, there were no senile plaques or Lewy bodies. The coincidence of typical motor neuron disease and Parkinson disease may be coincidental, but Qureshi and colleagues described 13 patients in whom both disease processes began within a brief time of one another and considered them to be related. In the variant described by Tandaran and colleagues, an autosomal dominant syndrome of Charcot-Marie-Tooth neuropathy was combined with ptiosis, Parkinson syndrome, and dementia, again without Lewy bodies or senile plaques. Yet other variants have been described by Schmitt and coworkers and by Mata and colleagues. Hudson has reviewed 42 sporadic cases in which ALS-parkinsonism-dementia were combined (see References).

The Guamanian Parkinson-dementia-ALS complex deserves separate comment because it constitutes a large number of carefully studied cases with almost uniform clinical and pathologic features. The disease occurs in the indigenous Chamorro peoples of Guam and the Marianas islands, predominantly in men between ages 50 and 60. Progressive parkinsonism and dementia are combined with upper or lower motor neuron disease (ALS is also common among the Chamorro), leading to death in 5 years. The pathologic changes, described by Hirano and others, consist of severe cortical atrophy with neurofibrillary tangles but, conspicuously, no plaques are detectable, even with sensitive neurochemical staining. As in Parkinson disease, the substantia nigra and to a lesser extent other pigmented nuclei are depopulated of nerve cells but contain no Lewy bodies. Cases with amyotrophy show an appropriate anterior horn cell loss.

One is tempted to conclude that the spastic pseudosclerosis of Jakob should not be considered as a disease type, and certainly everyone agrees that the term pseudosclerosis (also used for the Westphal-Strümpell form of hepatocerebellar degeneration) is meaningless.

Familial Dementia with Spastic Paraparesis

From time to the authors the families have encountered families in which several members developed a spastic paraparesis and a gradual failure of intellect during the middle adult years. The mental horizon of the patient narrowed gradually, and the capacity for high-level thinking diminished; in addition, the examination showed appropriately exaggerated tendon reflexes, clonus, and Babinski signs. In one such family the illness had occurred in two generations; in another, three brothers in a single generation were afflicted. Skre described two recessive types of hereditary spastic paraplegia in Norway, one with onset in childhood, the other in adult life. In contrast to the dominant form (see further on), the recessive types displayed evidence of more widespread involvement of the nervous system, including dementia, cerebellar ataxia, and epilepsy. Also, Cross and McGusk have observed a recessive type of paraplegia accompanied by dementia beginning in adolescence. They named it the Mast syndrome, after the afflicted family.

Worster-Drought and others have reported the pathologic findings in two cases of this type. In addition to senile plaques and neurofibrillary changes, there was demyelination of the subcortical white matter and corpus callosum and a “patchy but gross swelling of the arterioles,” which gave the staining reactions for amyloid (“Scholz’s perivascular plaques”). Van Bogaert and associates published an account of similar cases that showed the characteristic pathologic features of Alzheimer disease.

Adult forms of metachromatic leukodystrophy and adrenoleukodystrophy may present with a similar clinical picture (Chap. 37). Another interesting association of familial spastic paraplegia is with progressive cerebellar ataxia. Fully one-third of the cases that we have seen with such a spastic weakness were also ataxic and would fall into the category of spinoocerebellar degenerations. Yet another variant of this group of diseases has been described by Farmer and colleagues; the intellectual deterioration was subacute with ataxia, chorea, and the main clinical features of dementia, dysarthria, dysphagia, and incontinence, evolving in that order. Postmortem examinations of two patients disclosed calcification in the globus pallidus, neuronal loss in the dentate nuclei, and destruction of myelinated fibers in the centrum semiovale.

Adult Polycyclicus Body Disease

Under this title Roffballe and colleagues described a distinct type of progressive neurologic disease in adults, characterized clinically by spasticity, chorea, dementia, and polyneuropathy. It is also referred to as sensory polyneuropathy. Structures that closely resembled Lafora bodies and corpora amylacea were found in large numbers in both central and peripheral nervous systems (mainly in axons) and also in astrocytes. These basophilic, periodic acid–Schiff (PAS)–positive structures, up to 40 mm in size, were made up of glucose polymers (polycyclans) and were readily apparent in sural nerve biopsies. Some were found in the heart and liver.

More recently, Rifat and associates have reviewed the findings in 25 cases of this disease—one observed personally and 24 that had been reported previously. The dementia appears to be relatively mild, consisting of impairment of retentive memory, dysnomia, dyscalculia, and sometimes expressive dysphasia and deficits of “visual integration”; this is overshadowed by the rigidity and spasticity of the limbs and the peripheral nerve disorder. Nerve conduction velocities are diminished and leg muscles are denervated. Moderate degrees of generalized cerebellar atrophy, multifocal areas of white matter rarefaction, and increased iron deposition in the putamina are disclosed by MRI. The finding of polycyclicus axon inclusion in biopsied nerve confirms the diagnosis. The disease was sometimes misdiagnosed as
DISEASES CHARACTERIZED BY ABNORMALITIES OF POSTURE AND MOVEMENT

Parkinson Disease (Paralysis Agitans)

This common disease, known since ancient times, was first cogently described by James Parkinson in 1817. In his words, it is characterized by “involuntary tremulous motion, with lessened muscular power, in parts not in action and even when supported; with a propensity to bend the trunk forward, and to pass from a walking to a running pace, the senses and intellect being unimpaired.” Strangely, his essay contains no reference to rigidity or to slowness of movement, and it stresses unduly the reduction in muscular power. The same criticism can be leveled against the term paralysis agitans, which appeared for the first time in 1841, in Marshall Hall’s textbook Diseases and Derangements of the Nervous System.

Certain aspects of the natural history of the disease are of interest. As a rule, it begins between 40 and 70 years of age, with the peak age of onset in the sixth decade. It is infrequent before 30 years of age (only 4 of 380 cases in one series), and most series contain a somewhat larger proportion of men. Trauma, emotional upset, exposure to cold, "rigid personality," and so on, among many other factors, have been suggested as predisposing to the disease, but there is no convincing evidence to support any such claims. The possible relationship to repeated cerebral trauma and to the “punch-drunk” syndrome (dementia pugilistica, paralysis agitans) is provided by several documented cases (Lees).

Critically, Parkinson’s disease is observed in all countries, all ethnic groups, and all socioeconomic classes, although the incidence in blacks is only one-quarter that in whites. In Asians, the incidence is one-third to one-half that in whites. A lack of concordance of Parkinson disease in twins appears to negate the role of genetic factors, but a study of dopamine metabolism utilizing PET scanning has shown that 75 percent of asymptomatic twins of Parkinson patients had evidence of striatal dysfunction and only a small portion of dicyclic twins showed these changes (Piccini et al.). These data suggest a more substantial role for an inherited trait in cases of ostensibly sporadic disease. Also, Krüger and colleagues have reported a 13-fold increased susceptibility to the disease in patients who harbor a combination of a-synuclein and apolipoprotein E genotypes (see below).

While familial cases are decidedly rare, Gohe and colleagues have described two large kindreds (probably related and originating from a small town in southern Italy) in which 41 patients in four generations were affected. The illness in their cases was characteristic of Parkinson disease both clinically and pathologically, the only unusual features being a somewhat earlier onset (mean age 46 years), a relatively rapid course (10 years from onset to death), and a reported incidence of tremor in one. These observations suggested that the disease has autosomal dominant inheritance (see below), although others also studied clinically (onset in third decade, prominence of dystonia) and pathologically (absence of Lewy bodies) from classic Parkinson disease. It was in the latter kindred and in three Greek families that Polymeropoulos et al. identified a locus on chromosome 4q that contained a mutation for a-synuclein, a main component of the Lewy body. Other families in which there have been multiple inherited cases of Parkinson disease are associated with gene defects at other sites (but still mostly on chromosome 4). These genetic data have been reviewed by Dunnett and Björklund.

The disease is common. In North America there are approximately 1 million patients, constituting about 1 percent of the population over the age of 65 years. The incidence in all countries where vital statistics are kept is similar. Considering its frequency, coincidence in a family on the basis of chance occurrence might be as high as 5 percent.

Clinical Features

In the core syndrome of expressionless face, poverty and slowness of voluntary movement, “resting” tremor, stooped posture, axial instability, rigidity, and festination gait has been fully described in Chap. 4, and only certain diagnostic problems and variants in the clinical picture need to be considered here. The early symptoms may be difficult to perceive and are often overlooked. Advancing years have a way of rendering the spine and limbs less pliable and elastic, and in the senium the gait may become short-stepped and then reduced to a shuffle. The voice tends to become soft and monotonous. Hence it is all too easy to attribute the early symptoms of Parkinson disease to the effects of aging. For a long time the patient may not be conscious of the inroads of the disease; at first the only complaints may be of aching of the back, neck, shoulders, or hips and of vague weakness. A slight stiffness and slowness of movement or a reduction in the natural swing of one arm during walking are ignored, until one day it occurs to the physician or to a member of the family that the patient has Parkinson disease. Infrequency of blinking, as pointed out originally by Pierre Marie, is often a helpful early sign. The usual rate (12 to 20 blinks per minute) is reduced in the parkinsonian patient to 5 to 10. And when the patient looks back over the spinning of the palm to the side, the first evidence of the disease (sign) a reduction in movement of the fingers (demonstration of the palmar hallucinosis of the hallmark of the disease). At this stage the patient may have either type of tremor or both.

We have been less impressed with rigidity and hypertonus as important early findings. They tend to appear in the more advanced stages of the disease. Once rigidity develops, it is constantly present; it can be felt by the palpating finger and seen as a salience of muscle groups even when the patient relaxes. When the examiner passively moves the limb, a mild resistance appears from the start (without the short free interval that characterizes spasticity), and it continues evenly throughout the movement, in both flexor and extensor groups, being interrupted only by the cogwheel phenomenon. Both the rigidity and its cogwheel feature can be elicited by having the patient occupy the opposite limb with a motor task requiring some degree of concentration, such as tracing circles in the air or touching each finger to the thumb. Postural hypertonus predominates in the flexor muscles of trunk and limbs and confers on the patient the characteristic flexed posture. Particulars of the parkinsonian disorders of muscle tone, stance, and gait are discussed further in Chap. 4 and Chap. 7.

Regarding the quality of volitional and postural movements, a few additional points should be made. The patient is slow and ineffective in attempts to deliver a quick answer. Strangely, his essay contains no reference to rigidity or to slowness of movement, and it stresses unduly the reduction in muscular power. The same criticism can be leveled against the term paralysis agitans, which appeared for the first time in 1841, in Marshall Hall’s textbook Diseases and Derangements of the Nervous System.

As the disorder of movement worsens, all customary activities show the effects. Handwriting becomes small (micrographia), tremulous, and cramped, as first noted by Charles. The voice softens and the speech seems hurried and monotonous; the voice becomes less audible and finally the patient only whispers. Exceptionally, “mumbling” is an early complaint. Caeeebeke and coworkers refer to the speech disorder as a "hypokinetic dysarthria"; they attribute it to respiratory, phonatory, and articulatory dysfunction. The consumption of a meal takes an inordinately long time. Each morsel of food must be swallowed before the next bite is taken. Walking becomes reduced to a shuffle; the patient frequently loses his balance, and in walking forward or backward must "chase the body's center of gravity" with a series of small corrective steps to avoid falling (festination). Defense and righting reactions are faulty. Falls do occur, but surprisingly infrequent given the degree of postural instability. Gait is typically improved by sensory guidance, as by holding the patient at the elbow, whereas obstacles have the opposite effect, at times causing the patient to "freeze" in place. Difficulty in turning over in bed is a characteristic feature as the illness advances, but the patient rarely volunteers this information.

While familial cases are decidedly rare, Golbe and colleagues have described two large kindreds (probably related and originating from a small town in southern Italy) in which 41 patients in four generations were affected. The illness in their cases was characteristic of Parkinson disease both clinically and pathologically, the only unusual features being a somewhat earlier onset (mean age 46 years), a relatively rapid course (10 years from onset to death), and a reported incidence of tremor in one. These observations suggested that the disease has autosomal dominant inheritance (see below), although others also studied clinically (onset in third decade, prominence of dystonia) and pathologically (absence of Lewy bodies) from classic Parkinson disease. It was in the latter kindred and in three Greek families that Polymeropoulos et al. identified a locus on chromosome 4q that contained a mutation for a-synuclein, a main component of the Lewy body. Other families in which there have been multiple inherited cases of Parkinson disease are associated with gene defects at other sites (but still mostly on chromosome 4). These genetic data have been reviewed by Dunnett and Björklund.
Shaving or applying lipstick becomes difficult, as the facial muscles become more inimoble and rigid.

Persistent extension or clawing of the toes, jaw clenching, and other fragments of dystonia may enter the picture but rarely are early findings.

As noted above, these various motor impediments and tremor characteristically begin in one limb (more often the left) and spread to one side and later to both sides, until the patient is quite helpless. Yet in the excitement of some unusual circumstance (a fire, for example), the patient is capable of brief but remarkably effective movement (kinesia paradoxica).

Regarding other elicitable neurologic signs, there is an inability to inhibit blinking in response to a tap over the bridge of the nose or glabella (Myerson sign), but grasp and suck reflexes are not present and buccal and jaw jerks are rarely enhanced. Commonly there is an impairment of upward gaze and convergence; if noted early in the disease, this raises the possibility of progressive supranuclear palsy. The bradykinesia may extend to eye movements, in that patients may show a delay in the initiation of gaze to one side, slowing of conjugate movements (decreased maximal saccadic velocity), hypometric saccades, and breakdow of pursuit movements into small saccades. There are no sensory changes. Drooling is troublesome; an excess flow of saliva has been assumed, but actually the problem is one of failure to swallow with normal frequency. Seborrhea and excessive sweating are probably secondary as well, the former due to failure to cleanse the face sufficiently, the latter to effects of the constant motor activity. Postural instability can be elicited by tugging at the patient’s shoulders from behind and noting the lack of a small step backwards to maintain balance. The tendon reflexes vary, as they do in normal individuals, from being barely elicitable to brisk. Even when parkinsonian symptoms are confined to one side of the body, the reflexes are usually equal on the two sides, and the plantar responses are flexor. Exceptionally, the reflexes on the affected side are slightly more brisk, which raises the question of corticospinal involvement; but the plantar reflex remains flexor. In these respects, the clinical picture differs from that of corticobasal ganglionic degeneration, in which rigidity, hyperactive tendon reflexes, and Babinski signs are combined with apraxia (see further on). There is a tendency to syncope in some cases; this was found by Rajput and Rozdilsky to be related to cell loss in the sympathetic ganglia. However, syncope is never as prominent as in striatogniral degeneration.

At times, Parkinson disease is complicated by a dementia, a feature that had been commented upon by Charcot. The reported frequency of this combination varies considerably, based on the selection of patients and type of testing. An estimate of 10 to 15 percent (Mayeux et al.) is generally accepted and matches our experience. The incidence increases with advancing age; approaching 65 percent in Parkinson patients above 80 years of age. In some instances of Parkinson disease with dementia, MRI reveals lesions in the cerebral white matter (in T1-weighted images) not seen in parkinsonians without dementia. The pathologic basis of the dementia in Parkinson disease is discussed below.

The overall course of the disease is quite variable. In the majority of patients, the mean period of time from inception of the disease to a chairbound state is 7.5 years (Hoehn and Yah; Martilla and Rimne). On the other hand, as many as one-third of cases are relatively mild and remain stable for 10 years or more.

Diagnosis Early in the course of Parkinson disease, when only a slight asymmetry of stride or an inopposite of one hand is present and tremor has yet to appear and impart the unmistakable stamp of the disease, a number of small signs already alluded to may be helpful in diagnosis. These include a reduced blink rate, the Myerson (facial) sign, a lack of arm swing, digital impedance (a tendency for rapid alternating movements to be slowed, to assume a tremor rhythm, or to be blocked altogether) and perceptible rigidity of one arm when the opposite limb is occupied in a motor task such as tracing circles in the air. Lack of a Babinski sign or of increased tendon reflexes in the affected limbs eliminates a corticospinal lesion as the cause of slowed movements, and lack of a grasp reflex helps to exclude a premotor cerebral disorder.

The main difficulty in diagnosis is to distinguish Parkinson disease from the many parkinsonian syndromes, some caused by other degenerative diseases and some by medications or toxins. Parkinson disease is far more common than any of the syndromes that resemble it. Bradykinesia and rigidity of the limbs and axial muscle sparing are shared symptoms, but only in Parkinson disease is “resting” tremor an early sign, and it remains prominent even late in the illness.

The typical signs of Parkinson disease, when present in their entirety, impart an unmistakable clinical picture. When not all the signs are evident, there is no alternative but to re-examine the patient at several-month intervals until it is clear that Parkinson disease is present or until the signature of another degenerative process becomes evident (e.g., vertical gaze impairment in progressive supranuclear palsy; dystonia with fainting, bladder, or vocal cord signs in striatogniral degeneration, or spasticity in corticobasal degeneration). If the patient’s symptoms warrant, a beneficial response to levodopa also gives a reasonably secure although not entirely conclusive indication of the presence of Parkinson disease. The other parkinsonian syndromes are for the most part unchanged by the drug.

As pointed out on page 813, the epidemic of encephalitis lethargica (von Economo encephalitis) that spread over western Europe and the United States after the First World War left great numbers of parkinsonian cases in its wake. No definite instance of this form of encephalitis had been recorded before the period 1914–1918, and virtually none has been seen since 1930; hence postencephalitic parkinsonism is no longer a diagnostic consideration. Rarely, a Parkinson-like syndrome has been described with other forms of encephalitis (particularly with Japanese V virus and eastern equine encephalitis).

In England and Europe an “arteriopathic” or “arteriosclerotic” form of Parkinson disease was at one time much diagnosed, but we have never been convinced of its reality. Pseudobulbar palsy from a series of lacunar infarcts or fromBinswanger disease (page 878) can cause a clinical picture simulating certain aspects of Parkinson disease. Yet it move to observe the clinical features, spasticity and rigidity (unilateral, and often segmental) are prominent, the presence of levodopa is diagnostic. If the patient’s symptoms warrant, a beneficial response to levodopa also gives a reasonably secure although not entirely conclusive indication of the presence of Parkinson disease. The other parkinsonian syndromes are for the most part unchanged by the drug.

Normal-pressure hydrocephalus can create a syndrome that resembles Parkinson disease, particularly in regard to gait and postural instability and at times to bradykinesia; but rigid postures, slowness of alternating movements, hypokinetic ballistic movements, and resting tremor are not part of the clinical picture.

Senile (familial or essential) tremor is distinguished by its fine, quick quality, its tendency to become manifest during volitional movement and to disappear when the movement is in a position of repose, and the lack of associated slowness of movement, flexed postures, etc. The head is more often involved in senile tremor than in Parkinson disease. Some of the slower, alternating forms of essential tremor are difficult to distinguish from parkinsonian tremor, and one can only wait to see whether it is the first manifestation of Parkinson disease.

Progressive supranuclear palsy (see further on) is characterized by rigidity and dystonic postures of the neck and shoulders, a staring and immobile countenance, and a tendency to topple when walking—all of which are suggestive of Parkinson disease. Inability to produce vertical saccades and, later, paralysis of upward and downward gaze and eventually of lateral gaze with retention of reflex eye movements establish the diagnosis in most cases. Strict adherence to the diagnostic criteria for progressive supranuclear palsy also permits its differentiation from corticobasal degeneration and Machado-Joseph disease—all of which are discussed in other parts of this chapter.

Paucity of movement, unchanging attitudes and postural sets, and a slightly stiff and unbalanced gait may be observed in patients with an anergic or hypokinetic disease—all of which are discussed in other parts of this chapter.

In Parkinson disease, this raises the possibility of progressive supranuclear palsy. The bradykinesia may extend to eye movements, in that patients may show a delay in the initiation of gaze to one side, slowing of conjugate movements (decreased maximal saccadic velocity), hypometric saccades, and breakdow of pursuit movements into small saccades. Seborrhea and excessive sweating are probably secondary as well, the former due to failure to cleanse the face sufficiently, the latter to effects of the constant motor activity. Postural instability can be elicited by tugging at the patient’s shoulders from behind and noting the lack of a small step backwards to maintain balance. The tendon reflexes vary, as they do in normal individuals, from being barely elicitable to brisk. Even when parkinsonian symptoms are confined to one side of the body, the reflexes are usually equal on the two sides, and the plantar responses are flexor. Exceptionally, the reflexes on the affected side are slightly more brisk, which raises the question of corticospinal involvement; but the plantar reflex remains flexor. In these respects, the clinical picture differs from that of corticobasal ganglionic degeneration, in which rigidity, hyperactive tendon reflexes, and Babinski signs are combined with apraxia (see further on). There is a tendency to syncope in some cases; this was found by Rajput and Rozdilsky to be related to cell loss in the sympathetic ganglia. However, syncope is never as prominent as in striatogniral degeneration.

All in all, if one adheres to the strict definition of Parkinson disease—bradykinesia, “resting” tremor, postural changes and instability, cogwheel rigidity, and response to l-dopa—errors in diagnosis are few. Yet in a series of 100 cases, studied clinically and pathologically by Hughes and associates, the diagnosis was inaccurate in 25 percent. The reasons are that about this number of Parkinson patients do not have the characteristic tremor and about 10 percent do not respond to l-dopa. These authors noted that early dementia and autonomic disorder and the presence of ataxia and corticospinal signs were reliable exclusion criteria.
Pathology and Pathogenesis

It is now accepted that a loss of pigmented cells in the substantia nigra and other pigmented nuclei (locus ceruleus, dorsal motor nucleus of the vagus) is the most constant finding in both idiopathic and postencephalitic Parkinson disease. The substantia nigra is visibly pale to the naked eye; microscopically, the pigmented nuclei show a marked depletion of cells and replacement gliosis, findings that enable one to state with confidence that the patient must have suffered neurodegeneration. Also, many of the remaining cells of the pigmented nuclei contain eosinophilic cytoplasmic inclusions with a faint halo, called Lewy bodies. These are seen in practically all cases of idiopathic Parkinson disease. They were present in a few postencephalitic cases as well, but in the latter neuro fibrillary tangles were more unusual. Furthermore, both of these cellular abnormalities appear occasionally in the substantia nigra of aging, nonparkinsonian individuals. Possibly the individuals with Lewy bodies would have developed Parkinson disease if they had lived a few more years. Noteworthy is the finding by McGeer et al that nigral cells normally diminish with age, from a maximal complement of about 425,000 to 200,000 at age 60. Tyrosine-hydroxylase, the rate-limiting enzyme for dopamine, diminishes correspondingly. These authors found that in patients with Parkinson disease, the number of pigmented neurons was reduced to about 30 percent of that in age-matched controls. Using more refined counting techniques, Pakkenberg and coworkers estimated the average total number of pigmented neurons to be 550,000 and to be reduced by 66 percent in Parkinson patients. The number of nonpigmented neurons in their control subjects was 260,000 and again was reduced in patients by 24 percent. Thus, aging contributes importantly to nigral cell loss, but the cell depletion is so much more marked in Parkinson disease that some factor other than aging must also be operative.

Other depletions of cells are widespread, but they have not been quantitatively evaluated and their significance is less clear. There is neuronal loss in the mesencephalic reticular formation, near the substantia nigra. These cells project to the thalamus and limbic lobes. In the sympathetic ganglia, there is slight neuronal loss and Lewy bodies are seen; this is also true of the pigmented nuclei of the lower brainstem as well as of the putamen, caudatum, pallidum, and substantia innominata of the thalamus. In the substantia nigra, in the putamen, and in the inferior olivary nucleus and related nuclei throughout the brainstem, small pigment granules and periaqueductal gray matter and spinal cord are affected little or not at all. The lack of a consistent lesion in either the striatum or the pallidum is noteworthy in view of the reciprocal connections between the striatum and the substantia nigra and the depletion of striatal dopamine that characterizes the parkinsonian state.

The statistical data relating Parkinson and Alzheimer diseases are difficult to assess because of different methods of examination from one reported series to another (Quinn et al). Nevertheless, the overlap of the two diseases is much more than fortuitous, as indicated in an earlier part of this chapter. In our own pathologic material, the majority of the demented Parkinson patients showed Alzheimer-type changes, but there were several in whom few plaques or neurofibrillary changes could be found or in whom the cortical neuronal loss was accompanied by a widespread distribution of Lewy bodies (Lewy body dementia, discussed earlier, on page 1120).

Of great interest in recent years has been the observation, both in human opiate addicts and in monkeys, that a neurotoxin (known as MPTP) can produce irreversible signs of parkinsonism and selective destruction of cells in the substantia nigra (as described on page 105). The toxin, ingested by persons who self-administered an analgesic of meperidine, was shown to bind with high affinity to an extraneuronal enzyme, monoamine oxidase, which transformed it to a toxic metabolite, pyridinium MPTP. The latter is bound by the melanin in the dopaminergic nigral neurons in sufficient concentration to destroy the cells. The precise mechanism by which MPTP produces the Parkinson syndrome is unsettled. One hypothesis is that the inner segment of the globus pallidus is rendered hyperactive because of reduction of the GABA influence of the subthalamic nucleus. The theory of an environmental toxin as a cause of Parkinson disease has been greatly stimulated by the MPTP findings. (Uhl et al)

By combining a decarboxylase inhibitor (carbidopa or benserazide), which is unable to penetrate the central nervous system (CNS), with L-dopa, the decarboxylation of L-dopa to dopamine is greatly diminished in peripheral tissues. This permits a greater proportion of L-dopa to reach nigral neurons and, at the same time, a reduced number of side effects of L-dopa to be observed. Combinations of levodopa-carbidopa (L-dopa/carbidopa) tablets are generally available in a 10:1 or 4:1 ratio and the benseridze combination in a 4:1 ratio. The initial dose of levodopa-carbidopa is typically one-half of a 100-mg/25-mg tablet given two or three times daily and increased slowly until optimum improvement is achieved, usually up to a maximum of two tablets administered four times daily, or a similar dose of the 250-mg/25-mg combination. A newer class of catechol-O-methyltransferase (COMT) inhibitors, typified by tolcapone, extends the plasma half-life and the duration of L-dopa effect by preventing its breakdown in the liver and thus increasing its bioavailability as compared with carbidopa. But these drugs require further study, for there have been several complications and rare unexplained deaths after their use.

The use of levodopa-carbidopa preparations may reduce dyskinesias in some patients (Hutton and Morris) in the advanced stages of disease, but our experience with these drugs given earlier in the course has been less impressive. In transferring a patient from conventional L-dopa/carbidopa preparations to the long-acting formulation, the frequency of administration can be roughly halved while the total amount of L-dopa remains unchanged. Nevertheless, the overlap of the two diseases is more than fortuitous, as indicated in an earlier part of this chapter. In our own pathologic material, the majority of the demented Parkinson patients showed Alzheimer-type changes, but there were several in whom few plaques or neurofibrillary changes could be found or in whom the cortical neuronal loss was accompanied by a widespread distribution of Lewy bodies (Lewy body dementia, discussed earlier, on page 1120).

At present, L-dihydroxyphenylalanine (L-dopa) is unquestionably the most effective agent for the treatment of Parkinson disease, and the therapeutic results, even in those with far-advanced disease, are much better than have been obtained with other drugs, even newer ones that act as dopamine agonists. As mentioned earlier, some degree of response is so nearly universal that many neurologists use it as a diagnostic criterion. The theoretical basis for the use of this compound rests on the observation that striatal dopamine is depleted in patients with Parkinson disease but that the remaining nigral cells are capable of producing dopamine by taking up its precursor, L-dopa. The neurons of the striatum that are targets of nigral projections are not depleted and remain receptive to any dopamine released by nigral cells. However, the number of remaining nigral neurons that convert L-dopa to dopamine becomes inadequate and the receptivity to dopamine of the striatal target neurons becomes excessive, possibly as a result of denervation hypersensitivity; this results in both a reduced response to L-dopa and to paradoxical and excessive movements (dyskinesias) with each dose.

By combining a decarboxylase inhibitor (carbidopa or benseridze), which is unable to penetrate the central nervous system (CNS), with L-dopa, the decarboxylation of L-dopa to dopamine is greatly diminished in peripheral tissues. This permits a greater proportion of L-dopa to reach nigral neurons and, at the same time, a reduced number of side effects of L-dopa to be observed. Combinations of levodopa-carbidopa (L-dopa/carbidopa) tablets are generally available in a 10:1 or 4:1 ratio and the benseridze combination in a 4:1 ratio. The initial dose of levodopa-carbidopa is typically one-half of a 100-mg/25-mg tablet given two or three times daily and increased slowly until optimum improvement is achieved, usually up to a maximum of two tablets administered four times daily, or a similar dose of the 250-mg/25-mg combination. A newer class of catechol-O-methyltransferase (COMT) inhibitors, typified by tolcapone, extends the plasma half-life and the duration of L-dopa effect by preventing its breakdown in the liver and thus increasing its bioavailability as compared with carbidopa. But these drugs require further study, for there have been several complications and rare unexplained deaths after their use.

Long-acting preparations of levodopa-carbidopa may reduce dyskinesias in some patients (Hutton and Morris) in the advanced stages of disease, but our experience with these drugs given earlier in the course has been less impressive. In transferring a patient from conventional L-dopa/carbidopa preparations to the long-acting formulation, the frequency of administration can be roughly halved while the total amount of L-dopa remains unchanged. The absorption of the long-acting drug, however, is approximately 70 percent, often necessitating a slight increase in total dose. To facilitate the treatment of morning rigidity and tremor, the long-acting tablet can be broken in half to speed absorption or a small dose of conventional medication can be given at the same time. Often some degree of dyskinesia must be accepted as the price to be paid for the therapeutic effect.

Bromocriptine, pergolide, and lisuride are synthetic ergot derivatives whose action in Parkinson disease is explained by their direct stimulating effect on dopamine (D_) receptors, which are located on nigrostriatal corticostriatal and corticobulbar nigral projections. The nonergot dopamine agonists apomorphine and pramipexole seem to be tolerated well and have a duration of effectiveness similar to that of other D_ agonists; these agents are very helpful in supplementing L-dopa and are now increasingly popular as the sole therapeutic agent before L-dopa is instituted. Rascol and colleagues have reported that the use of ropinirole during the first 5 years of the parkinsonian illness controlled the symptoms satisfactorily and, in addition, reduced the incidence of dyskinesias, compared to treatment with L-dopa alone (Uhl et al).

Bromocriptine and pergolide are less frequent and less intense than L-dopa-induced dyskinesias and may be useful in patients who cannot tolerate L-dopa. The dosage of bromocriptine should be increased by 7.5 to 10 mg/day in three to four divided doses, and the dosage increased very slowly to an optimal level of 40 to 60 mg daily; levodopa-carbidopa should be reduced concomitantly by 50 percent. A dose of 5 to 10 mg of bromocriptine has about the equivalent effect of 100/25 mg levodopa/carbidopa. It has a longer duration of action than L-dopa and causes nausea and vomiting less often, but otherwise the action and side effects of the two drugs are much the same. Even small doses of these drugs, when first introduced, can produce a prolonged episode of hypotension. Our observations are in agreement with those of Marsden, who found that of 263 patients, all but 82 had abandoned one of the ergot dopamine agonists after 6 months because of lack of effect or adverse reactions. Nevertheless, a proportion of patients continue to benefit for up to 3 years. Ropinirole and pramipexole are useful in smoothing the effects of L-dopa and allowing a reduction in its dose. As with the ergot-based dopamine agonists, they can be utilized in some patients as the sole treatment for a limited time. They may produce sudden and unpredictable sleepiness, similar to narcolepsy, and patients should be warned of this possibility in relation to driving. More data are required to judge the efficacy of initiating therapy with a dopamine agonist rather than with L-dopa combinations.

Because of the side effects of levodopa and of dopamineergic medications, particularly in older patients, some neurologists avoid all types of pharmacotherapy if the patient is in the early phase of the disease and the parkinsonian symptoms are not troublesome. When the symptoms become more annoying, initial therapy with either amantadine 100 mg bid or an anticholinergic medication may be advised. Only when the symptoms begin to interfere with work and social life or falling becomes a threat is a carbidopa/levodopa preparation introduced, and then at the lowest possible dose—10/100 mg bid or tid. This dose is slowly increased until maximal benefit

Polymeropoulos et al
is achieved.

Another approach, now controversial, has been to initiate the treatment of new cases of Parkinson disease with the monoamine oxidase inhibitor selegiline, 5 mg bid, and to continue its use until symptoms become disabling, at which point L-dopa or a dopamine agonist is initiated. Selegiline inhibits the intracerebral metabolic degradation of dopamine, and clinical trials conducted by the Parkinson Study Group have suggested that it slows progression of the disease in its early stages. Subsequent observations, however, have not confirmed the view that selegiline markedly alters the natural course of the disease, and we use it infrequently.

As already mentioned, L-dopa is not without significant side effects, so that its use is limited in some circumstances. Approximately two-thirds of patients tolerate the drug initially without serious adverse effects. Postural hypotension, especially at the initiation of treatment, especially in those with advanced disease, is common. Many patients are first troubled by nausea, especially if the medication is not taken with meals, and a few have orthostatic hypotensive episodes. Nausea usually disappears after several weeks of continued use or can be alleviated by the specific dopaminergic chemoreceptor antagonist domperidone. Coincident psychiatric symptoms may also present problems and are to be expected in 15 to 25 percent of patients, particularly in the elderly. Depression is occasionally a serious problem, even to the point of suicide; development of these in these circumstances, for example, and their doses must be determined. This combination of movement and psychiatric disorders is difficult to treat, and one must institute an antidepressant regimen or one of the newer class of antipsychotic medications that are associated with few extrapyramidal side effects, as described below and in Chapter 50. Trazodone has been helpful in treating depression and insomnia, which may be a major problem. The selective serotonin reuptake inhibitors are useful in antidepressant decisions, but some patients report worsening of parkinsonian symptoms. Excitement and aggressiveness appear in a few. A return of libido may lead to sexual assertiveness.

Confusion and delusions (hallucinations and delusions), seen in advanced cases of Parkinson disease when high doses of L-dopa are required, is first treated by attempting to reduce the dose of the drug. If this is not possible, the typical neuroleptic clonazepam, clozapine, risperidone, or quetiapine in low doses are often successful (Friedman and Lomnitz). The side effects of these drugs include sleepiness, orthostatic hypotension, sialorrhea, and the most serious, agranulocytosis, requiring regular monitoring of the blood count. Clonazepam has been said to provide an additional benefit of suppressing dyskinesias in advanced Parkinson disease (Dalsgaard et al). However, this unpredictable change in the patient, in a matter of minutes or from one hour to the next, from a state of relative mobility to one of complete or nearly complete immobility. These disorders eventually appear in about 75 percent of patients within 5 years. Almost a certain daily dose, which varies from patient to patient, very few patients escape these effects, forcing a reduction in dosage.

If involuntary movements are induced by relatively small doses of L-dopa, the therapeutic effect may be enhanced to some extent by the addition of other dopaminergic agents, such as pergolide, bromocriptine, or the newer nonergot preparations, such as ropinirole and pramipexole (see below) and, to some extent, amantadine. The use of long-acting preparations of L-dopa may also be helpful in reducing dyskinesias, as mentioned above. Amantadine, an antiviral agent, is thought to act by releasing dopamine from striatal neurons; it also has an anticholinergic property. It is given in doses of 50 to 100 mg three times daily. Its benefit appears almost immediately but tends to be slight. In addition to anticholinergic symptoms (dry mouth, etc.), the side effects are similar to those of L-dopa but are much milder. Edema of the legs has been troublesome in some patients. However, amantadine is effective in combination with L-dopa and may reduce the dyskinesias and motor fluctuations associated with advanced disease (Verhaegen et al). Given alone or in combination with L-dopa, it offers a modest alternative treatment for patients with early Parkinson disease or those who are having unfavorable effects with standard doses of L-dopa.

The notion that the administration of L-dopa early in the disease might reduce the period over which it remains effective has been largely dispelled, but some experts continue to adhere to this idea. Cederbaum et al, who reviewed the course of the illness in 307 patients over a 7-year period, found no evidence that the early introduction of L-dopa treatment predisposes to the development of motor response fluctuations, dyskinesia, and dementia. Also, the multicenter study reported by Diamond et al indicated that patients who were given L-dopa early in the disease actually survived longer and with less disability than those who were started late.

Anticholinergic agents have long been in use and are still given occasionally, either in conjunction with L-dopa or to patients who cannot tolerate the latter drug. Several synthetic preparations are available, the most widely used being procyclidine (Artane) and benztropine mesylate (Cogentin) and amantadine (see above). When tremor is the most prominent symptom, we have had success with the related drug ethopropazine (Parsolid, Parstain in Canada). In order to obtain maximum benefit from the use of these drugs, they should be given in gradually increasing dosage to the point where toxic effects appear: dryness of the mouth (which can be beneficial when drooling of saliva is a problem), blurring of vision from pupillary mydriasis (for which corrective glasses may be indicated), constipation, and, sometimes urinary retention (especially with prostatism). Unfortunately, mental confusion, slow, confusional states, hallucinations, and impairment of memory—especially in patients with already impaired mental function—are frequent side effects of these drugs and sharply limit their usefulness. Ethopropazine, 50 to 200 mg daily, is given in divided doses. We have effectively managed cases of isolated parkinsonian tremor in young patients using anticholinergic drugs alone. The optimum dosage level is usually 50 to 150 mg daily. The anticholinergic side effects, which may be severe, must be closely monitored. Because these drugs may worsen akathisia, depression, anxiety, and even hallucinations. Some patients function well in the morning and much less well in the afternoon, or vice versa. In such cases, and for end-of-dose effects (as above), one must titrate the dose of L-dopa and utilize more frequent doses during the 24-h day; combining it with a dopamine agonist or use of the long-acting preparations may be helpful. Sometimes temporarily withdrawing L-dopa and at the same time substituting other medications will control the on-off phenomenon.

Based on the hypothesis that dietary-derived amino acids antagonize the clinical effects of L-dopa, the use of a low-protein diet has been advocated as a means of controlling the motor fluctuations described above (Pincus and Barry). Symptoms can often be reduced by the simple expedient of eliminating dietary protein from breakfast and lunch. Moreover, this dietary regimen may permit the patient to reduce the total daily dose of L-dopa. Such dietary manipulation is worth trying in appropriate patients; it is not harmful, and most of our patients who have persisted with this diet have reported improvement in their symptoms or an enhanced effect of L-dopa.

Surgical Measures Until recently, success with L-dopa had practically replaced the use of ablative surgical therapy. The latter involves the stereotactic placement of lesions in either the globus pallidus, ventrolateral thalamus, or subthalamic nucleus, contralateral to the side of the body chiefly affected. The best results have been obtained in relatively young patients, in whom unilateral tremor or rigidity, rather than akinesia, are the predominant symptoms. The symptoms that have responded least well to operation (or to treatment with L-dopa) are postural imbalance and instability, paroxysmal akinesia, blader and bowel disturbances, dystonia, and speech difficulties. In the last decade, through the work of Lahtinen and others, this mode of therapy has been revived and expanded. Under precise stereotactic control and with placement of a lesion in the posterior and ventral (medial) part of the globus pallidus, improvement of contralateral parkinsonian symptoms has been effected more reliably than in the past. Also, postoperatively, there is an enhanced responsiveness to L-dopa and a reduction of drug-induced dyskinesias. To what extent the improvement in L-dopa treatment predisposes to the development of motor response fluctuations, dyskinesia, and dementia, and also, the multicenter study reported by Diamond et al indicated that patients who were given L-dopa early in the disease actually survived longer and with less disability than those who were started late.

Long-term treatment with L-dopa or dopamine receptor agonists has not prevented the slow advance of the disease. With progressive loss of nigral cells, there is an increasing inability to store L-dopa and periods of drug effectiveness become shorter. In some instances, the patient becomes so sensitive to L-dopa that as slight an excess as 10 mg daily will precipitate choreoathetosis; if the dose is lowered by the same amount, the patient may develop disabling rigidity. With the end-of-dose loss of effectiveness and on-off phenomenon, which with time become increasingly frequent and unpredictable, the patient may experience pain, respiratory distress, akathisia, depression, anxiety, and even hallucinations. Some patients function well in the morning and much less well in the afternoon, or vice versa. In such cases, and for end-of-dose effects (as above), one must titrate the dose of L-dopa and utilize more frequent doses during the 24-h day; combining it with a dopamine agonist or use of the long-acting preparations may be helpful. Sometimes temporarily withdrawing L-dopa and at the same time substituting other medications will control the on-off phenomenon.

Based on the hypothesis that dietary-derived amino acids antagonize the clinical effects of L-dopa, the use of a low-protein diet has been advocated as a means of controlling the motor fluctuations described above (Pincus and Barry). Symptoms can often be reduced by the simple expedient of eliminating dietary protein from breakfast and lunch. Moreover, this dietary regimen may permit the patient to reduce the total daily dose of L-dopa. Such dietary manipulation is worth trying in appropriate patients; it is not harmful, and most of our patients who have persisted with this diet have reported improvement in their symptoms or an enhanced effect of L-dopa.
reduce the dose of L-dopa. It should be mentioned that most groups have abandoned the pallidum as a surgical target in favor of the subthalamic nucleus.

Recently, through the use of implanted electrodes, the sites that are the targets of ablative procedures have been subjected to high-frequency stimulation—with virtually identical if not better results. In particular, high-frequency stimulation of the subthalamic nucleus has produced impressive improvement in all features of the disease (L limbs et al). Long-term studies are in progress to determine the persistence of these effects and their merits in comparison to ablative lesions.

The cerebral implantation of adrenal medullary tissue from 8- to 10-week-old human fetuses has provided a modest but undeniable improvement in motor function (Spencer and colleagues), and some patients also appear to have benefited from the striatal implantation of human fetal and porcine nigral cells and autologous adrenal cells. These procedures are performed by many centers, but the failure of grafts to survive and to function properly has led to the abandonment of these procedures has subsided, and it seems unlikely that they will have wide applicability in the treatment of Parkinson disease in the near future. Investigation into these possible usefulness continues.

Finally, in the management of the patient with Parkinson disease, one must not neglect the maintenance of optimum general health and neuromuscular efficiency by a planned program of exercise, activity, and rest; expert physical therapy and exercises such as those performed in yoga may be of help in achieving these ends. Sleep may be aided by the soporific antidepressants. Postural imbalance can be greatly mitigated by the use of a cane or walking frame. Hypotensive episodes respond to 0.5 mg of fludrocortisone (Florinef) each morning. In addition, the patient often needs much emotional support in dealing with the stress of the illness, in comprehending its nature, and in carrying on courageously in spite of it.

---

Striatonigral Degeneration and Multiple System Atrophy

Closely related to Parkinson disease clinically but with a different pathologic basis is a state designated by Adams and colleagues as striatonigral degeneration. The pathologic changes were found by chance in one of the four children who had been diagnosed by Gallyas silver technique. Moreover, appropriate control studies to determine whether the argyrophilic glial inclusions are found in neurons as well. These cytoplasmic aggregates have been referred to as "oligodendroglial cytoplasmic inclusions." Although the term "oligodendroglial" has been given us an allocation to the remaining cells the degenerative changes in the putamina tend to a lesser extent in the caudate nuclei. These structures were greatly reduced in size and had lost most of their neurons—even more of the small than the large ones and more on the side opposite the clinical picture. The findings were suggestive of the striatal lesions of Huntington chorea except that the cell loss was greater in the putamen than in the caudatum. Secondary pallidal atrophy (mainly a loss of striatopalidal fibers) was present. In the fourth patient there was, in addition, an advanced olivopontocerebellar degeneration.

Following the original report, in 1964, many patients were recognized in whom the changes of striatonigral and olivopontocerebellar degeneration (page 1148) were combined and in some of whom the symptoms and signs of cerebellar ataxia actually preceded the parkinsonian manifestations. Equalily frequent is a predominantly extrapyramidal syndrome accompanied by autonomic dysfunction, as described below.

Shy-Drager Syndrome

Nearly half of the patients with striatonigral degeneration are handicapped by orthostatic hypotension, which proves at autopsy to be associated with loss of sympathetic ganglion cells in the paravertebral chain. This condition is known as Shy-Drager syndrome. In this series, the syndrome followed the development of the disease in only 5 percent, but ataxia was eventually obvious in half of the group. The illness, on the other hand, was more severe than Parkinson disease, since more than 40 percent of patients were confined to a wheelchair or otherwise severely disabled within 5 years. These observations generally match the findings in a group of 188 patients described by Quinn and colleagues. In that series, parkinsonism was evident at some time in 89 percent of patients and was accompanied with cerebellar signs in half, pyramidal signs in 70 percent, and autonomic features in 77 percent. The other main presentation was with ataxia of gait, and this was accompanied by pyramidal signs in 69 percent; one-quarter of the patients had parkinsonism alone.

Multiple System Atrophy

Because of the recognition that the clinical and pathologic features of sporadic striatonigral degeneration, with or without autonomic failure, and those of olivopontocerebellar atrophy often coexist, each component expressing itself variably in any individual, Graham and Oppenheimer, in 1969, proposed the term multiple system atrophy (MSA), which has gained wide acceptance. Several large series of cases of this complex syndrome have now been published, providing a perspective on the frequency and nature of its components.

In the Brain Tissue Bank of the Parkinson Disease Society of Great Britain, MSA accounted for 13 percent of cases that had been identified during life as idiopathic Parkinson disease. All of the patients with MSA had one or more symptoms of autonomic failure (postural hypotension, urinary urgency or retention, urinary or fecal incontinence, impotence, loss of sweating, dry mouth, miosis, and urinary retention or incontinence). Vocal cord palsy is an important and sometimes the initial manifestation of the autonomic disorder, causing dysphonia or even stridor and airway obstruction, and requiring tracheostomy (see page 565).

Progressive Supranuclear Palsy

Spencer et al.

Papp et al.

Chin and Goldman

Lantos

Spencer et al.

Spencer and colleagues
In 1963 Richardson, Steele, and Olszewski crystallized medical thought about a clinicopathologic entity—progressive supranuclear palsy, or PSP—to which there had been only ambiguous reference in the past. The condition is not rare or unusual. By 1972, when Steele reviewed the subject, 73 cases (22 with postmortem examinations) had been described in the medical literature, and several examples are to be found in every large neurologic center; the present authors encounter approximately five new cases yearly, most of them not previously diagnosed. Rare familial cases have been described in which the pattern of inheritance is compatible with autosomal dominant transmission (Brown et al; de Yébenes et al). No toxic, encephalitic, racial, or geographic factor has been incriminated as a possible cause.

**Clinical Features** Characteristically the disease has its onset in the sixth decade (range 45 to 75 years) with some combination of difficulty in balance, abrupt falls, visual and ocular disturbances, slurred speech, dysphagia, and vague changes in personality, sometimes with an apprehensiveness and fretfulness suggestive of an agitated depression. The commonest early complaint is unsteadiness of gait and unexplained falling. At first the neurologic and ophthalmologic examinations may be unrevealing, and it may take a year or longer for the characteristic syndrome—comprising supranuclear ophthalmoplegia, pseudobulbar palsy, and axial dystonia—to develop fully.

Difficulty in voluntary vertical movement of the eyes, often downward but sometimes upward and involving voluntary saccades first, is a characteristic and relatively early feature in more than half of the cases. A related but more subtle sign has been the finding of hypometric saccades in response to an optokinetic drum or striped cloth moving vertically in one direction (usually best seen with stripes moving downward) compared to the saccades with the targets moving in the opposite direction or horizontally. Later, both the ocular pursuit and reflex movements deteriorate and eventually all voluntary eye movements are lost, first the vertical ones and then the horizontal ones as well. However, if the eyes are fixated on a target and the head is turned, full movements can be obtained, proving the supranuclear, nonparalytic character of the gaze disorder. Other prominent oculomotor signs are sudden jerks of the eyes during fixation, cogwheel pursuits, movements, and hypometric saccades of long duration (Troost and Daroff). Bell’s phenomenon (reflexive upturning of eyes on forced closure of the eyelids) and ability to converge are also lost, and the pupils then become small. The upper eyelids may be retracted, and the wide-eyed, unblinking stare, imparting an expression of perpetual surprise, is highly characteristic. Biphasic spasms and involuntary eye closure are prominent in some cases. In the late stages, the eyes may be fixed centrally, and all oculocephalic and vestibular reflexes may be lost as well. It should be emphasized, however, that a proportion of patients do not demonstrate these eye signs for a year or more after the onset of the illness.

The gait disturbance and repeated falling have proved difficult to analyze. Walking becomes more and more awkward and tentative; the patient has a tendency to totter and fall repeatedly but has no ataxia of the limbs or Romberg sign. Some patients tend to lean and fall backward (retropulsion). One of our patients, a large man, fell repeatedly, wrecked household furniture as he went down, yet careful examination provided no clue as to the basic defect in this “toppling phenomenon.”

Along with the oculomotor and balance disorders, there is a gradual stiffening and extension of the neck (in one of our cases it was sharply flexed), but this is not an invariable finding. The face acquires a staring, “worried” expression with a furrowed brow and staring demeanor, made more striking by the paucity of eye movements. A number of our patients have displayed mild dystonic postures of a hand or foot, especially as the illness advanced but occasionally early on. The limbs may be slightly stiff, with Babinski signs in a few cases.

The stiffness, slowness of movement, difficulty in turning and sitting down, and hypomimia may suggest a diagnosis of Parkinson disease. However, the expression of the PSP patient is more a matter of tonic grimace than of lack of movement, and the lack of tremor, erect rather than stooped posture, and prominence of the frontalis muscles also serve to distinguish PSP from Parkinson disease. The eye movements may be the most important sign of a PSP patient. The disorder becomes “masked,” speech is slurred, the mouth tends to be held open, and swallowing is difficult. Forced laughing and crying, said to be frequent, have been present in about half of our cases. Many patients complain of sleep disturbances. The total sleep time and rapid-eye-movement (REM) sleep are reduced, and spontaneous awakenings during the night are more frequent and longer than in normal individuals of the same age. Features such as focal limb dystonia, palsy, myoclonus, chorea, orofacial dyskinesias, and disturbances of vestibular function are observed in some cases. Finally the patient becomes anarctic, immobile, and quite helpless. Some patients do eventually become forgetful and appear apathetic and slow in thinking; a few are irritable and at times euphoric. Complaints of urinary frequency and urgency are very frequent in advanced cases. Dementia of some degree is probably present in many cases but is mild in most.

By MRI, one can, in advanced cases, visualize the atrophy of the mesencephalon (superior collicuit, red nuclei) giving rise to a “mouse ears” configuration. The CSF flow—most marked in the frontal lobes—and a lesser extent of oxygen utilization in central structures (Leenders et al) have disclosed a bilateral loss of neurons and gliosis in the periaqueductal gray matter, superior colliculus, subthalamic nucleus of Luys, red nucleus, pallidum, dentate nucleus, and pretectal and vestibular nuclei, and to some extent in the oculomotor nuclei. The neurons of the cerebral cortex have been involved in some cases (shown by staining of tau protein), but these changes apparently do not correlate with dementia. The cerebellar cortex is usually spared. Loss of the medullated fiber bundles arising from these nuclear structures has been observed. A remarkable finding has been the neurofibrillary degeneration of many of the residual neurons. The neurofibillar tangles are thick and often composed of single strands, either twisted or in parallel arrangement. We have followed several patients who had no disorder of eye movement during life but in whom the typical pathologic changes of PSP were found unexpectedly. In one such case there was a subcortical type of dementia, and in another, focal limb dystonia and parkinsonism.

The cause and nature of this disease are quite obscure. Attempts to transmit it to primates by inoculation of fresh brain tissue have failed. Conceivably, some cases originally considered to be instances of postencephalic parkinsonism were examples of PSP. Studies with PET have demonstrated a decrease in blood flow—most marked in the frontal lobes—and a lesser extent of oxygen utilization in central structures (Leenders et al). Striatal dopamine formation and storage have been significantly decreased compared with control values.

Progressive supranuclear palsy should be suspected whenever an older adult inexplicably develops a state of imbalance, frequent falls with preserved consciousness, and variable extrapyramidal symptoms, particularly dystonia of the neck, ocular paralyses, or a picture resembling pseudobulbar palsy. When only a parkinsonian syndrome without tremor is present, the main diagnostic consideration is striatonigral degeneration or the cortical-basal-ganglionic syndrome, described below.

L-Dopa has been found to be of slight but unexplained benefit in some of our patients, and combinations of L-dopa and anticholinergic drugs have been entirely ineffective in others. A marked response to these drugs should, of course, suggest the diagnosis of Parkinson disease. Recently, the drug zolpidem, a GABAergic agonist of benzodiazepine receptors, has been reported to ameliorate the akinesia and rigidity of PSP (Daniel et al); however, these observations require corroboration.

**Cortical-Basal-Ganglionic Syndromes**

Over the years, the authors have observed several elderly patients, both men and women, in whom the essential abnormality was a progressive extrapyramidal rigidity, combined with signs of cortical involvement. Sometimes a mild postural action tremor (beginning unilaterally and suggestive in some respects of Parkinson disease) was added. The relation of such cases to corticostriatal dopaminergic degeneration, described earlier, is indeterminate. The patients, though able to exert considerable muscle power, cannot effectively direct their voluntary actions. Attempts to move a limb to accomplish some purposeful act might result in a totally inappropriate movement, always with great enhancement of rigidity in the limb and in other affected parts, or the limb may drift off and assume an odd posture, such as an axial dystonia arising in the chest Wallis the observed arm. A remarkable finding has been the neuropsychologic involvement of many of the residual neurons. The neurofibrillary changes are thick and often composed of single strands, either twisted or in parallel arrangement. We have followed several patients who had no disorder of eye movement during life but in whom the typical pathologic changes of PSP were found unexpectedly. In one such case there was a subcortical type of dementia, and in another, focal limb dystonia and parkinsonism.

the patients with rigidity and in one-fifth with tremor; as the illness progressed, almost all the patients developed an asymmetrical or unilateral akinetic-rigid syndrome, various forms of gait disorder, and dysarthria. Stimulus-induced myoclonus and pyramidal signs, mentioned in other reports, were not prominent, and fewer than half the patients exhibited an alien-hand phenomenon; limitations of vertical gaze and frontal lobe release signs eventually became apparent in half of the patients.

Postmortem examination of several of our cases, reported by Rebeck and colleagues, has disclosed a combination of findings that stumps the disease process as unique. Cortical atrophy (mainly in the frontal and anterior parietal lobes) is associated with degeneration of the substantia nigra and, in one instance, of the dentatorubrothalamic fibers. The loss of motor nerve cells is fairly marked, but there is no gross lobar atrophy, as occurs in Pick disease. The neuronal degeneration may be more on one side than the other. There is moderate gliosis in the cortex and underlying white matter. Many of the residual nerve cells are swollen and chromatinic inclusions with restricted mitotic activity, a state that was pictured chromatolysis by Rebeck and colleagues; it resembles the central chromatolysis of axonal reaction. More recently, the affected neurons and adjacent glia have been shown to be filled with tau protein, but no Pick bodies, Alzheimer fibrillary changes, senile plaques, granulovascular changes, amyloid deposits, or Lewy bodies are seen. Both CT and MRI have demonstrated asymmetrical cerebral and pontine atrophy, and PET studies have shown thalamic and parietal metabolic asymmetries—a greater reduction of glucose metabolism on the side of the most extensive lesion (Heyd et al.).

Many investigators have searched unsuccessfully for clues as to the cause and pathogenesis of this disease. There is no family history. No organ other than the CNS is affected. The progression is relentless. None of the drugs in common use for spasticity, rigidity, and tremor has been helpful. We know of no attempt to transfer the disease to primates.

Marinescu has described a rather different state resembling more a severe form of Alzheimer disease, but with signs of both pyramidal and extrapyramidal disease (rigidity, tremor, nystagmus, incoordination, confusion, disorientation, and loss of memory). There was amyloidosis of blood vessels (so-called Schölzl’s perivascular plaques) in the cerebral white matter as well as in the liver and kidney. The disease bears some resemblance to the corticospinal degeneration (“spastic pseudoclorosis”) of Jakob discussed on page 1126. The relation of this disease to the corticopallidopontal and the pallidopyramidal syndromes first described by Davison (1932, 1954) is also uncertain. The features of eight such cases (“pallido-pyramidal syndrome”) have more recently been summarized by Tranchant and associates.

Dystonic Disorders

Dystonia Musculorum Deformans (Torsion Dystonia) Dystonia as a symptom has been discussed on pages 79 and 112. Here we are concerned with a disease or diseases of which dystonia is the major manifestation. Schwabé’s account, in 1908, of three siblings of a Jewish family who were afflicted with progressive involuntary movements of trunk and limbs probably represents the first description of the disease. In 1911, Oppenheim contributed other cases and coined the term dystonia musculorum deformans in the mistaken belief that the disorder was primarily one of muscle and always associated with deformity. Platani and Sterling, in the same year, first suggested that the disease might have a hereditary basis and gave it the more accurate name torticollis dystonia. At first thought to be a manifestation of hystera, it gradually came to be established as a morbidity entity with a preference for Russian and Polish Jews. Soon thereafter, a second hereditary form of torsion dystonia, affecting non-Jews, was defined. The epidemiologic study of Eldridge, who analyzed all reported primary cases up to 1970, revealed two patterns of inheritance: autosomal recessive, the predominant form which begins in early childhood, and autosomal dominant, which begins in later life, is more often associated with parkinsonian symptoms or myoclonus. Several subgroups have been defined—one type is responsive to levodopa, which is effective in about 75 percent of the cases. Another type is resistant to all another type is resistant to therapy.”

As indicated in Chap. 6, most instances of idiopathic (primary) dystonias that come to our attention, particularly the segmental or restricted types, do not conform to the classic hereditary types as defined above. In general, these more restricted types have a later onset and are relatively milder, more slowly progressive course, with a tendency to involve the axial or the distal musculature alone; only the paravertebral, cervical, or cranial muscles may be involved (focal dystonia including torticolis and blepharospasm). The change from focal to predominantly adult-onset dystonia is made more likely by the fact that, in adults, both the restricted and generalized forms may be sporadic or familial in type. Bressman et al., for example, have described a restricted (cervicodorsal) adult-onset form of dystonia in four generations of a non-Jewish family. The symptomatology included cervical dystonia, facial grimacing, dysarthria, and dysphonia. In one of their familial cases, a dystonia of the foot appeared during adolescence and later disappeared; we have also observed this to happen in spasmocortic dystonia, which is another form of restricted or segmental dystonia, described further on.

In a survey of idiopathic torsion dystonia in the United Kingdom by Fletcher and associates, both generalized and restricted varieties were included. The investigators concluded that approximately 85 percent of these cases were due to an autosomal dominant gene of low penetrance and that a small proportion represented new mutations. They could not confirm the existence of autosomal recessive X-linked patterns of inheritance in their patients. The risk of the disease in a first-degree relative of a familial case is about 25 percent.

Molecular genetic studies, though still incomplete, hold the promise of clarifying the classification of the heritable dystonias (see Chap. 4). An abnormal gene (DYT1), which codes for the protein torsin A, has been mapped to the long arm of chromosome 9q in both Jewish and non-Jewish families and is inherited in an autosomal dominant pattern. This gene probably accounts for the majority of inherited cases of generalized dystonia. Although the penetrance of the clinical trait in these families is low, PET scanning demonstrates hypermetabolism in the cerebellum, lenticular nuclei, and supplementary motor cortex in all carriers of the mutated gene. German Marinescu has described restricted adult-onset dystonia in which an X-chromosome mutation has also been described. The unique dopa-responsive dystonia, described below, has been mapped to chromosome 14q (Nypaard et al.).

The relationship of childhood and adolescent inherited varieties of generalized dystonia to the more common sporadic and restricted dystonias has not been settled, but a few individuals in affected families demonstrate only the most localized forms (e.g., writer’s cramp), arising in adulthood. The general rule stated above, however, still holds—namely, that the inherited variety that is tied to chromosome 9q begins early in life in one limb, followed by generalization of the dystonic movements, while in other types, some of which are heritable and some not, the cranioocular or another region is affected early and the condition does not spread.

Clinical Features The first manifestation of the idiopathic generalized dystonia general may be rather suble. The patient (usually a child between 6 and 14 years of age, less often an adolescent) begins intermittently and usually after activity (late in the day) to invert one foot, to extend one leg and foot in an unnatural way, or to hunch one shoulder, raising the question of a nervous tic. As time passes, however, the motor peculiarity becomes more persistent and interferes increasingly with the patient’s activities. Later, in the spine and shoulder or pelvic girdles become implicated in involvements of the spinal twisting movements. The spasms are intermittent at first, and in free intervals muscular tone and volitional movements are normal. Indeed, in some instances the muscles are hypotonic. Gradually the spasms become more frequent; finally they are continuous, and the body may become grotesquely contorted. Lateral and rotatory scoliosis are regular secondary deformities. For a time the disability relieves the spasms, but later they recur in proportion to the extent of the dystonic motor elements. The dystonic movement, in general, is progressive over a few years, and is restricted to Jewish patients with normal or even superior intelligence. The dominant form begins later, usually in late childhood and adolescence, progresses more slowly, and is not limited to any ethnic group.

With widening clinical experience, the spectrum of dystonic syndromes has been greatly expanded to include an array of hereditary and nonhereditary forms, both generalized and restricted, as well as symptomatic (secondary) types due to vascular, metabolic (Wilson and Hallervorden-Spatz disease), and other degenerative forms (Huntington chorea among many others.)

Pathology No agreement has been reached concerning the pathologic substrate of the disease. In several reported cases the focal degeneration of Hallervorden-Spatz disease, the lesions of Wilson disease or of kieniherus, the etat marbré of neonatal hypoxia, or the CT lucencies of familial striatal necrosis were observed in the basal ganglia of the patient. Obviously in these cases the dystonia was symptomatic of another disease. However, in the hereditary forms, which are the subject of this section, one cannot be certain of any specific lesions that would account for the clinical manifestations. The brain is grossly normal, and the ventricular size is not increased.

According to Zeman, who reviewed all the reported autopsy studies up to 1970, there are no significant changes in the striatum, pallidum, or elsewhere. This does not mean that the disease does not involve the basal ganglia, only that the pathologic or radiographic changes are not as evident in the classical cases as in the recent demonstration. Newer methods of identification of striatal cell types have proven those areas been adequately utilized. Despite the decrease in hemoglobin in the substantia nigra, the dopamine-β-hydroxylase is elevated in the plasma of patients with the autosomal dominant form of the disease and the plasma norepinephrine levels are also raised, but the meaning of these findings is not clear; PET scan changes have already been mentioned.
Treatment Early in the course of the illness, several drugs—including l-dopa, bromocriptine, carbamazepine, diazepam, and tetrabenazine—seem to be helpful, but only in a few patients, and the benefit is not lasting. Intrathecal baclofen has been somewhat more successful in children. The rare hereditary form of dystonia-parkinsonism (described below) responds well to small doses of l-dopa and dopamine agonists and is exceptional in this respect. Burke and coworkers advocate the use of very high doses (30 mg daily or more) of trihexyphenidyl (Artane). Apparently dystonic children can tolerate these high doses if they are raised gradually, by 5-mg increments weekly. In adults, high-dose anticholinergic treatment is less successful but worthy of a trial. Clonazepam is beneficial in some patients with segmental myoclonus. The most impressive results have been obtained by the use of stereotactic techniques to make lesions that are centered in the ventrolateral nuclei of the thalamus or in the pallidum–ansa lenticularis region. Some frightfully deformed children, unable to sit or stand, have been restored to near normalcy for a time. Approximately 70 percent of the patients in Cooper’s series were moderately to markedly improved by unilateral or bilateral operations, and, based on a 20-year follow-up study, the improvement was usually sustained. More recent studies have reported a somewhat less favorable but nonetheless clear-cut improvement (Tasaki et al; Andrew et al). The main risk of operation has been a corticospinal tract lesion, produced inadvertently by damaging the internal capsule.

Hereditary Dystonia-Parkinsonism (Segawa Syndrome, Dopa-Responsive Dystonia) Following the description of this disease by Segawa and colleagues in 1976, several other reports have drawn attention to this unique form of hereditary dystonia (Allen and Knopp; Deonna; Nygaard and Duvoisen). The pattern of inheritance in this disease is probably autosomal dominant, and there is no ethnic predilection. Nygaard and colleagues have found a linkage to chromosome 1q4. The dystonic manifestations become evident in childhood, usually between 4 and 8 years of age, females outnumber males in a ratio of 3:2. Often the legs are first affected by intermittent stiffening, with frequent falls and peculiar posturing, sometimes assuming an equinovarus position. The arms become involved as well as the truncal muscles; retrocollis or torticollis may appear. Within 4 to 5 years, all parts of the body including the bulbar muscles are involved. Sometimes parkinsonian features (rigidity, bradykinesia, postural instability) may already be detected early in the course of the illness, but characteristic symptoms are usually not evident for several years later. Among our own patients and in those of Deonna, there was in some instances a rigidity of the limbs as well as slowness of movement and tremor at rest, at all aspects more parkinsonian than dystonic. In still others, the clinical picture has been one of cerebellar spastic diplegia. Usually the symptoms disappear after a period of sleep and worsen as the day progresses. This diurnal variation was a notable feature in some but not all cases. Fluctuations of symptoms with exercise and menses and in the first month of pregnancy are features of some cases.

In one autopsied case, there was a reduction in the amount of tyrosine hydroxylase in the striatum and depigmentation but no cell loss in the substantia nigra (Rajput et al). The enzyme was also reduced in the striatum, as was the level of dopamine.

The unique feature of this juvenile dystonia-parkinsonism syndrome, as it has been called, is the dramatic response of both the dystonic and parkinsonian symptoms to treatment with l-dopa. As little as 10 mg/kg per day may eliminate the movement disorder and permit normal functioning. In this condition, unlike Parkinson disease, the dystonia can be controlled indefinitely without the development of tolerance or wearing-off effects. Segawa disease accounts for some cases that had been reported in the past as juvenile Parkinson disease.

Torticollis and Other Restricted Dyskinesias and Dystonias With advancing age, a large variety of degenerative movement disorders come to light. Supposedly there is loss of neurons in certain parts of the basal ganglia, but this has not been verified by appropriate pathologic studies. Groups of muscles begin to manifest arrhythmic involuntary spasms. The patient’s inability to suppress the dystonia and the recognition that it is for the most part beyond voluntary control distinguishes it from the common tics, habit spasms, and mannerisms described in Chap. 6. If the muscle contraction is frequent and prolonged, it is accompanied by an aching pain that may mistakenly be blamed for the spasm and the involved muscle may gradually undergo hypertrophy. Worsening under conditions of excitement and stress and improvement during quiet and relaxation are typical of this group of disorders and contributed in the past to the mistaken notion that the spasms had a psychogenic origin.

The most frequent and familiar type is torticollis, wherein an adult, more often a woman, becomes aware of a turning of the head to one side while walking. Usually this condition worsens gradually to a point where it may be more or less continuous, but in some patients it remains mild for years on end. When followed over the years, the condition is observed to remain limited to the same muscles (mainly the scalene, sternocleidomastoid, and upper trapezius). Occasionally torticollis is combined with dystonia of the arm and trunk, tremor, facial spasms, or dystonic writer’s cramp.

Other restricted dyskinesias involve the neck in combination with facial muscles, the orbicularis oris (blepharospasm and blepharoclonus), the throat and respiratory muscles (“spastic dysphonia,” orofacial dyskinesia, and respiratory and phonatory spasms), the hand as in writer’s cramp (graphospasm) or musician’s dystonia, and proximal leg and pelvic girdle muscles, where dyskinesia is elicited by walking. All these conditions and their treatment are discussed fully in Chap. 6.

Other Forms of Hereditary Dystonia Several familial movement-induced (kinesogenic) dystonic syndromes and a type that is not kinesogenic and arises suddenly in adolescence, at times with parkinsonian features, have been described (see page 83). There are other degenerative diseases that combine hereditary dystonia with neural deafness and intellectual impairment (Sciribu and Kennedy) and with amyotrophy in a paraplegic distribution (Gilman and Romanul).

Two other important diseases that fall into the category of hereditary dystonia have been described in Chap. 37. These are Hallervorden-Spatz disease and calcification of the basal ganglia—and, of course, Wilson disease may have dystonia as a central feature.

SYNDROME OF PROGRESSIVE ATAXIA

This topic was introduced in Chap. 5, and some of the congenital and acute acquired varieties are mentioned on pages 1010, 1021, and 1197. Here we consider only the chronic progressive forms of cerebellar disease, many of which are familial and which are more or less confined to this part of the nervous system, although a number of them may be involved to a varying degree. Many of them are so chronic that one would not expect a close correlation between their symptomatology and anatomic pathology, yet attempts to determine these relationships have generally been disappointing. Traditionally, the classic examples of chronic progressive cerebellar disease are subsumed under the system atrophies, but no one classification designed to bring precise order to these diseases has proved entirely satisfactory. Wilson wrote that “The group of degenerative conditions strung together by the common feature of ataxia is one for which no very suitable classification has yet been devised”—a statement that is as appropriate today as when it was written almost 60 years ago. Even recent insights provided by the tools of molecular genetics have not fully resolved the problem of classification, mainly because a single gene abnormality may be expressed by a number of different phenotypic syndromes.

Nevertheless, largely through the clinical and pathologic studies of Greenfield and the subsequent studies of Harding, a semblance of order has been brought to the classification of the hereditary ataxias. The classification proposed by Harding represents the most thorough and scholarly effort to meet this goal. Setting aside those of congenital type and those with an underlying metabolic disorder, she has grouped them by age of onset, pattern of heredity, and associated features. A number of new classifications of Cerebellum (Cofen, 1976; Table 1108), is used here. It divides the progressive cerebellar ataxias into three groups—the spinocerebellar ataxias, with unmistakable involvement of the spinal cord (Romberg sign, sensory loss, diminished tendon reflexes, Babinski signs); the pure cerebellar ataxias, with no other associated neurologic disorders; and the complicated cerebellar ataxias, with a variety of retinal, optic nerve, ocular-motor, auditory, pyramidal, extrapyramidal, peripheral nerve, and cerebrocortical inclusions. Inherited ataxias of early onset (before the age of 20 years) are usually autosomal recessive type; those of later onset may be autosomal recessive but are usually autosomal dominant.

In the approach to a patient with a heritable ataxia, we find such a classification—based on well-established clinical and pathologic features and patterns of mendelian inheritance—to be the most useful. The molecular genetic revolution of recent years is transforming our understanding of the inherited ataxias and has already disclosed a large number of unexpected relationships between specific genetic defects and other neural and nonneural disorders. These data are incorporated at appropriate points in the following discussion and are summarized at the end of the section.

Early-Onset Spinocerebellar Ataxias (Predominantly Spinal)

Friedreich Ataxia This is the prototype of all forms of progressive spinocerebellar ataxia and accounts for about half of all cases of hereditary ataxia in most large series (86 of 171 cases in Jørgen’s series). Friedreich, of Heidelberg, began in 1861 to report on a form of familial progressive ataxia that he had observed among nearby villagers. It was already known through the writings of Duchenne in Paris that locomotor ataxia was the prominent feature of spinal cord syphilis, i.e., tabes dorsalis, and it was Friedreich who demonstrated that a nonsyphilitic hereditary type also existed. This concept was greeted with some skepticism, but soon Friedreich himself affirmed the existence of the new disease and other case reports appeared in England, France, and the United States. In 1882, in a thesis on this
Available soon!
Predominantly Cerebellar (Cortical) Forms of Hereditary Ataxia

Soon after the publication of Friedreich's descriptions of a spinal type of hereditary ataxia, reports began to appear of somewhat different diseases in which the ataxia was related to degenerative changes in the cerebellum and brainstem rather than the spinal cord. Claims of their independence from the spinal type were based largely on a later age of onset, a more definite hereditary transmission—usually of autosomal dominant type, the persistence or hyperactivity of tendon reflexes, and the more frequent concurrence of ophthalmoplegia, retinal degeneration, and optic atrophy. Several of these clinical features, particularly briskness of tendon reflexes, are alien to the classic form of Friedreich ataxia.

By 1893 Pierre Marie thought it desirable to create a new category of hereditary ataxia that would embrace all of the non-Friedreich cases. He collated the familial cases of progressive ataxia that had been described by Fraser, Nonne, Sanger Brown, and Klippel and Durante (see Greenfield and Harding for references) and proposed that all of them were examples of an entity to which he applied the name heredodystaxie cerebellilose. Marie's proposition was based almost entirely on clinical observations—not his own but those made by the aforementioned authors. Later, as members of these families died, postmortem examinations disclosed that Marie's hereditary cerebellar ataxia included not one but several disease entities. Indeed, as pointed out by Holmes (1907) and later by Greenfield, in three of the four families the cerebellum showed no significant lesions at all. Yet there was by then no doubt of a separate class of predominantly cerebellar atrophies, some purely cortical and others associated with a variety of noncerebellar lesions.

Pure Cerebellar Cortical Atrophy Holmes in 1907 described a family of 8 siblings, of whom 3 brothers and 1 sister were affected by a progressive ataxia, beginning with a reeling gait and followed by clumsiness of the hands, dysarthria, tremor of the head, and a variable nystagmus. The ataxia began insidiously in the fourth decade and progressed slowly over many years. The late cerebellar cortical atrophy of Marie, Foix, and Alajouanine, reported in 1922, is probably the same disease. In their patients also, the onset was in later life (average age 57 years). The onset was usually insidious, rarely abrupt, and the progress was extremely slow (survival 15 to 20 years). Ataxia of gait, instability of the trunk, tremor of the hands and head, and slightly slowed, hesitant speech conformed to the usual clinical picture of a progressive cerebellar ataxia. Nystagmus was rare. Intelligence was usually preserved. The paresthetic reflexes were increased in many cases, the ankle jerks were often absent, and the plantar reflexes were said to be of extensor type in some. The last finding, in the absence of hyperreflexia and spasticity, must be accepted with caution, since withdrawal responses are often mistaken for extensor reflexes. In our own practices, sporadic forms of pure cerebellar degeneration have been as common as inherited ones. The differential diagnosis in the nonfamilial cases is quite broad, as discussed at the end of this section.

Postmortem examination of the Holmes-type cases disclosed a symmetrical atrophy of the cerebellum, involving mainly the anterior lobe and vermis, the latter being more affected than the hemispheres. The Purkinje cells were absent in the lingula, centralis, and pyramidis of the superior vermis and reduced in number in the quadrangularis, flocculus, biventral, and pyramidal lobes. The other cerebellar cortical neurons and granule cells were diminished in number, but the latter less so. The white matter was slightly pale in myelin stains. The roof nuclei and pontine nuclei were normal. There was cell loss in the dorsal and medial parts of the inferior olivary nuclei. A questionable pallor was noted in the corticospinal and spinocerebellar tracts in myelin stains of the spinal cord. The vermian atrophy and that of adjacent parts of the cerebellum can be visualized with great clarity in MR images (Fig. 39-3).

The pathologic findings in the cases of Marie, Foix, and Alajouanine were essentially the same. In further reports, both familial and sporadic cases of this type have been collected. The similarity of the pathologic (and clinical) changes to those of alcoholic cerebellar degeneration is at once apparent and should always raise the question of an alcoholic-nutritional cause in sporadic cases (Chap. 41).

Cerebellar Atrophy with Prominent Brainstem Lesions

Sporadic and Familial Olivopontocerebellar Atrophy A sporadically occurring instance of a disorder closely resembling the Holmes type of cortical cerebellar degeneration but with additional features of brainstem atrophy was described in 1900 by Déjerine and André-Thomas, who named it olivopontocerebellar atrophy (OPCA). The onset of symptoms was in the fifth decade of life, and the main manifestations were ataxia—first in the legs, then in the arms and hands and the bulbar musculature—a symptomatology common to all the cerebellar atrophies. As more and more cases of this type were collected (by 1943, Rosenhagen had collected 45 from the literature, to which he added 11 of his own), a hereditary pattern (autosomal dominant) was evident in some, and one or more long tracts in the spinal cord would be found to have degenerated. About half the cases later developed the symptoms of Parkinson disease with degeneration of nigral cells and, in a few, of striatal cells as well.

Notable findings in both the sporadic (Menzel and Déjerine-Thomas types) and the familial forms of OPCA are the extensive degeneration of the middle cerebellar peduncles, the cerebellar white matter, and the pontine, olivary, and arcuate nuclei; loss of Purkinje cells has been variable (Fig. 39-4). Most likely this degeneration represents a terminal "dying back" of axons of the pontine and olivary nuclei with secondary myelin degeneration.

The boundaries of the entity of hereditary OPCA have gradually been extended; Konigsmark and Weiner subdivided them into the following types: (1) hereditary (dominant) type of Menzel; (2) hereditary (recessive) type of Ficker-Winkler; (3) hereditary (dominant) type with retinal degeneration; (4) hereditary (dominant) type of Shut-Haymaker, with spastic paraplegia and areflexia; and (5) hereditary (dominant) type with dementia, ophthalmoplegia, and extrapyramidal signs. But even this...
classification does not do justice to the variable presentations. To do this can be added two additional types: (6) inherited cases of OPCA with neuropathy and slowed eye movements (as described by Wadia) and (7) cases with dystonia and a variety of other clinical findings, most of them in single cases (hemiballismus, athetosis, contractures of the legs, fixed pupils, ophthalmoplegia, ptosis, gaze palsy, deafness, retinal degeneration, mental retardation and epilepsy, claw foot and scoliosis, incontinence, parkinsonian symptoms and signs, dementia). Even a neonatal type is known. Some are detailed further on, under "Other Complicated Hereditary Cerebellar Ataxias." Cases of sporadic olivopontocerebellar atrophy are more common and tend to occur at an older age than the familial ones, and nystagmus, optic atrophy, retinal degeneration, ophthalmoplegia, and urinary incontinence are generally not observed. However, there are numerous variants that include mild extrapyramidal and sensory signs, some of which are of Portuguese-Azorean origin. One such variant was described by Woods and Schaumburg in 1972 under the name nigrospinocerebellar degeneration with nuclear ophthalmoplegia. The disorder was characterized by an autosomal dominant pattern of inheritance and by a slowly progressive ataxia beginning in adolescence or early adult life, in association with hyperreflexia, extrapyramidal (parkinsonian) rigidity, dystonia, bulbar signs, distal motor weakness, and optic atrophy. There was no impairment of mental functions, and the authors have seen, the extrapyramidal symptoms were mainly rigidity and slowness of movement. There were no signs of corticospinal involvement. The conjunction of a Parkinson syndrome with cerebellar ataxia was reminiscent of certain cases of multiple system atrophy except for an earlier age of onset and the prominence of dystonia, apraxia, and ophthalmoplegia. Postmortem examination disclosed a degeneration of the dentate nuclei and spino cerebellar tracts and a loss of anterior horn cells and neurons of the pons, substantia nigra, and oculomotor nuclei. The heredoataxia was unaccompanied by polyneuropathy, which was an important feature of the disease in Portuguese emigrants, described earlier by Nakano and colleagues as Machado disease, this being the name of the progenitor of the afflicted family.

A similar affected Azorean family named Joseph was described by Rosenberg and colleagues (1976) under the name of autosomal dominant striatal atrophy. The disease had its onset in early adult life and was characterized by progressive ataxia of gait, followed by dystonia, nystagmus, slowness of eye movements, reduced facial mobility, slow lingual movements, fasciculations of face and tongue, dystonic postures, rigidity of the limbs, cerebellar tremor, hyperreflexia, and Babinski signs. Rosenberg and coworkers considered the disorder to be a striatonglial degeneration on the basis of their findings in one autosomal case. The choice of this designation was unfortunate, insofar as the clinical and pathologic picture was quite unlike that of the striatanglial degeneration reported by Adams and associates. The diagnosis of striatonglial degeneration was also disputed by Nielsen and by Romana, who were able to study the brain of the patient reported by Rosen n and colleagues.

Under the name Azorean disease of the nervous system, Romana and colleagues described yet another family of Portuguese-Azorean descent, many members of which were affected by a syndrome comprising a progressive ataxia of gait, parkinsonian features, limitation of conjugate gaze, fasciculations, areflexia, nystagmus, ataxic tremor, and extensor plantar responses; the pathologic changes closely resembled those described by Woods and Schaumburg. Rosenberg and coworkers compared the genetic, clinical, and pathologic features of their cases with those described in other Portuguese-Azorean families and concluded that all of them represent a single genetic entity with variable expression. This concept of the disease has been corroborated by the further observations of Rosenberg and of Fowler, who studied 20 patients with the Machado-Joseph-Azorean disease over a 10-year period.

This disease is not limited to Azoreans. Cases conforming to the above descriptions have now been observed among black, Indian, and Japanese families (Sakai et al, Yuasa et al, Bharucha et al). Cancel and colleagues have found an unstable number of CAG repeating sequences on chromosome 14 and named the disorder, which corresponds to Machado-Joseph disease, type 3 spinocerebellar ataxia (SCA 3).

There is no treatment. Early diagnosis of patients at risk is possible by the examination of ocular movements. In asymptomatic patients, Hotson and associates found dysmetric horizontal and vertical saccades similar to those in symptomatic ones. In fully developed cases, the MRI findings are characteristic—reduced width of the superior and middle cerebellar peduncles, atrophy of the front pes and temporal lobes, and smallness of the pons and globus pallidus (Murata et al).

Dentatorubropallidoluysian Atrophy (DRPLA) This is a rare familial disorder, described mostly in Japan and in small European pockets, in which symptoms of cerebellar ataxia are coupled with those of choreoathetosis and dystonia, but including, in isolated instances, myoclonus, parkinsonism, epilepsy, or dementia. Pathologically there is degeneration of the dentatorubral and pallidoluysian systems (Smith; Iizuka et al). The main diagnostic consideration when chorea is prominent is the separation of this disorder from Huntington disease (Warner et al). The gene defect in four European families has been identified as an unstable CAG trinucleotide repeat on chromosome 12 (Warner et al). As with Huntington chorea, this disease is inherited as an autosomal dominant trait and there is an inverse correlation between the age of onset and the size of the expansion repeat. Diagnosis can be confirmed by means of DNA analysis.

Dentatorubral Degeneration In 1921, Ramsay Hunt published an account of 6 patients (2 of whom were twin brothers) in whom myoclonus was combined with progressive cerebellar ataxia. The age of onset in the 4 nonfamilial cases was between 7 and 17 years, and the cerebellar ataxia followed the myoclonus by an interval of 1 to 20 years. Hunt named this disorder dysynergia cerebellaris myoclonica. In the twin brothers there were signs of Friedreich ataxia: postmortem examination revealed a degeneration of the posterior columns and spino cerebellar tracts but not of the corticospinal tracts. The only lesion in the cerebellum was an atrophy and sclerosis of the dentate nuclei with degeneration of the superior cerebellar peduncles. Louis-Bar and Van Bogaert in 1947 reported a similarly affected family. The heredoataxia was unaccompanied by signs of polyneuropathy, which was an important feature of the disease in Portuguese emigrants, described earlier by Nakano and colleagues as Machado disease, this being the name of the progenitor of the afflicted family. Earlier (1914), under the title of dysynergia cerebellaris progressiva, Hunt had drawn attention to a progressive disease in young individuals manifest by what he considered to be a pure cerebellar syndrome. One of the three patients described in this paper died 13 years after the onset of her illness, and necropsy disclosed cavitary lesions in the ventricular nuclei, cerebellum, and pons and a diffuse increase of Alzheimer (type 2) glial cells, associated with nodular cirrhosis of the liver—i.e., findings typical of progressive dentricular degeneration (Wilson disease). Hunt’s reports emphasize the hazard of classifying cerebellar ataxias on the basis of the clinical findings alone, a point made effectively by Holmes in relation to the hereditary cerebellar ataxia of Marie (see earlier).

Other Complicated Hereditary Cerebellar Ataxias In addition to the ones enumerated earlier, briefly mentioned here are the hereditary ataxias, all rare, with optic atrophy; the autosomal recessive syndrome of cerebellar ataxia with pigmentary retinal degeneration and congenital deafness; an autosomal dominant hereditary ataxia with muscular atrophy, retinal degeneration, and diabetes mellitus; Friedreich ataxia with juvenile parkinsonism; the autosomal recessive ataxia with cataracts, oligophrenia, pyramidal signs, and ataxia in 2 brothers; the autosomal recessive hearing loss and cerebellar ataxia. Details regarding these rare ataxias and appropriate references can be found in the monograph on the inherited ataxias edited by Kerk et al. Pollock and Kies have described yet another late-life form of hereditary cerebellar ataxia with near global loss of pain and temperature sensation (due to loss of primary sensory afferents).

One adult form of hereditary cerebellar ataxia is paroxysmal in nature; the episodes occur without explanation and last several hours, leaving the patient normal between episodes or with only minimal ataxia of the limbs and nystagmus (Srigue et al). It is the only cerebellar ataxia that responds to oral acetazolamide (see Chap. 5 and page 1021). Of related interest is spino cerebellar atrophy type 6, in which a mutation occurs on chromosome 19 in the gene that codes for a voltage-gated calcium channel, resulting in progressive ataxia, dystonia, and loss of proprioception. This gene is also implicated in the acetazolamide-responsive paroxysmal ataxia.

Genetics of the Heredodegenerative Ataxias Probably the many atactic disorders just described are genetically distinct. As indicated above, autosomal recessive Friedreich ataxia is due to an expanded GAA repeat on chromosome 9q (Camuzio et al). Larger GAA expansions correlate with an earlier age of onset. The diagnostic molecular test for the GAA expansion is useful for diagnosis, particularly for atypical cases with late onset (Durr et al). The rarer recessive type that is precipitated by vitamin E deficiency shows GAA repeats on chromosome 8q, which codes for a t- aco-pherol transport gene (see page 1224).

Among the autosomal dominant cerebellar ataxias of later onset, molecular-gene studies have identified mutant genes at seven chromosomal loci. Five of these eight forms of autosomal dominant ataxia are known to be caused by expanded CAG-trinucleotide repeats (SCA types 1, 3, 6, and 7 and dentatobrubro paliidoluysian atrophy, or DRPLA). However, the mechanism by which the resultant increase in glutamine components affects cell dysfunction remains speculative. Tabulated below...
are the chromosomal loci of the cerebellar atrophies and their genetic terminology and related neural abnormalities:

6p: SMA 1; ophthalmoparesis, pyramidal and extrapyramidal signs; included in this group are most of the olioivopontocerebellar atrophies

12q: SMA 2; slowed saccades

12p: Dentatorubropallidoluysian atrophy

14q: SMA 3; the Machado-Joseph phenotype with several allelic variants

16q: SMA 4; sensory neuropathy and pyramidal signs

10 centromeric: SMA 5

3p: SMA 7; retinal degeneration

19p: SMA 6; related to the alpha subunit of a voltage-dependent calcium channel; a different mutation at the same locus causes the acetazolamide-responsive episodic ataxia

In addition, several types of autosomal dominant episodic ataxia have been analyzed and found to be linked to chromosomes 12p (a potassium channel gene) and 19p (a calcium channel gene), as mentioned earlier.

**Differential Diagnosis**

Sporadic forms of cerebellar ataxia in adults are in some instances traceable to strokes involving cerebellar pathways (Safe et al). Some are alcoholic-nutritional in origin, and a few are related to abuse of drugs (especially anticonvulsants, which may in a few cases cause a permanent ataxia). The paraneoplastic variant of cerebellar degeneration enters into the differential diagnosis; as a rule it occurs mostly in women with breast or ovarian cancers and evolves much more rapidly than any of the heredodegenerative forms. The more rapid onset of ataxia and the presence of anti-Purkinje cell antibodies (anti-Yo; page 724) are central to making the distinction. From time to time one observes an idiopathic variety of subacute cerebellar degeneration, particularly in women; clinically this disorder is indistinguishable from the paraneoplastic variant except that no relationship to neoplasm can be discerned (Roopen). Rare cases of ataxia have been associated with celiac disease and Whipple disease. The ataxias caused by transmissible agents are discussed in Chap. 33, and the metabolic ataxias are discussed further in Chap. 37. Of these, late-onset GM2 gangliosidosis may simulate a cerebellar degeneration in adults (page 1021).

Treatment has been unsatisfactory and is limited to devising strategies to prevent falling. Amantadine 200 mg daily for several months has shown limited benefit in some studies (Borel et al).

**Hereditary Polymericnolus**

The syndrome of quick, arrhythmic, involuntary single or repetitive twitches of a muscle or group of muscles was described in Chap. 6, where it was pointed out that the condition has many causes. Those due to hereditary metabolic diseases are presented in Chap. 37. Familial forms are known, one of which, associated with cerebellar ataxia, was discussed earlier (dyssynergia cerebellaris myoclonica of Ramsay Hunt). But there is another disease, known as hereditary essential benign myoclonus, that occurs in relatively pure form unaccompanied by ataxia (page 108). In the latter condition, it may at times be difficult to evaluate coordination because willed movement is interrupted by the myoclonus and may be mistaken for intention tremor. Only by slowing the voluntary movement can the myoclonus be reduced or eliminated. This myoclonic disease is inherited as an autosomal dominant trait. It becomes manifest early in life; once established, it persists with little or no change in severity throughout life, often with rather little disability. It can, by its natural course, be differentiated from some of the hereditary metabolic diseases such as the Usher and Leber congenital amauroses, the M養toni syndromes, and the adrenoleukodystrophy.

**SYNDROME OF MUSCULAR WEAKNESS AND WASTING WITHOUT SENSORY CHANGES**

**Motor System Disease**

This general term is used to designate a progressive degenerative disorder of motor neurons in the spinal cord, brainstem, and motor cortex, manifest clinically by muscular weakness, atrophy, and corticospinal tract signs in varying combinations. It is a disease of middle life, for the most part, and progresses to death in a matter of 2 to 6 years or longer in exceptional cases.

Customarily, motor system disease is subdivided into several types on the basis of the particular grouping of symptoms and signs. The most frequent form, in which amyotrophy and hyperreflexia are combined, is called amyotrophic lateral sclerosis, or ALS (amyotrophy is the term applied to denervation atrophy and weakness of muscles). Less frequent are cases in which weakness and wasting occur alone, without evidence of corticospinal tract dysfunction; for these the term progressive spinal muscular atrophy is used. When the weakness and wasting predominate in muscles innervated by the motor nuclei of the lower brainstem (i.e., muscles of the jaw, face, tongue, pharynx, and larynx), it is customary to speak of progressive bulbar palsy (bulb being the old name for the medulla oblongata). In a small proportion of patients the clinical state is dominated for a time by spastic weakness, hyperreflexia, and Babinski signs, lower motor neuron affection becoming apparent at a later stage of the illness. Primary lateral sclerosis designates a rare form of motor system disease in which the degenerative process remains confined to the corticospinal pathways (Ppringle et al). The present authors believe that the pure spastic paraplegias without amyotrophy represent a special class of disease, hence they are described separately. There is also a relatively common familial form of spastic paraplegia in which the disease process may be confined to the corticospinal tracts or, in some cases, combined with posterior column or other neurologic signs.

Special types of spinal muscular atrophy are particularly frequent in infancy and childhood. Indeed, they are the leading cause of heritable infant mortality and, after cystic fibrosis, the most frequent form of serious autosomal recessive disease (Pearn). The best known is the Werndig-Hoffmann type of infantile spinal muscular atrophy (SMA type I); but there are other familial forms beginning in later childhood, adolescence, or adult life (SMA types II and III, or the Wohlfart-Kugelberg-Welander type). Despite the clinical heterogeneity of the heritable childhood spinal muscular atrophies, they all map to a single locus on chromosome 5q—i.e., they are genetically homogeneous (Gililam et al; Hohnitzwitz et al). This group of early-onset spinal muscular atrophies is genetically distinct from familial ALS, in which linkage analysis has identified a gene defect on chromosome 21 (Siddique et al). In respect to the more common nonfamilial forms, there is no reason to believe that the subgroups are anything other than variants of a single pathologic process—namely an upper and lower motor neuron degeneration or atrophy of unknown etiology.

**History**

Credit for the original delineation of amyotrophic lateral sclerosis is appropriately given to Charcot. With Joffry in 1869 and Gombault in 1871, he studied the pathologic aspects of the disease. In a series of lectures given from 1872 to 1874, he gave a lucid account of the clinical and pathologic findings. Although called Charcot’s disease, amyotrophic lateral sclerosis (the term recommended by Charcot) has been preferred in the English-speaking world. Duchenne had earlier (1858) described labioglossolaryngeal paralysis, a term that Wachsmuth in 1864 changed to progressive bulbar palsy. In 1869 Charcot called attention to the nuclear origin of progressive bulbar palsy, and in 1882 Déjerine established its relationship to amyotrophic lateral sclerosis. Most authors credit Aran and Duchenne with the discovery of the disease, although some believe the description by Charcot was the first.
Pathologic studies have identified a relatively stereotyped pattern of reduced numbers of Betz cells in the frontal and prefrontal motor cortex, indicative of a general loss of function in the motor system. This finding, combined with the observation of degeneration in the associated structures, suggests an important diagnostic criterion of the disease is progression for 3 years without evidence of lower motor neuron dysfunction. A rare type of progressive bulbar palsy is characterized by signs of corticospinal tract disease—such as delayed or diminished reflexes and reduced strength—but these signs develop over a longer period of time, typically more than 1 year. The disease may progress slowly, and the patient may develop symptoms characteristic of motor neuron disease, including weakness and atrophy of the proximal muscles, fasciculations, and hyperreflexia. In some cases, the disease may be familial, with autosomal dominant inheritance. The presence of a paraproteinemia, specifically IgM with antibodies against the GM1 ganglioside, is another feature that may be present in some cases.

Other Patterns of Evolution In addition to the specializations discussed further on, there are numerous patterns of neumuroskeletal involvement other than the one just described. A leg may be affected before the hands. A foot drop with weakness and wasting of the preterminal muscles may be incorrectly attributed to peroneal nerve compression until weakness of the gastrocnemius and other muscles betrays a more widespread involvement of lumbosacral nerves. In our experience this clinical amyotrophy is nearly as frequent as the brachial-manual type. Another variant is the early involvement of thoracic, abdominal, or posterior neck muscles, the last being one of the main causes of head falling in older individuals. Yet another pattern is of early diaphragmatic weakness; such cases come to attention because of the course of proximal limb or shoulder girdle amyotrophy with onset at an early age is also well known and simulates muscular dystrophy (Wohlfart-Kugele-Welander disease—page 1161). On several occasions we have observed a pattern involving the arm and leg on the same side, first with spasticity and then with some degree of amyotrophy; this is sometimes called the hemiplegic, or Mills, variant. More often this condition turns out to be due to multiple sclerosis. The first manifestations may be a spastic weakness of the legs; a diagnosis of primary lateral sclerosis may be made (discussed further on), and only after a year or two do the hand and arm muscles weaken, waste, and fasciculate. It is a case of this type that led to the inclusion of spastic paraparesis as a variant of ALS. Early signs of weakness and wasting of the foot may also be the exclusive symptoms for years or two. From time to time, as the disease advances, very mild distal sensory loss is observed in the feet without explanation, but perioral and gingival evoked potentials, as noted below; if the sensory loss is definite and an early feature, the diagnosis must remain in doubt. Rarely in North America, ALS has been observed in conjunction with a frontotemporal dementia and with Parkinson disease (page 1126), a complex similar to that observed among the natives of Guam.

The course of this illness, irrespective of its particular mode of onset and pattern of evolution, is inexorably progressive. Half the patients succumb within 3 years of onset and 90 percent within 6 years (Mulder et al). The variants of motor neuron disease that occur with regularly and have distinguishing clinical features are described below.

**Progressive Muscular Atrophy** This type of motor system disease is more common in men than in women, in a ratio of 3.6:1 (Chio et al). In about half the patients, progressive muscular atrophy (PMA) takes the form of a symmetrical (sometimes asymmetrical) wasting of intrinsic hand muscles, slowly advancing to the more proximal parts of the arms; less often, the legs and thighs are the sites of onset of atypical weakness; less often still, the proximal parts of the limbs are affected before the distal parts. These purely nuclear amyotrophies tend to progress at a slower pace than the usual case of ALS, some patients surviving for 15 years or longer. Chio and colleagues, who analyzed the factors affecting life expectancy in 155 patients with PMA, found that younger patients had a more benign course—the 5-year survival was 72 percent in patients with PMA before age 50 and 50 percent in patients with onset after age 50. Some of the most chronic variables of PMA are that the patients are typically dexterous and that they differ from ALS only in that the tendon reflexes are diminished or absent and there are no fasciculations or muscle cramps. Fasciculations and cramping are variably present. The main disease to be distinguished from PMA is the rare immune-mediated motor neuropathy that occurs with or without multifocal block of electrical conduction (page 1411). The presence of a paraproteinemia, specifically IgM with antibodies against the GM1 ganglioside, the findings of focal conduction block or sensory nerve abnormalities on the EMG implies the presence of an immune neuropathic disease rather than one of the motor neuron type.

**Progressive Bulbar Palsy** Here reference is made to a condition in which the first and dominant symptoms relate to weakness of muscles innervated by the motor nuclei of the lower brainstem, i.e., muscles of the jaw, face, tongue, pharynx, and larynx. This weakness gives rise to an early defect in articulation, in which there is difficulty in the pronunciation of lingual (r, l, f), labial (b, m, p, f), dental (d, t, l), and palatal (k, x) consonants. As the condition worsens, syllables lose their clarity and run together until finally speech becomes unintelligible. In other patients, slurring is due to spasticity of the tongue, pharyngeal, and laryngeal muscles or to a combination of atrophic and spastic weakness, as indicated below. Defective modulation of the voice with variable degrees of rasping and nasality is another characteristic feature; hoarseness is rarely noted. The reflex is lost, and the palatal and tympanic muscles of speech are abnormal. Fasciculations and muscle cramps also become evident; the bulbus of food cannot be manipulated and may lodge between the cheek and teeth; and the pharyngeal muscles do not force it properly into the esophagus. Liquids and small particles of food find their way into the trachea or the nose. The facial muscles, particularly of the lower face, weaken and sag. Fasciculations are evident on the surface of the tongue and occasionally on the skin of the face and neck. The chin may also quiver from fascicular twitches, but diagnosis of the disease should not be made on the basis of fasciculations alone, i.e., in the absence of weakness or atrophy. Fasciculations in themselves may be entirely benign or a part of the syndrome of myokymia or of “continuous muscular activity” (page 1568).

The jaw jerk may be present or exaggerated at a time when the musculature of mastication are markedly weak. In fact, spasticity of the jaw muscles may be so pronounced that the slightest tap on the chin will evoke clonus and blinking; rarely, attempts to open the mouth elicit a “bulldog” reflex (jaws snap shut involuntarily). Spastic weakness of the oropharyngeal muscles may be the initial manifestation of bulbar palsy and may at times surpass signs of atrophic weakness; pseudobulbar signs (pathologic laughter and crying) may reach extreme degrees. This is the only common clinical situation in which spas tic and atrophic bulbar palsy coexist. Strangely, the ocular muscles always escape.

As with other forms of motor system disease, the course of bulbar palsy is inexorably progressive. Eventually the weakness spreads to the respiratory muscles and deglutition fails entirely; the patient dies of aspiration pneumonia, usually within 2 to 3 years of onset. About 25 percent of cases of motor neuron disease develop with bulbar symptoms, but rarely if ever does the sporadic form of progressive bulbar palsy run its course as an independent syndrome (pure heredofamilial forms of progressive bulbar palsy in the adult are known but are rare). Practically always, after a few months, the other manifestations of ALS become evident. In general, the earlier the onset of the bulbar involvement in the course of ALS, the shorter the course of the disease.

**Primary Lateral Sclerosis** This entity, like ALS, is a form of motor neuron disease, although we consider it to be a separate process. Virtually all patients in whom the signs of corticospinal tract degeneration betray the presence of ALS will develop indications of lower motor neuron disease within 1 year, usually earlier. Those who remain with restricted bilateral signs of upper motor neuron disease often turn out to have multiple sclerosis, a slow compression of the spinal cord by spondylosis or neumuroskeletal compression. The presence of a paraproteinemia, specifically IgM with antibodies against the GM1 ganglioside, or the finding of focal conduction block or sensory nerve abnormalities on the EMG implies the presence of an immune neuropathic disease rather than one of the motor neuron type.
condition is often mistaken for Wohlfart-Kugelberg-Welander disease or ALS. A number of cases of this type have been uncovered in Ashkenazi Jews by the use of infantile as Tay-Sachs disease (quite obscure. We favor the explanation that atrophy of anterior horn cells with aging brings to light a critically depleted motor neuron population (see further on).

Some patients who have recovered from paralytic poliomyelitis may develop progressive muscular weakness 30 or 40 years later; the nature of this relationship is restricted amyotrophy, only the vocal cords became paralyzed over a period of years in adult life; only later were the hands affected.

As mentioned earlier, a major consideration is the differentiation of progressive muscular atrophy from chronic motor polyneuropathy with or without multifocal polymyositis. This may suggest the pseudobulbar palsy of lacunar disease. A crural form of progressive muscular atrophy may be confused with diabetic polyradiculopathy or polymyositis, muscular dystrophy, and especially the inherited familial (Betz cells in the motor cortex; this is evident as frontal lobe atrophy on the MRI in primary lateral sclerosis, but it is not a prominent finding in most cases of ALS (Kiernan and Hudson). Other fibers in the ventral and lateral funiculi are depleted, imparting a characteristic pallor in myelin stains. Some pathologists have interpreted this as evidence of involvement of nonmotor neurons and hence object to the term motor system disease. However, we regard this condition as due to a loss of collateral motor neurons that contribute to the larnia propria. One observes the same effect in severe, long-standing poliomyelitis.

Neuropathologic studies of cases of ALS with dementia are few in number. In addition to the usual affection of motor neurons, these cases have shown an extensive neuronal loss, gliosis, and vacuolization involving the premotor area, particularly the superior frontal gyrus and the inferolateral cortex of the temporal lobes. The histologic changes of Alzheimer or Pick disease have not been seen in our cases; neurofibrillary degeneration has been observed but is inconsequential in comparison to that seen in the Guamanian Parkinson-dementia-ALS complex (Finlayson et al; Mitsuyama). Attempts to transmit this ALS dementia syndrome to subhuman primates have been unsuccessful.

Pathology The principal finding in ALS is a loss of nerve cells in the anterior horns of the spinal cord and motor nuclei of the lower brainstem. Large neurons tend to be affected before small ones. Lost cells are replaced by fibrous astrocytes. Many of the surviving nerve cells are small, shrunken, and filled with lipofuscin. Occasionally, an ill-defined cytoplasmatic inclusion body is seen. According to some reports, swelling of the proximal axon is an early finding, presumably antedating visible changes in the cell body itself. The anterior roots are thin, and there is a disproportionate loss of large myelinated fibers in motor nerves (Bradley et al). The muscles show typical denervation atrophy of different ages. Whitehouse and coworkers found a depletion of muscarinic, cholinergic, glycnergic, and benzodiazepine receptors in regions of the spinal cord where motor neurons had disappeared.

The corticospinal tract degeneration is most evident in the lower parts of the spinal cord, but it can be traced up through the brainstem to the posterior limb of the internal capsule and corona radiata by means of fat stains, which show the macrophages that accumulate in response to the myelin degeneration. There is a loss of Betz cells in the motor cortex; this is evident as frontal lobe atrophy on the MRI in primary lateral sclerosis, but it is not a prominent finding in most cases of ALS (Kiernan and Hudson). Other fibers in the ventral and lateral funiculi are depleted, imparting a characteristic pallor in myelin stains. Some pathologists have interpreted this as evidence of involvement of nonmotor neurons and hence object to the term motor system disease. However, we regard this condition as due to a loss of collateral motor neurons that contribute to the larnia propria. One observes the same effect in severe, long-standing poliomyelitis.

Neuropathologic studies of cases of ALS with dementia are few in number. In addition to the usual affection of motor neurons, these cases have shown an extensive neuronal loss, gliosis, and vacuolization involving the premotor area, particularly the superior frontal gyrus and the inferolateral cortex of the temporal lobes. The histologic changes of Alzheimer or Pick disease have not been seen in our cases; neurofibrillary degeneration has been observed but is inconsequential in comparison to that seen in the Guamanian Parkinson-dementia-ALS complex (Finlayson et al; Mitsuyama). Attempts to transmit this ALS dementia syndrome to subhuman primates have been unsuccessful.

Diagnosis Motor system disease may be simulated by a central spondylotic bar or ruptured cervical disc, but with these latter conditions there is usually pain in the neck and shoulders, limitation of neck movements, and sensory changes; the lower motor neuron affection is restricted to one or two spinal segments. Electrophysiology is helpful if not decisive in differentiating these disorders, as indicated above. Already mentioned in the diagnosis of ALS is the finding of active denervation in three limbs and in paraspinal, facial, and tongue muscles. A mild hemiparesis or monoparesis due to multiple sclerosis may for a time be difficult to distinguish from early ALS. Progressive spinal muscular atrophy may be differentiated from peroneal muscular atrophy (Charcot-Marie-Tooth neuropathy) by the lack of family history, the complete lack of sensory change, and different EMG patterns. Motor system disease beginning in the proximal limb muscles may be misdiagnosed as a limb-girdle type of muscular dystrophy. The main considerations in relation to progressive bulbar palsy are myasthenia gravis and, less often, polymyositis, muscular dystrophy, and especially the inherited (Kennedy) type of bulbospinal atrophy, which is discussed further on. The spastic form of bulbar palsy may suggest the pseudobulbar palsy of lacunar disease. A crural form of progressive muscular atrophy may be confused with diabetic polyradiculopathy or polymyositis.

As mentioned earlier, a major consideration is the differentiation of progressive muscular atrophy from chronic motor polyneuropathy with or without multifocal conduction block and related disorders, in which there is an idiopathic motor axonopathy. These distinctions are made by careful, extensive conduction studies and needle EMG examinations (Chap. 46), they are discussed with the peripheral neuropathies (Chap. 46). There is also a rare form of subacute poliomyelitis (possibly viral) in patients with lymphoma or carcinoma; it leads to an amyotrophy that progresses to death over a period of several months.

Over the years, the authors have occasionally encountered a patient with a localized amyotrophy of the leg or arm that became arrested and did not advance over a decade or two. Several reports of such a partial spinal amyotrophy have appeared in recent years (Kolodny and Raghavan); they are discussed with the peripheral neuropathies (Chap. 46). There is also a rare form of subacute poliomyelitis (possibly viral) in patients with lymphoma or carcinoma; it leads to an amyotrophy that progresses to death over a period of several months.

Some patients who have recovered from paralytic poliomyelitis may develop progressive muscular weakness 30 or 40 years later; the nature of this relationship is quite obscure. We favor the explanation that atrophy of anterior horn cells with aging brings to light a critically depleted motor neuron population (see further on).

An observation of interest is the finding of a form of progressive spinal muscular atrophy in patients with GM1 gangliosidosis, the storage disease that presents in infancy as Tay-Sachs disease (Koldny and Raghavan). The onset is in late adolescence and early adult life and the atrophic paralysis is progressive, so that this condition is often mistaken for Wohlfart-Kugelberg-Welander disease or ALS. A number of cases of this type have been uncovered in Ashkenazi Jews by the use of lysosomal enzyme analysis.
Pathogenesis
The pathogenesis of sporadic motor system disease is not known. Of considerable interest has been the discovery of a mutant gene that codes for the enzyme Cu-Zn superoxide dismutase (SOD) in some familial cases of ALS (Rosen et al) and of an abnormality of the gene for a subunit of the neurofilament protein in other cases (Simpson et al). More recessive and rare recessive forms have been described (Siddique et al, 1996). The former is reflected in a 20 to 50 percent reduction in SOD enzyme activity in affected patients and has led to speculation that an excess of free radicals attributable to the enzyme deficiency allows a slow destruction of neurons. This explanation is probably an oversimplification. An enhancement of excitotoxic glutamatergic activity due to the SOD defect has been proposed as an alternative explanation and is supported by a putative response to treatment with certain glutamate blockers (see further on). Whether these enzymatic and biochemical abnormalities extend to the sporadic type of ALS is unknown, but this approach is providing the most provocative avenues for research.

Trauma, particularly traction injury of an arm, has been reported from time to time as an antecedent event in patients with ALS, but a causative relationship has not been established. Younger and coworkers have reported a higher incidence of paraproteinemia in patients with motor system disease than can be accounted for by chance. Many other examples of disordered immune function have been described in patients with motor system disease, but a coherent explanation of ALS as an autoimmune disease has not emerged. It has never been proved that intoxication with heavy metals (lead, mercury, aluminum) can cause motor system disease. Rare instances of PMA and ALS have been described in patients who had suffered a remote attack of poliomyelitis; these probably represent chance occurrences. There is little evidence that such cases represent a reactivation of the virus or the presence of some other infectious agent. The progressive weakness that occurs some 30 to 40 years after recovery from polio should not be confused with PMA, as indicated above.

Treatment
There is no specific treatment for any of the motor neuron diseases; only supportive measures can be utilized. It has been our practice to give the patient some idea of the seriousness of the condition but not to make the devastating statement that it is invariably fatal. Usually it is advisable to give medication of some type “to try to slow the progression of the disease,” even though none is known to be definitely effective. Guanidine hydrochloride and injections of cobra venin, gangliosides, interferons, high-dose intravenous cyclophosphamide, and thyrotropin-releasing hormone are but some of a long list of agents that have been tried to arrest the process, but these claims either have been discredited or remain uncorroborated. Benson and colleagues have reported that the antioxidant agent riulzole appears to slow the progression of ALS and improve survival in patients with disease of bulbar onset, but add, at best, only 3 months to life expectancy. This claim requires confirmation but is supported by the slight beneficial effects of niulzole and gabapentin, another glutamate inhibitor, on a model of the familial disease in which a mutant superoxide dismutase has been produced in mice.

In the early stages of ALS, physical therapy is useful in maintaining mobility, but overwork of the muscles generally leads to fatigue and cramps. In the early stages of respiratory failure, nasally applied positive pressure is helpful in assisting sleeping and avoiding daytime somnolence in patients who are able to tolerate the device. Food should be cut into small pieces and dry foods, such as toast, avoided; milk shakes may be tolerated best. A mechanized bed and structural accommodations in the home that facilitate entry of a wheelchair and use of the bath or shower as well as thick-handled utensils make life easier for the patient. The treatment of spasticity, the main concern in primary lateral sclerosis and occasionally a source of difficulty in ALS, is discussed on page 1155.

Complex and sometimes unresolvable decisions must be made by the patient regarding the level of treatment desired as the disease progresses. When the time is appropriate and the patient is receptive or—as often happens with the availability of information on the Internet—the patient raises these issues, we broach the subject of tracheostomy, respiratory support, and feeding tubes and reassure the patient that under no circumstances will he be allowed to suffocate or suffer physical pain in any way. In a survey of 460 of our colleagues, a surprisingly small number of patients with ALS chose to have a tracheostomy or gastrostomy, and their views early in the illness tended to hold true later. Free access to the neurologist and, if desired by the patient, regular visits for advice can be very reassuring to the patient and family. Hospice-type care is often needed in the last weeks of illness in patients who can otherwise be cared for at home, and morphine or similar drugs as well as anxiolytic agents should be used liberally to ease discomfort, respiratory distress, and anxiety in the final days.

Heredofamilial Forms of Progressive Muscular Atrophy and Spastic Paraplegia

Infantile Spinal Muscular Atrophy (Werdnig-Hoffmann Disease)
This is the classic form of spinal muscular atrophy of hereditary type. It was first described by Werdin in 1891 and 1894, by Hoffman in 1893, and, at about the same time, by Thomsen and Bruce. The cases described by these authors all involved infants. Further clinical analyses, however, indicated the inadequacy of this narrow grouping. Brandt, in his study of 112 Danish patients, found that in about one-third the weakness was present at birth, and in 97 the onset was in the first year of life; in 9 patients, the disease was not recognized until after the first year of life. Of the patients with early-onset disease, 53 had died by the end of the first year, but 8 of those with a later onset survived for 4 to 10 years. In 1956 Walton, and later Wofhaf and colleagues and Kügelberg and Weisland (see below), identified milder forms of spinal muscular atrophy in which the onset was between 2 and 17 years and walking was still possible in adult life. Byers and Banker, in a study of 52 patients, subdivided them into three groups on the basis of age of onset; in one group the disease was recognized at birth or in the first month or two of life; in a second, between 6 and 12 months; and in a third, after the first year. Again, in their last group, it was not unusual for the patient to survive into adolescence and adult life. In a few of the late-onset types, signs of corticospinal tract involvement are conjoined, and Bonduella has also included some patients with areflexia, pes cavus, Babinski signs, choreiform movements, and mental retardation in this group. More recently, the designations SMA I, II, and III have been introduced, based largely on the age of onset (Table 39-1).

Familial spinal muscular atrophy that begins in infancy and childhood is inherited mainly as an autosomal recessive trait. Autosomal dominant and rarer recessive forms have been described (Siddique et al, 1995). Both dominant and rarer recessive forms have been described (Siddique et al, 1996). Several different mutations have been found in the gene at what has been termed the “survival of motor neuron” (SMN) site. Although the gene product is not known, it has been proposed that the amount of this product may determine the severity of disease. Affected siblings demonstrate very similar clinical patterns of disease, but the same gene error gives rise to very different phenotypes in different families, so that modifying nongenetic attributes must be playing a role.

Finally, it should be reiterated that clinical disorders more or less similar to the spinal muscular atrophies may occur occasionally in certain hereditary metabolic disorders. Other experts have described a patient who began experiencing weakness at 9 years of age, cramps, and progressive deterioration; adolescence in what proved to be a variant of hexosaminidase A (GM1) deficiency, and biopsy of rectal mucosa showed nerve cells with the typical membranous cytolytic bodies of Tay-Sachs disease. Others have reported similar cases. A progressive motor neuron or motor nerve disorder has also been observed in glycogen storage disease affecting anterior horn cells. Motor nerve fibers also suffer damage in metachromatic and globoid body leukopheralathies, and, as mentioned, this may occur in adults, in association with paraproteinemia and multiple myeloma and as a paraneoplastic process.

Clinical Manifestations (Early-Onset Classic Type; SMA II) The most frequent form of these spinal muscular atrophies, the severe infantile type, is a common disease, occurring once in every 20,000 live births. After cystic fibrosis, it is the most common cause of death from a recessively inherited disease. Characteristically the infant, usually born normally, is noted from birth to be unnaturally weak and limp (“floppy”). Some mothers report that fetal movement in utero had been less than expected or lacking altogether. In severe cases, arthrogryposis at ankles and wrists or dislocation of the hips is noted at birth (page 1530). The muscle weakness in

Familial spinal muscular atrophy that begins in infancy and childhood is inherited mainly as an autosomal recessive trait. Autosomal dominant and X-linked patterns of inheritance have been described (Siddique et al, 1995). Both dominant and rarer recessive forms have been described (Siddique et al, 1996). Several different mutations have been found in the gene at what has been termed the “survival of motor neuron” (SMN) site. Although the gene product is not known, it has been proposed that the amount of this product may determine the severity of disease. Affected siblings demonstrate very similar clinical patterns of disease, but the same gene error gives rise to very different phenotypes in different families, so that modifying nongenetic attributes must be playing a role.

Finally, it should be reiterated that clinical disorders more or less similar to the spinal muscular atrophies may occur occasionally in certain hereditary metabolic disorders. Other experts have described a patient who began experiencing weakness at 9 years of age, cramps, and progressive deterioration; adolescence in what proved to be a variant of hexosaminidase A (GM1) deficiency, and biopsy of rectal mucosa showed nerve cells with the typical membranous cytolytic bodies of Tay-Sachs disease. Others have reported similar cases. A progressive motor neuron or motor nerve disorder has also been observed in glycogen storage disease affecting anterior horn cells. Motor nerve fibers also suffer damage in metachromatic and globoid body leukopheralathies, and, as mentioned, this may occur in adults, in association with paraproteinemia and multiple myeloma and as a paraneoplastic process.
these children is generalized from the beginning, and death comes early, usually within the first year. Other infants seem to develop normally for several months before the weakness becomes apparent. In these, the trunk, pelvic, and shoulder-girdle muscles are at first disproportionately affected, while the fingers and hands, toes and feet, and cranial muscles retain their mobility. Hypotonia accompanies the weakness, and since passive displacement of articulated parts in testing muscle tone is easier to judge than power of contraction at this early age, it may be singled out as the dominant clinical characteristic. As a rule the tendon reflexes are unobtainable. Volume of the neonate is diminished but is difficult to be certain to sit and creep and even to walk with support; these with later onset may survive for several years and even into adolescence or early adult life, as already mentioned.

Laboratory data of confirmatory value are few. Muscle enzymes in the serum are usually normal, rarely elevated. The EMG, if performed at a late enough stage of development, displays fibrillations, probably the most characteristic finding of the disorder. Motor unit potentials are diminished in number and, in the more slowly evolving cases, some are larger than normal (giant or polyphasic potentials reflecting reinnervation). Motor nerve conduction velocities are normal or fall in the low-normal range (these are normally slower in infants than in adults). Early electrophysiologic studies may also give ambiguous results.

**Pathologic Findings** Muscle biopsy after 1 month of age reveals a typical picture of group atrophy; shortly after birth this change is difficult to discern. Aside from denervatory atrophy, the essential abnormalities are in the anterior horn cells in the spinal cord and the motor nuclei in the lower brainstem. Nerve cells are greatly reduced in number, and many of the remaining ones are in varying stages of degeneration; a few are chromatolytic and contain cytoplasmic inclusions. It is not unusual for some of the former to become able to sit and creep even to walk with support; those with later onset may survive for several years and even into adolescence or early adult life, as already mentioned.

**Diff erential Diagnosis** The major problem in diagnosis is to distinguish Werdnig-Hoffmann disease from an array of other diseases that cause hypotonia and delayed motor development in the neonate and infant. Certain myopathies (as described in Chap. 52), the glycogenoses, and disorders of fatty acid metabolism frequently present in this way. The preservation of tendon reflexes and relative lack of progression of muscle weakness distinguish these latter disorders. The muscle biopsy, if studied properly, usually yields the correct diagnosis. Because of the gravity of the diagnosis, muscle biopsy should be performed if there is any suspicion of spinal muscular atrophy. If studied properly, the biopsy usually yields the correct diagnosis.

Certain forms of muscular dystrophy, notably myotonic dystrophy, which is about twice as frequent as Werdnig-Hoffmann disease, may become manifest in the neonatal period and interfere with sucking and motor development (Chap. 52). As a rule, the weakness is not as severe or diffuse as that in Werdnig-Hoffmann disease. Also, a number of polyneuropathies may cause a serious degree of weakness in early childhood. Unfortunately, in respect to the latter, adequate sensory testing is not possible because of the patients' age, but the CSF protein is often elevated. Again, diagnosis is greatly facilitated by nerve-muscle biopsy and measurement of nerve conduction velocities. The latter are reduced but must be interpreted with caution because of incomplete development of axons and of myelination in the first months of life. The needle EMG examination shows subtle signs of denervation that cannot be easily distinguished from the finding in the spinal muscular atrophy. Muscle examinations of parents and siblings may disclose a clinically apparent neuropathy. Polyomyositis of childhood may also simulate both muscular dystrophy and motor neuron disease (page 1482).

Mental retardation with a flaccid rather than spastic weakness of the limbs is another major category of disease that must be distinguished. Also, certain of the poliomyelonecephalopathies and leukodystrophies may weaken muscles and abolish tendon reflexes, but usually there is evidence of cerebral involvement. The same may be said of the Down syndrome, cretinism, and achondrodysplasia. Finally, very sick children with celiac disease, cystic fibrosis, and other chronic diseases may be hypotonic to the point of simulating neuromuscular disease. Usually speech is not delayed and tendon reflexes are preserved in these purely medical states, and strength returns as the medical problem is corrected.

There remains, after the assiduous study of the "floppy infant," a group of cases of hypotonia and motor underdevelopment that cannot be classified. The term amyotonia congenita (Oppenheim) was once applied to all of this group but is now obsolete. Walton devised the term benign congenital hypotonia to designate patients who manifest opossum and floppy limbs in infancy and a delay in sitting up and walking and who improve gradually, some completely and others incompletely. Neither of these terms serves the purpose of precise diagnosis, and so they should be abandoned. It is likely that among this group there are other examples of congenital myopathy that await differentiation by application of modern histochernical, ultrastructural, and genetic techniques.
Progressive Bulbar Palsy (Fazio-Londe Syndrome) Fazio in 1892 and Londe in 1893 described the development of a progressive bulbar palsy in children, adolescents, and young adults. There is progressive paralysis of the facial, lingual, pharyngeal, laryngeal, and sometimes ocular muscles. The illness usually presents with dysarthria, dysphagia, dysphonia, and dyspnoea, which first become increasingly pronounced until the time of death some years after onset. In a few patients there is a late development of corticospinal signs and sometimes ocular palsies. Also jaw and oculomotor weakness appears occasionally, and in one case there was progressive deafness. The disease is rare, only 24 well-described examples having been recorded in the medical literature by 1992 (McShane et al). Inheritance may be autosomal dominant, as in Fazio’s original case, and rarely X-linked, but it is more likely to be autosomal recessive. Pathologically the hypoglossal, facial, and trigeminal motor nuclei. In a few cases, the nerve cells in the ocular motor nuclei were also diminished. This disease, the few times we have encountered it, had to be differentiated from myasthenia gravis, a pontomedullary glioma, and brainstem multiple sclerosis.

Hereditary Spastic Paraplegia with Diplegia (Strümpell-Lorrain Disease) This disease was described by Seeligmuller in 1874 and later by Strümpell in Germany and Lorrain in France; it has now been identified in nearly every part of the world. The pattern of inheritance is usually autosomal dominant, less often recessive (one family has shown X-linked inheritance), and the onset may be at any age from childhood to the senium. Harding divided the disease into two groups, the more common one beginning before age 35 with a late onset (40 to 50 years); the former type often shows sensory loss, urinary symptoms, and kinetic tremor. The clinical picture is that of a gradual development of spastic weakness of the legs with increasing difficulty in walking. In the tendon reflexes are hyperactive and the plantar reflexes extensor. In the pure form of the disease, sensory and other nervous functions are entirely intact. If the onset is in childhood, as many cases are, a common orthopedic problem arises of arched and shortened feet and there is a shortening (pseudoscotoma) of calf muscles, forcing the child or adolescent to “be-walk.” In children, the legs appear to be underdeveloped, and they are rather thin in both children and adults. Sometimes the knees are slightly flexed; at other times the legs are fully extended (gruov recurvatum) and adducted. Weakness is variable and difficult to estimate. Sphincteric function is usually retained. Subtle sensory loss in the feet has been reported. The arms are variably involved. In some patients, the arms appear to be spared even though the legs are not. Some authors are more lenient. In others, the hands are stiff, movements are clumsy, and speech is mildly dysarthric. Conjoined findings such as nystagmus, ocular palsies, optic atrophy, pigmentary macular degeneration, ataxia (both cerebellar and sensory), sensorimotor polyneuropathy, ichthyosis, patchy skin pigmentation, epilepsy, and dementia have all been described in isolated families (see further on).

The few available pathologic studies have shown that, in addition to degeneration of the corticospinal tracts throughout the spinal cord, there is thinning of the columns of Goll, mainly in the lumbosacral regions, and of the spino cerebellar tracts, even when no sensory abnormalities had been detected during life. These were the pathologic findings described by Strümpell in his original (1880) report of two brothers with spastic paraplegia; one of them, in addition, had a cerebellar syndrome but again there were no sensory abnormalities. A reduction in the number of Betz and anterior horn cells has also been reported.

Inheritance and Pathogenesis Several genetic mutations have given rise to this disease. The uncomplicated autosomal dominant variety has been linked so far to chromosomes 2p, 8q, 14q, and 15q, the 2q variety being most frequent and most often associated with dementia; the recessive variety has been linked to 8p, 15q (the most frequent), and 16p. This very probable type occurs in the family with a variety of the congenital ocular motor neuron disease (Grady-Lange disease); the true frequency of thinning of the corpus callosum, and 16q callosum. As is true with many similar genetic diseases, the common variety associated with a mutation on 2p shows great variability in clinical presentation within and among families, as has been pointed out by Nielsen and colleagues. Rare X-linked types have been associated with two sites on the long arm of the chromosome, one of which is an allelic variant of the Pelizaeus-Merzbacher disease (see the above). In only a few of these kindred have the genes responsible for disease been identified. A protein called paraplegin, a metalloprotease of the mitochondrial inner membrane, has been related to the 16q mutation. A defect in oxidative phosphorylation has been demonstrated in these patients and in theory is related to the abnormal gene product. The genetics of the hereditary spastic paraplegias has recently been reviewed by Figlewicz and Bird.

Differential Diagnosis In this disorder, one must always consider an incipient spinal cord or foramen magnum tumor, cervical spondylosis, multiple sclerosis (this was the clinical diagnosis in Strümpell’s original cases), Chiari malformation, compression of the cord by a variety of congenital bony malformations at the cranio cervical junction, and a number of chronic myelitides—Lyme disease, lupus erythematosus, sarcoidosis, acquired immune deficiency syndrome (AIDS), adrenomyeloneuropathy, primary lateral sclerosis (described earlier in this chapter), and tropical spastic paraparesis.

Variants of Familial Spastic Paraplegia The neurologic literature contains a large number of descriptions of familial spastic paraplegia combined with other neurologic abnormalities. Some of the syndromes had developed early in life, in conjunction with moderate degrees of mental retardation. Nevertheless the rest of the neurologic picture appeared many years after birth and was progressive. Some idea of the number of these “hereditary paraplegia-plus” syndromes and the diverse combinations in which they may present is conveyed in the recent review by Gout and colleagues. Again, it is hardly possible to describe each of these symptoms in any degree of detail. The following list includes the best-known entities. But if the term hereditary spastic paraplegia is to have any neurologic significance, it should be applied only to the relatively rare, pure form of the progressive syndrome. The common “atypical” cases—with amyotrophy, cerebellar ataxia, tremors, dystonia, atrophy, retinal degeneration, amenorrhea, and dementia—should be put in separate categories and their identity retained for nosologic purposes until such time as some biochemical and genetic data related to pathogenesis are forthcoming. Separable also are all the congenital nonprogressive types of spastic diplegia and ataxia. The following list includes the best-known entities:

1. Hereditary spastic paraplegia with spinocerebellar and ocular symptoms (Ferguson-Critchley syndrome). This syndrome is characterized by a disorder of gaze, optic atrophy, cerebellar ataxia, and spastic paraparesis. Most impressive are the manifestations of spinocerebellar ataxia beginning during the fourth and fifth decades of life accompanied by weakness of the legs, alterations of mood, pathologic crying and laughing, dysarthria and dysphagia, dysesthesis of limbs, and cortical signs of dementia including the athetosis of the face and tongue. Sensation is diminished in the upper limbs. The whole picture resembles that of a hereditary spastic diplegia of the adult type.

2. Hereditary spastic paraplegia with extrapyramidal signs. Action and static tremors, parkinsonian rigidity, dystonic tongue movement, and attheros of the limbs have all been found in combination with spastic paraplegia. Gilman and Romana have reviewed the literature on this subject. The picture of parkinsonism with spastic weakness and other cortical signs has been the most frequent combination, in the authors’ experience.

3. Hereditary spastic paraplegia with optic atrophy. This is known as Behn syndrome or optic atrophy—ataxia syndrome, since cerebellar signs are usually concurrent. Members of one large family reported by Bruyn and West also had attheros. The syndrome is transmitted as an autosomal recessive trait, with onset in infancy and slow progression.

4. Hereditary spastic paraplegia with macrocephaly with mental retardation (Kilenn syndrome). Spastic paraplegia with macrocephaly, ophthalmoplegia, and central retinal degeneration constitutes the syndrome described in 1969 by Kilenn. While the mental retardation is stationary, the spastic weakness and retinal changes are of late onset and progressive. When ophthalmoplegia is added, it is called the Barnard-Traboul syndrome.

5. Hereditary spastic paraplegia with mental retardation or dementia. Many of the children with progressive spastic paraplegia either have been mentally retarded since early life or have appeared to regress mentally as other neurologic symptoms developed. Examples of this syndrome and its variants are too numerous to be reviewed here but are contained in the review of Gilman and Romana. The cerebral atrophy of Gilman and Romana, with the onset in infancy of spastic weakness of the legs in association with mental retardation, stands somewhat apart because of the associated ichthyosis.

6. Hereditary spastic paraplegia with polyneuropathy. We have observed several patients in whom a sensorimotor polyneuropathy was combined with unmistakable signs of corticospinal disease. The age of onset was in childhood or adolescence, and the disability progressed to the point where the patient was chair-bound by early adult life. In two of the cases, a sural nerve biopsy revealed a typical hypotrophic polyneuropathy; in a third case there was only a depletion of large myelinated fibers. The syndrome resembles the myeloneuropathy of adrenoleukodystrophy.

7. Spastic paraparesis with distal muscle wasting (Broyer syndrome). This disorder is transmitted as an autosomal recessive trait. Onset is in childhood with amyotrophy of the hands, followed by spasticity and contractures of the lower limbs. Cerebellar signs (mild), attheros, and deafness may be added.

SYNDROME OF PROGRESSIVE BLINDNESS

There are two main classes of progressive blindness in children, adolescents, and adults: progressive optic neuropathy and retinal (pigmentary or tapetoretinal) degeneration. Of course there are many congenital anomalies and retinal diseases beginning in infancy that result in blindness and microphthalmia. Some of those of neurologic interest were already described briefly in connection with the hereditary spastic paraplegias and in Chapter 13.

Hereditary Optic Atrophy of Leber Although familial amaurosis was described in the early eighteenth century, it was Leber in 1871 who gave the definitive description of this disease and traced it through many generations. The family studies of Nikoskeinian and coworkers indicate that all daughters of carrier mothers become carriers themselves, a type of transmission that is determined by inheritance of defective mitochondrial DNA from the mother (Wallace et al). In an extensive review of Leber hereditary optic
atrophy by the National Hospital group in London, some of the clinical variations are described. Common to all their cases was the presence of a pathogenic mitochondrial DNA abnormality (Riordan-Eva et al), but this may occur at one of several sites (page 1140). Thus, Leber optic atrophy has been added to the growing list of mitochondrial diseases, which, as a group, are discussed in detail in Chap. 37.

In most patients, the visual loss begins between 18 and 22 years, but the range of age of onset is much broader. Usually the visual loss has an insidious onset and a subacute evolution, but it may evolve rapidly, so as to suggest a retrobulbar neuritis; moreover, in these latter instances, aching in the eye or brow may accompany the visual loss. Subjective visual phenomena are reported by some. Usually both eyes are affected simultaneously, though in some one eye is affected first, followed by the other after an interval of several weeks or months. In practically all cases, the second eye is affected within a year of the first. In the unimpaired eye, abnormalities of visual evoked potentials may precede impairment of visual acuity (Carroll and Mastaglia).

Once started, the visual loss progresses over a period of weeks to months. Characteristically, central vision is affected before peripheral, and there is a stage in which bilateral central scotomata are readily demonstrated. Early on, perception of blue-yellow is deficient, while that of red and green is relatively preserved. In the more advanced stages, however, the patients are totally color-blind. Constriction of the fields may be added later. At first there may be swelling and hyperemia of the discs, but soon they become atrophic. Peripapillary vasculopathy, consisting of tortuosity and arteriovenous shunting, is the primary structural change, and this has been present also in asymptomatic offspring of carrier females.

As visual symptoms develop, fluorescein angiography shows shunting in the abnormal vascular bed, with reduced filling of the capillaries of the papillomacular bundle. Although patients are left with dense central scotomata, it is of some importance that the visual impairment is seldom complete; in some patients, relative stabilization of visual function occurs. In a few, there may be a surprising improvement.

Examination of the optic nerve lesion shows the central parts of the nerves to be degenerated from papillae to the lateral geniculate bodies, i.e., the papillomacular bundle are particularly affected. Presumably axis cylinders and myelin degenerate together, as would be expected from the loss of nerve cells in the superficial layer of the retina. Both astrocytic glial and endoneurial fibroblastic connective tissue are increased.

Congenital optic atrophy (of which recessive and dominant forms are known), retrobulbar neuritis, and nutritional optic neuropathies are the main considerations in differential diagnosis.

**Retinitis Pigmentosa**

This remarkable retinal abiotrophy, known since Helmholtz first invented the ophthalmoscope in 1851, usually begins in childhood and adolescence. Unlike the optic atrophy of Leber, which affects only the third neuron of the visual neuronal chain, retinitis pigmentosa affects only the retinal layers, both the neuroepithelium and pigment epithelium (see Fig. 13-1). For this combination, Leber proposed the term tapetoretinal degeneration, thinking it preferable to retinitis pigmentosa, since there is no evidence of inflammation. The incidence of this disorder is two or three times greater in males than in females. Inheritance is more often autosomal recessive than dominant; in the former, consanguinity plays an important part, increasing the likelihood of the disease by approximately 20 times. Sex-linked types are also known. It is estimated that 100,000 Americans are afflicted with this disease.

One form of retinitis pigmentosa is linked to chromosome 3, where the gene for the photosensitive rod-cell protein opsin (which, in combination with vitamin A, forms rhodopsin) is located. When light strikes rhodopsin in the normal eye, the opsin releases vitamin A, and this initiates the sequence of changes that activate the rods. As a consequence of the gene abnormality, the quantity of opsin and rhodopsin in retinitis pigmentosa is reduced; one amino acid building block (proline) in the protein is substituted by histidine (Dryja et al).

The first symptom is usually an impairment of twilight vision (nystagmatism). Under dim light, the visual fields tend to constrict; but slowly, as the disease progresses, there is permanent visual impairment in all degrees of illumination. The perimacular zones tend to be the first and most severely involved, giving rise to partial or complete ring scotomata. Peripheral loss sets in later. Usually both eyes are affected simultaneously, but cases are on record where one eye was affected first and more severely. Color vision is lost relatively late. The electrical activity of the retina (measured by the electroretinogram) is extinguished, in contrast to the Leber type of optic atrophy, in which it is retained.

Ophthalmoscopic examination shows the characteristic triad of pigmentary deposits that assume the configuration of bone corpuscles, attenuated vessels, and pailor of the optic discs. The pigment is due to clumping of epithelial cells that migrate from the pigment layer to the superficial parts of the retina as the rod cells degenerate. The pigmentary change spares only the cones, so that eventually the world is perceived by the patient as though he were looking through narrow tubes.

Syndromes to which retinitis pigmentosa may be linked are oligophrenia, obesity, syndactyly, and hypogonadism (Bardet-Biedl syndrome); hypogonitality, obesity, and mental deficiency (Laurence-Moon syndrome); Friedreich and other types of spinocerebellar and cerebellar ataxia; spastic paraplegia and quadriplegia with Laurence-Moon syndrome; neurogenic amyotrophy, myopia, and color blindness; polyneuropathy and deafness (Refsum disease); deaf mutism; Cockayne syndrome and Bassen-Kornzweig disease; and several mitochondrial diseases—particularly progressive external ophthalmoplegia and Kearns-Sayre syndromes.

Differential diagnosis includes the Batten form of cereboretinal degeneration, Pelizaeus-Merzbacher disease, and Gaucher disease as well as the various forms of celiac lipofuscinosis and retinal infections such as syphilis, toxoplasmosis, and cytomegalic inclusion disease.

Virtual blindness is the outcome in many cases, but in others the visual failure stops short of that. It is doubtful whether any of the many proposed modes of therapy (sympathectomy, steroids, vitamins A and E) have any effect in halting the progress of the disease.

**Stargardt Disease**

This is a bilaterally symmetrical, slowly progressive macular degeneration, differentiated from retinitis pigmentosa by Stargardt in 1909. In essence it is a hereditary (usually autosomal recessive) tapetoretinal degeneration or dystrophy (the latter term being preferred by Waardenburg), with onset between 6 and 20 years, rarely later, and leading to a loss of central vision. The macular region becomes gray or yellow-brown with pigmentary spots, and the visual fields show central scotomata. Later the periphery of the retina may become dystrophic. The lesion is well visualized by fluorescein angiography, which discloses a virtually pathognomonic “dark choroid” pattern. Activity in the electroretinogram is diminished or abolished. Both dominantly inherited Stargardt disease and the closely related cone-rod dystrophy have been linked to a defect on chromosome 6p in some families and 13q in others; the less common recessive variety has been mapped to 1p. In the former type, the protein is substituted by histidine (Dryja et al).

**SYNDROME OF PROGRESSIVE DEAFNESS** (See pages 296–299)

There is an impressive group of hereditary, progressive cochleovestibular atrophies that are linked to atrophies and degenerations of the nerve system. These are the subject of an informative review by Konigsmark. Such neuro-otologic syndromes must be set alongside a group of five diseases that affect the auditory and vestibular components exclusively: dominant progressive nerve deafness; dominant, low-frequency hearing loss; senile-linked dysacusis; early-onset neural deafness; and hereditary episodic vertigo and hearing loss. The last of these is of special interest to neurologists because both balance and vestibular nerves exclusively: dominant progressive nerve deafness; dominant, low-frequency hearing loss; dominant midfrequency hearing loss; sex-linked, late onset, neural deafness; and several mitochondrial diseases—particularly progressive external ophthalmoplegia and Kearns-Sayre syndromes.

It should be pointed out that in 70 percent of cases of hereditary deafness, there are no other somatic or neurologic abnormalities. To date, three separate autosomal mutations have been identified that are associated with this pure “nonsyndromic” type of hereditary deafness. In one such family from Costa Rica, the gene codes for protein that regulates the polymerization of actin, the major cytoskeletal component of the hair cells of the inner ear (see review by Pennesi). More recently, a number of mitochondrial disorders have been associated with deafness alone as well as with a number of the better-characterized mitochondrial syndromes (see Chap. 37). The age of onset of hearing loss in the pure forms has been variable, extending well into adulthood.
Hereditary Hearing Loss with Retinal Diseases

Konigsmark has separated this overall category into three subgroups: patients with typical retinitis pigmentosa, those with Leber optic atrophy, and those with other retinal changes.

With respect to retinitis pigmentosa, four syndromes are recognized. Retinitis pigmentosa in combination with congenital hearing loss is referred to as the Usher syndrome. Retinitis pigmentosa and hereditary hearing loss may also be combined with polyneuropathy (Refsum syndrome); with hypogonadism and obesity (Alstrom syndrome); and with dwarfism, mental retardation, premature senility, and photosensitive dermatitis (Cockayne syndrome).

Hereditary hearing loss with optic atrophy forms the core of four syndromes: dominant optic atrophy, ataxia, muscle wasting, and progressive hearing loss (Sylvester disease); recessive optic atrophy, polyneuropathy, and neural hearing loss (Rosenberg-Chutorian syndrome); optic atrophy, hearing loss, and juvenile diabetes mellitus (Tunbridge-Paley syndrome); and optocochleodeantegrate degeneration with optic atrophy, hearing loss, quadriaparesis, and mental retardation (Nysse−van Bogaert syndrome).

Hearing loss has also been observed with other retinal changes, two of which might be mentioned: Norrie disease, with retinal malformation, hearing loss, and mental retardation (oculoacousticoocerebral degeneration), and Small disease, with recessive hearing loss, mental retardation, narrowing of retinal vessels, and muscle atrophy. In the former, the infant is born blind, with a white vascularized retinal mass behind a clear lens; later the lens and cornea become opaque. The eyes are small and the iris is atrophied. In the latter, the optic fundi show tortuosity of vessels, telangiectases, and retinal detachment. The nature of the progressive generalized muscular weakness has not been ascertained.

Hereditary Hearing Loss with Diseases of the Nervous System

There are several conditions in which hereditary deafness accompanies degenerative disease of the peripheral or central nervous system. Those associated with mitochondrial encephalopathies have already been mentioned. The other main ones with autosomal inheritance include the following:

1. Hereditary hearing loss with epilepsy. The seizure disorder is mainly one of myoclonus. In one dominantly inherited form, photomyoclonus is associated with mental deterioration, hearing loss, and nephropathy (Herrmann disease). In May-White disease, also inherited as an autosomal dominant trait, myoclonus and ataxia accompany hearing loss. Congenital deafness and mild chronic epilepsy of recessive type have also been observed (Latham-Monro disease).

2. Hereditary hearing loss and ataxia. Here Konigsmark was able to delineate five syndromes, the first two of which show a dominant pattern of heredity, the last three a recessive pattern: plebalidism, ataxia, and neural hearing loss (Teller syndrome); hearing loss, hyperuricemia, and ataxia (Rosenberg-Bergstrom syndrome); ataxia and progressive hearing loss (Lichtenstein-Knorr syndrome); ataxia, hypogonadism, mental deficiency, and hearing loss (Richards-Rundlies syndrome); ataxia, mental retardation, hearing loss, and pigmentary changes in the skin (Jeune-Tommasi syndrome).

3. Hereditary hearing loss and other neurologic syndromes. These include dominantly inherited sensory radial neuropathy (Denny-Brown); progressive polyneuropathy, hyphocosiosis, skin atrophy, eye defects (myopia, cataracts, atypical retinitis pigmentosa), bone cysts, and osteoporosis (Flynn-Aird syndrome); chronic polyneuropathy and nephritis (Lemieux-Neemeh syndrome); congenital pain asymbolia and auditory imperception (Osuntokun syndrome); and bulboptoline paralysis (facial weakness, dystharia, dysphagia, and atrophy of the tongue with fasciculations) with progressive neural hearing loss. The onset of the last syndrome occurs at 10 to 35 years of age; the pattern of inheritance is autosomal recessive. The disease progresses to death. It resembles the progressive hereditary bulbar paralysis of Fazio-Londe except for the progressive deafness and loss of vestibular responses. Regrettably, in most of these syndromes, there are no data regarding labyrinthine function.

The details of these many syndromes are contained in Konigsmark’s review. The syndromes are listed in Table 15-1 and have been summarized here in order to increase awareness of the large number of hereditary neurologic diseases for which the clue is provided by the detection of impaired hearing and labyrinthine function.

CHAPTER REFERENCES

The acquired metabolic disorders of the nervous system are classified according to their most common modes of clinical expression. Not included are the diseases due to nutritional deficiencies and those due to exogenous drugs and toxins, which can be considered metabolic in the broad sense; these are presented in the following chapters.

An important segment of neurologic medicine, and one that is seen with great frequency in general hospitals, consists of disorders in which a global disturbance of cerebral function (encephalopathy) results from failure of some other organ system—heart and circulation, lungs and respiration, kidneys, liver, pancreas, and the endocrine glands. Unlike the diseases considered in Chapter 37, in which a genetic abnormality affects many organs and tissues, including the brain, the cerebral disorders discussed in this chapter are strictly secondary to derangements of the visceral organs themselves. They stand at the interface of internal medicine and neurology.

Relationships of this type, between an acquired disease of some thoracic or abdominal organ and the brain, have rather interesting implications. In the first place, recognition of the neurologic syndrome may be a disease to the diagnosis of the systemic disease; indeed, the neurologic symptoms may be more informative and significant than the symptoms referable to the organ primarily involved. Moreover, these encephalopathies are often reversible if the systemic dysfunction is brought under control. Neurologists must therefore have an understanding of the underlying medical disorder, for this may provide the means of controlling the neurologic part of the disease. In other words, the therapy for what appears to be a neurologic disease lies squarely in the field of internal medicine—a clear reason why every neurologist should be well trained in internal medicine. Of more theoretical importance, the investigation of the acquired metabolic diseases provides new insights into the chemistry and pathology of the brain. To select a single example, the discovery of an episodic encephalopathy that is associated with advanced liver disease and portocaval shunts opened a vast new area in brain chemistry, pertaining to the effect of ammonia on glutamine metabolism, and has brought to light an intriguing histopathologic change—a relatively pure hyperplasia of protoplasmic astrocytes. Each visceral disease affects the brain in a somewhat different way, and since the pathogenic mechanism is not completely understood in any of them, the study of these metabolic diseases promises rich rewards to the scientist.

In Table 40-1 the acquired metabolic diseases of the nervous system are classified according to their most common modes of clinical expression. Not included are the diseases due to nutritional deficiencies and those due to exogenous drugs and toxins, which can be considered metabolic in the broad sense; these are presented in the following chapters.

Table 40-1 Classification of the acquired metabolic disorders of the nervous system

**METABOLIC DISEASES PRESENTING AS A SYNDROME OF CONFUSION, STUPOR, OR COMA**

The syndrome of impaired consciousness, its general features, the terms used to describe it, and the mechanisms involved in its genesis are discussed in Chap. 17, which serves as an introduction to this section. There it is pointed out that metabolic disturbances are frequent causes of impaired consciousness and that their presence must always be considered when there are no focal signs of cerebral disease and both the imaging studies and the cerebrospinal fluid (CSF) are normal. Intoxication with alcohol and other drugs figures prominently in the differential diagnosis. The main features of the reversible metabolic encephalopathies are mental confusion, typified by disorientation and inattentiveness and accompanied in certain instances by asterixis, tremor, and myoclonus, usually without signs of focal cerebral disease such as hemiparesis, hemianopia, hemianesthesias, or a disorder of the cranial nerves. This state may progress in stages to one of stupor and coma.

Slowing of the background rhythms in the electroencephalogram (EEG) reflects the severity of the metabolic disturbance. With few exceptions, usually pertaining to cerebral edema, imaging studies are normal.

Laboratory examinations are highly informative in the investigation of the acquired metabolic diseases. In every patient with symptoms suggestive of a metabolic encephalopathy, the following determinations should be made: serum Na, K, Ca, glucose, BUN, NH₃, and osmolality. If there is evidence of hypoxia or the patient is known to have chronic obstructive airway disease, determination of arterial pH, PₐO₂, and PₐCO₂ are carried out as well. Serum osmolality can be measured directly or calculated from the values of Na (in meq/L), K (in meq/L), glucose (in mg/dL), and BUN (in mg/dL), using the following formula:

\[
\text{Serum osmolality} = 2([\text{Na}] - [\text{K}]) + \frac{\text{glucose}}{18} + \frac{\text{BUN}}{3}
\]

When there is a discrepancy between the calculated and the directly measured osmolalities, it can be assumed that additional circulating ions are present. Most often they are derived from an exogenous toxin or drug such as mannitol, but renal failure, ketonemia, and an increase of serum lactate may also result in the accumulation...
of small molecules that contribute to the serum osmolality.

Where an exogenox toxin is suspected of causing an encephalopathy and in all cases where the cause is unknown, a "toxic screen" of blood and urine, using high-pressure liquid chromatography, should be obtained. A point to be remembered is that the brain may be damaged, even to an irreparable degree, by a disturbance of blood chemistry (e.g., hypoglycemia, hypoxia) that is no longer present when the patient is first seen.

Ischemic-Hypoxic Encephalopathy

Here the basic disorder is a lack of oxygen to the brain, the result of failure of the heart and circulation or of the lungs and respiration. Often both are responsible and one cannot say which predominates; hence the ambiguous allusion in clinical records to "cardiorespiratory failure."

Ischemic-hypoxic encephalopathy in various forms and degrees of severity is one of the most frequent and disastrous cerebral accidents encountered in the emergency department and recovery rooms of every general hospital. The medical conditions that most often lead to it are (1) myocardial infarction or ventricular arrhythmia, external or internal hemorrhage, and septic or traumatic shock—in all of which cardiac function fails before that of respiration; (2) suffocation from drowning, strangulation, aspiration of vomitus, food, or blood, compression of the trachea by a mass or hemorrhage, or tracheal obstruction by a foreign body; (3) carbon monoxide (CO) poisoning, in which respiration fails first and then the cardiovascular system; (4) diseases that paralyze the respiratory muscles (Guillain-Barré syndrome, amyotrophic lateral sclerosis, myasthenia gravis, and the CNS diffusely, but the medulla specifically, again with respiratory failure being the initial factor, followed by cardiac failure; and (5) a general anesthesia accident during which the patient is exposed to inspired gas that is oxygen-deficient.

The terms anoxic, anemic, and stagnant, introduced by Barcroft to designate the various forms of anoxia, are now little used in clinical medicine, since the ultimate effect of all three is the same—namely, to deprive the brain and other organs of their critical oxygen supply.

The oxygen content of the blood is the product of hemoglobin concentration and the oxygen saturation of the hemoglobin molecule. At normal temperature and pH, hemoglobin is 90 percent saturated at an oxygen partial pressure of 60 mmHg and still 75 percent saturated at 40 mmHg, i.e., the oxygen saturation curve is not linear.

Reduced to the simplest formulation, a deficient supply of oxygen to the brain is due either to a failure of cerebral perfusion (ischemia) or to a reduced amount of circulating arterial oxygen, the result of diminished oxygen saturation or insufficiency of hemoglobin. The neurologic effects of these two are subtly different.

Physiology of Ischemic and Hypoxic Damage

Physiologic mechanisms of a homeostatic nature protect the brain under conditions of both ischemia and hypoxia. When the cerebral blood flow is reduced, there is a compensatory dilatation of resistance vessels, which maintains blood flow at a constant rate (autoregulation). When the cerebral blood pressure falls below 60 to 70 mmHg, increased oxygen extraction still allows normal energy metabolism to continue. In total ischemia, the tissue is depleted of its sources of energy in about 5 min, although longer periods are tolerated under conditions of barbiturate coma and hypothermia. Energy failure due to hypoxia is counteracted by an autoregulatory increase in cerebral blood flow; at a P O2 of 25 mmHg, the increase is approximately 400 percent. A similar increase in flow occurs with a decrease in hemoglobin to 20 percent of normal, but here a decrease in viscosity also facilitates the circulatory response.

Ischemic injury from systemic hypotension differs from that due to pure anoxia. In ischemia, the main damage takes the form of incomplete infarctions in the border zones between major cerebral territories. With anoxia, necrosis in parts of the hippocampus and deep folia of the cerebellum are particularly vulnerable. With more severe degrees of either ischemia or hypoxia, there is first selective damage to certain layers of cortical neurons, and later, generalized damage of all the cerebral cortex, deep nuclei, and cerebellum. Nuclei of the brainstem are relatively resistant to anoxia and hypotension and stop functioning only after the cortex has been badly damaged.

In most of the clinical situations in which the brain is deprived of adequate oxygen, there is a combination of ischemia and hypoxia, but one or the other usually predominates. The cellular pathophysiology of neuronal and tissue damage in cerebral and cerebellar cortices and pallidum under conditions of ischemia is discussed in Chap. 34. Essentially, the mechanism in hypoxic-ischemic injury is an arrest of all aerobic metabolic processes necessary to sustain the Krebs (tricarboxylic acid) cycle and the electron transport system. The neurons, if completely deprived of their source of energy, proceed to catabolize themselves in an attempt to maintain their activity, and in so doing are damaged to a degree that does not permit their survival, i.e., they undergo necrosis. The accumulation of catabolic products (particularly lactic acid) in the interstitial tissue contributes to the parenchymal damage. Also, there is some experimental evidence that excitatory neurotransmitters, particularly glutamate, contribute to the rapid development of brainstem lesions after conditions of anoxia and ischemia (Choi and Rothman); how this pertains to clinical situations is uncertain. Ultimately, massive calcium influx through a number of different membrane channels is thought to participate in the process of cerebral destruction.

There is also a phenomenon of delayed neurologic deterioration after anoxia that is not understood but may be due to the blockage or exhaustion of some enzymatic process during the period when brain metabolism is restored or even increased (as it is in hyperthermia or possibly with seizures or increased motor activity).

Clinical Features of Anoxic Encephalopathy

Mild degrees of hypoxia without loss of consciousness induce only inattention, poor judgment, and motor incoordination. In our experience there have been no lasting clinical effects in such cases, though Hornebin and colleagues found, on psychologic testing, a slight decline in visual and verbal long-term memory and mild aphasic errors in Himalayan mountaineers who had ascended to altitudes of 18,000 to 29,000 ft. These observations make the point that profound anoxia may be well tolerated if it is arrested at an early stage. We have seen several patients with advanced pulmonary disease who were fully awake when their arterial oxygen pressure was in the range of 30 mmHg. This level, if it occurs abruptly, causes coma. An important clinical rule is that degrees of hypoxia that at no time abolish consciousness rarely if ever cause permanent damage to the nervous system.

In the circumstances of severe global ischemia with prolonged loss of consciousness, the clinical effects can be quite variable. With cardiac arrest, for example, consciousness is lost within seconds, but recovery will be complete if breathing, oxygenation of blood, and cardiac action are restored within 3 to 5 min. Beyond 5 min there is usually permanent injury. As shown in experimental models, one of the reasons for the irreversibility of the lesion is swelling of the endothelium and blockage of circulation into the ischemic cerebral tissues (nore-flavor phenomenon; Ames et al). Clinically, however, it is difficult to judge the precise degree of hypoxia, since slight hypoxia or an imperceptible blood pressure may have served to maintain the circulation to some extent. Hence some individuals have made an excellent recovery after cerebral hypoxia that allegedly lasted 8 to 10 min or longer. Normal body temperatures, as might occur when the body is immersed in ice-cold water, greatly prolong the tolerable period of hypoxia. Generally speaking, anoxic patients who demonstrate intact brainstem function (as indicated by normal pupillary light and ciliospinal responses, "doll's-head" eye movements, and oculovestibular reflexes) have a more favorable outlook for recovery of consciousness and perhaps all of their abilities. Conversely, absence of these brainstem reflexes, even after circulation and oxygenation have been restored, particularly fixed pupils to light, implies a grave outlook in most circumstances, as elaborated further on.

Most patients who have suffered severe but lesser degrees of hypoxia will have stabilized their breathing and cardiac activity by the time they are first examined; yet recovery will be complete if breathing, oxygenation of blood, and cardiac action are restored within 3 to 5 min. Beyond 5 min there is usually permanent injury. As shown in experimental models, one of the reasons for the irreversibility of the lesion is swelling of the endothelium and blockage of circulation into the ischemic cerebral tissues (nore-flavor phenomenon; Ames et al). Clinically, however, it is difficult to judge the precise degree of hypoxia, since slight hypoxia or an imperceptible blood pressure may have served to maintain the circulation to some extent. Hence some individuals have made an excellent recovery after cerebral hypoxia that allegedly lasted 8 to 10 min or longer. Normal body temperatures, as might occur when the body is immersed in ice-cold water, greatly prolong the tolerable period of hypoxia. Generally speaking, anoxic patients who demonstrate intact brainstem function (as indicated by normal pupillary light and ciliospinal responses, "doll's-head" eye movements, and oculovestibular reflexes) have a more favorable outlook for recovery of consciousness and perhaps all of their abilities. Conversely, absence of these brainstem reflexes, even after circulation and oxygenation have been restored, particularly fixed pupils to light, implies a grave outlook in most circumstances, as elaborated further on.

Most patients who have suffered severe but lesser degrees of hypoxia will have stabilized their breathing and cardiac activity by the time they are first examined; yet they may be profoundly comatose, with the eyes slightly divergent and motionless but with reactive pupils, the limbs inert and flaccid or intensely rigid, and the tendon reflexes diminished. Within a few minutes after cardiac action and breathing have been restored, generalized convulsions and also isolated or grouped myoclonic seizures may be seen. The seizures, if severe and recurrent, double or treble the oxygen need of cerebral tissues. If the damage is severe, coma persists, decerebrate postures may be present or may occur in response to painful stimuli, and bilateral Babinski signs can be evoked. In the first 24 to 48 h, death may terminate this state in a setting of rising temperature, deepening coma, and circulatory collapse. Tragically, however, the individual may survive for an indefinite period in a state that is variously referred to as cortical death, irreversible coma, or persistent vegetative state (see Chap. 17).

With this severe degree of injury, the cerebral and cerebellar cortices and parts of the thalamus are partly or completely destroyed but most often brainstem-spinocerebellar structures survive. Some patients remain mute, unresponsive, and unaware of their environment for weeks, months, or years. Long survival is usually attended by some degree of improvement, but the patient appears to know nothing of his present situation and to have lost all past memories, power of reasoning, and capacity for meaningful social interaction and continued existence. One has only to observe such patients and their families to appreciate the gravity of the problem, the heartache, and the tremendous expense of medical care. The only person who does not appear to suffer is the patient.

With lesser degrees of anoxic-ischemic injury, the patient improves after a period of coma. Some of these patients quickly pass through this acute posthypoxic phase and proceed to make a full recovery; others are left with varying degrees of permanent disability.
Brain Death Syndrome (See also Chap. 17). This represents the most severe degree of oxygen lack, usually caused by circulatory arrest (ischemic anoxia), and is manifest by a state of complete unawareness and unresponsiveness with abolition of all brainstem reflexes. Natural respiration cannot be sustained; only cardiac action and blood pressure are maintained. No electrical activity is seen in the EEG (it is isoelectric). This is the brain death syndrome (see page 371). At autopsy one finds that most if not all the gray matter of cerebral, cerebellar, and brainstem structures, and in some instances even of the spinal cord, has been severely damaged.

One must exercise caution in concluding that a patient has irreversible brain damage, because anesthesia, intoxication with certain drugs, and hypothermia may also cause deep coma and an isoelectric EEG but permit recovery. Therefore it is advisable to repeat the clinical and laboratory tests after an interval of a day or two, during which time the results of toxic screening also become available. Such cases have been brought increasingly to public attention because of ethical and moral issues pertaining to discontinuation of medical therapy. The authors' experience corroborates the general notion that the vital functions of patients with the brain death syndrome usually cannot be sustained for more than several days; in other words, the problem settles itself. In exceptional cases, however, the provision of adequate fluid, vasopressor, and respiratory support will preserve the somatic organism in a comatose state for longer periods.

Posthypoxic Neurologic Syndromes The permanent neurologic sequelae or posthypoxic syndromes observed most frequently are (1) persistent coma or stupor, described above, and, with lesser degrees of cerebral injury, (2) dementia with or without extrapyramidal signs, (3) extrapyramidal (parkinsonian) syndrome with cognitive impairment (discussed in relation to CO poisoning), (4) choreoathetosis, (5) cerebellar ataxia, (6) intention or action myoclonus, and (7) a Korsakoff amnesic state. If ischemic hypoperfusion dominates, the patient may also display the manifestations of watershed infarctions, situated between the end territories of the major cerebral vessels, the main syndromes being (8) visual agnosias and "cortical blindness" and (9) proximal arm and shoulder weakness, sometimes accompanied by hip weakness (referred to as a "man in the barrel syndrome"). Seizures may or may not continue to be a problem. These sequelae rarely occur in pure form; usually they overlap in various combinations, although any one of them may predominate.

Delayed Postanoxic Encephalopathy This is a relatively uncommon and unexplained phenomenon. Initial improvement, which appears to be complete, is followed after a variable period of time (1 to 4 weeks in most instances) by a relapse, characterized by apathy, confusion, irritability, and occasionally agitation or mania. Most patients survive this second episode, but some of them are left with serious mental and motor disturbances (Choi; Plum et al.). In still other cases there appears to be progression of the initial neurologic syndrome, with additional weakness, shuffling gait, diffuse rigidity and spasticity, spastic incontinence, coma, and death after 1 to 2 weeks. Exceptionally, there is yet another chronic syndrome in which an episode of hypoxia is followed by slow deterioration, which progresses for weeks to months until the patient is mute, rigid, and helpless. In such cases the basal ganglia are affected more than the cerebral cortex and white matter (Booij and Richardson).

Prognosis of Hypoxic-Ischemic Brain Injury Several logistic models have been developed to predict the outcome of anoxic-ischemic coma. All of them utilize certain simple criteria, involving loss of motor, verbal, and pupillary functions in various combinations. The most often cited and extensive such study, by Levy and colleagues, based on 150 patients who remained in coma for at least 6 h after cardiac arrest, has provided the following guidelines. Mortality from this state is high: 20 percent on the first day and 64 percent at the end of 1 week. Most patients destined to recover awaken within a brief period of time; thus, 17 percent of their patients who recovered were conscious by 3 days, and by 2 weeks the number of conscious patients had risen only by 2 percent. At the other extreme were 31 percent of patients who appeared to be in the vegetative state at 1 day; of this group, 70 percent survived for 1 week, and only 3 patients in all recovered.

Once intubation is excluded, the presence of fixed dilated pupils and paralysis of eye movement for 24 to 48 h, along with absence of motor responses to painful stimuli, signify irreversible cerebral damage. We have never observed deep coma of this type lasting 5 days or more to be attended by full recovery. The question of what to do with such cases of protracted coma is a problem for a patient or his family, and not a medical problem. The most that can be expected of the neurologist is to state the level and degree of brain damage, its cause, and the prognosis based on his own and published experience. One prudently avoids heroic, lifesaving therapeutic measures once the nature of this state has been determined with certainty.

Treatment of Hypoxic-Ischemic Encephalopathy Treatment is directed mainly to the prevention of an initial critical degree of hypoxic injury. After a clear airway is secured, the use of cardiopulmonary resuscitation, a cardiac defibrillator, or pacemaker has its place, and every second counts in their prompt utilization. Once cardiac and pulmonary function are restored, there is experimental evidence that reducing cerebral metabolic requirements by hypothermia and by barbiturates or glutamate-blocking medication may prevent the delayed worsening referred to above. However, attempts to demonstrate any of these beneficial effects by controlled trials have failed. Vasodilator drugs and calcium channel blockers are also of no proven benefit. Oxygen may be of value during the first hours but is probably of little use after the blood becomes well oxygenated. Corticosteroids theoretically help to aly airway (possibly cellular) swelling, but again their therapeutic benefit has not been corroborated by clinical trials or practice.

Seizures should be controlled by the methods indicated in Chap. 16. If they are severe, continuous, and unresponsive to the usual anticonvulsant drugs, controlled respiration, continuous infusion of a drug such as midazolam, and eventually neuromuscular blocking agents may have to be used. Often the seizures cease after a few hours and are replaced by polymyoclonus. For the latter, clonazepam, 8 to 12 mg daily in divided doses, may be useful, but the commonly used anticonvulsants have little effect in our experience. This state of spontaneous and stimulus-sensitive myoclonus as well as persistent limb posturing usually presages a poor outcome. The delayed movement-induced myoclonus and ataxic tremor that appear after the patient awakens, described by Lance and Adams, is a special issue that is discussed on page 110. Its treatment requires the use of multiple medications.

Carbon Monoxide Poisoning

Strictly speaking, carbon monoxide (CO) is an exogenox toxin, but it is considered here because it produces a special type of anoxia and one that is frequently associated with delayed neurologic deterioration. The extreme affinity of CO for hemoglobin (over 200 times that of oxygen) drastically reduces the oxygen content of blood and the subject to prolonged hypoxia and acidosis. Cardiac toxicity and hypotension generally follow. Whether CO also has a direct toxic action on neuronal components is not settled. The effects on the brain appear to be similar those caused by cardiac arrest. Neurologists are likely to encounter instances of CO poisoning in burn units and in patients who have attempted suicide or have been exposed accidentally to a faulty furnace or to car exhaust in a closed garage.

Early symptoms include headache, nausea, dyspnea, confusion, dizziness, and clumsiness. These occur when the carboxyhemoglobin level reaches 20 to 30 percent. Exposure to relatively low levels of CO from faulty furnaces and gas engines should be suspected as the cause of recurrent headaches and confusion that clear upon hospitalization or other change of venue. A cherry-red color of the skin may appear but is actually an infrequent finding; cyanosis is more common. At slightly higher levels of carboxyhemoglobin, blindness, visual field defects, and papilledema develop, and levels of 50 to 60 percent are associated with coma, decerebrate or decorticate posturing, seizures in a few patients, and generalized slowing of the EEG rhythms. CT scanning is normal or shows mild cerebral edema, or, if hypotension has been profound, the same types of border-zone infarctions that are seen after cardiac arrest.

Delayed neurologic deterioration 1 to 3 weeks (sometimes much longer) after CO exposure occurs more frequently with CO poisoning than with other forms of cerebral hypoxia. In Choi's survey, this feature was observed in 3 percent of 2360 cases of CO poisoning and in 12 percent of those ill enough to be admitted to a hospital. Extrapyramidal features (parkinsonian gait and bradykinesia) predominated. Three-quarters of such patients were said to recover within a year. Discrete lesions centered in the globus pallidus bilaterally and sometimes the inner portion of the putamina are characteristic of CO poisoning that had produced coma (Fig. 40-1), but similar lesions may be seen after drowning, strangulement, and other forms of anoxia. The common feature among the delayed-relapse patients seems to be anoxic brain injury (before the occurrence of ischemia). The basing string lesions that may be observed on CT scans because of delayed neurologic sequelae do not occur, but they are almost invariably present between 1 and 4 weeks in patients who develop a delayed extrapyramidal syndrome. In less affected patients, we have seen such lesions resolve.
Figure 40-1  Unenhanced CT scan of brain of a 30-year-old woman who attempted suicide by carbon monoxide inhalation. The only neurologic residua were a mild defect in retentive memory and areas of decreased attenuation in the pallidum bilaterally (arrows).

Because the half-life of CO is greatly reduced by the administration of hyperbaric oxygen at 2 or 3 atmospheres, this treatment is recommended when the carbon monoxide concentration is greater than 40 percent or if the patient is comatose or having seizures (Myers et al). It is not known whether this treatment reduces the incidence of neurologic sequelae.

High-Altitude (Mountain) Sickness

Acute mountain sickness is another special form of cerebral hypoxia. It occurs when a sea-level inhabitant abruptly ascends to a high altitude. Headache, anoxemia, nausea and vomiting, weakness, and insomnia appear at altitudes above 8000 ft; even modest physical exertion at this level causes dyspnea in unconditioned individuals. On reaching higher altitudes, there may be ataxia, tremor, abnormal behavior, drowsiness, and hallucinations. At 16,000 ft, according to Griggs and Shandling, some individuals develop asymptomatic retinal hemorrhages, and it is suggested that such hemorrhages may also occur in the cerebral white matter. With more prolonged stays at these altitudes or with further ascent, affected individuals show mental impairment that may progress to coma. Hypoxemia is intensified during sleep, as ventilation diminishes. Reference was made earlier to the observation of Hombein et al of a mild but possibly lasting memory impairment in even acclimated mountaineers who had been exposed for several days.

Chronic mountain sickness, sometimes called Monge disease, is observed in long-term inhabitants of high-altitude mountainous regions. Pulmonary hypertension, cor pulmonale, and secondary polycythemia are the main features. There is usually hypercarbia as well, with the expected mental dullness, slowness, fatigue, nocturnal headache, and sometimes papilledema (see below).

Sedatives, alcohol, and a slightly elevated PO2 in the blood all reduce one's tolerance to high altitude. Dexamethasone and acetazolamide prevent and counteract mountain sickness to some extent. The most effective preventive measure is acclimatization by a 2- to 4-day stay at intermediate altitudes of 6000 to 8000 ft.

Hypercapnic Pulmonary Disease

Chronic emphysema, chronic fibrous lung disease, neuromuscular weakness, and in some instances an inadequacy of the respiratory centers lead to chronic respiratory acidosis, with an elevation of Pco2 and a reduction in arterial Po2. The clinical syndrome described by Austen et al comprises headache, papilledema, mental dullness, drowsiness, confusion, stupor and coma, and asterixis. Some patients have a degree of superimposed fast-frequency tremor. The headache tends to be generalized, frontal, or occipital in location and intense, persistent, steady, and aching in type; nocturnal occurrence is a feature in some cases. The papilledema is bilateral but may be slightly greater in one eye than in the other, and hemorrhages may encircle the choked disc (a late finding). Visual acuity is undiminished and visual fields are full. Tendon reflexes are lively and plantar reflexes may be extensor. Intermittent drowsiness, indifference to the environment, inattentiveness, reduction of psychomotor activity, inability to perceive all the items in a sequence of events, and forgetfulness constitute the more subtle manifestations of this syndrome and may prompt the family to seek medical help. Such symptoms may last only a few minutes or hours, and one cannot count on their presence at the time of a particular examination. In fully developed cases, the CSF is under increased pressure. P co2 may exceed 75 mmHg and the O2 saturation of arterial blood ranges from 85 percent to no less than 40 percent. The EEG shows slow activity in the delta or theta range, which is sometimes bilaterally synchronous.

The mechanism of the cerebral disorder is said to be CO2 narcosis, but the biochemical details are not all known. Normally the CSF is slightly acidic in comparison to the blood, and the Pco2 of the CSF is about 10 mmHg higher than that of the blood. With respiratory acidosis, the pH of the CSF falls (in the range of 7.15 to 7.25) and cerebral blood flow increases because of cerebral vasodilatation. However, the brain rapidly adapts to respiratory acidosis through the generation and secretion of bicarbonate by the choroid plexuses. Brain water also increases, mainly in the white matter. In animal models of hypercarbia, NH3 is elevated, which may explain the similarity of the syndrome to that of hyperammonemia (Herrera and Kazemi).

The most effective therapeutic measures are ventilation with a positive-pressure device, using oxygen if there is hypoxia; treatment of heart failure; phlebotomy to reduce the viscosity of the blood; and antibiotics to suppress pulmonary infection. Often these measures result in a surprising degree of improvement, which may be maintained for months or years. The danger of administering morphine, which depresses the respiratory center (now insensitive to CO2), and the danger of oxygen inhalation, which in these circumstances removes the major stimulus to the respiratory center, are now widely recognized; patients treated with oxygen have lapsed into coma.

Unlike pure hypoxic encephalopathy, prolonged coma due to hypercapnia is relatively rare and in our experience has not led to irreversible brain damage. Papilledema and jerky, intermittent lapses of sustained muscular contraction (asterixis) are important diagnostic features. The syndrome is apt to be mistaken for a brain tumor, confusional psychosis of other type, or a disease causing chorea or myoclonus. In the latter case, hypercapnia must be distinguished from other metabolic diseases presenting as chronic extrapyramidal syndromes, as described later in this chapter.

Hypoglycemic Encephalopathy

This condition is relatively infrequent but is an important cause of confusion, convulsions, stupor, and coma; as such, it merits separate consideration as a metabolic disorder of the brain. The essential biochemical abnormality is a critical lowering of the blood glucose. At a level of about 30 mg/dl, the cerebral disorder takes the form of a confusional state, and one or more seizures may occur; at a level of 10 mg/dL, there is profound coma that may result in irreparable injury to the brain if not corrected immediately by the administration of glucose.

The normal brain has a glucose reserve of 1 to 2 g (30 mmol per 100 g of tissue), mostly in the form of glycogen. Since glucose is utilized by the brain at a rate of 60 to 80 mg/min, the glucose reserve will sustain cerebral activity for only about 30 min once blood glucose is no longer available. Glucose is transported from the blood to the brain by a carrier system. When glucose enters the brain, it either undergoes glycolysis or is stored as glycogen. During normal oxygenation (aerobic metabolism), glucose is converted to pyruvate, which enters the Krebs cycle; during anaerobic metabolism, lactate is formed. The oxidation of 1 mol of glucose requires 6 mol of O2. Of the glucose taken up by the brain, 85 to 90 percent is oxidized; the remainder enters an amino acid pool and is utilized in the formation of proteins and other substances—notably neurotransmitters, and particularly gamma-aminobutyric acid (GABA).

The brain is the only organ, besides the heart, that suffers severe functional and structural impairment under conditions of hypoglycemia. The pathophysiology of the cerebral disorder has not been fully elucidated. It is known that hypoglycemia reduces O2 uptake and increases cerebral blood flow. As with anoxia and ischemia, there is experimental evidence that the excitatory amino acid glutamate is ultimately involved in the destruction of neurons. The levels of several brain phospholipid proteins and other substances—notably neurotransmitters, and particularly gamma-aminobutyric acid (GABA). Some patients have a degree of superimposed fast-frequency tremor. The headache tends to be generalized, frontal, or occipital in location and intense, persistent, steady, and aching in type; nocturnal occurrence is a feature in some cases. The papilledema is bilateral but may be slightly greater in one eye than in the other, and hemorrhages may encircle the choked disc (a late finding). Visual acuity is undiminished and visual fields are full. Tendon reflexes are lively and plantar reflexes may be extensor. Intermittent drowsiness, indifference to the environment, inattentiveness, reduction of psychomotor activity, inability to perceive all the items in a sequence of events, and forgetfulness constitute the more subtle manifestations of this syndrome and may prompt the family to seek medical help. Such symptoms may last only a few minutes or hours, and one cannot count on their presence at the time of a particular examination. In fully developed cases, the CSF is under increased pressure. P co2 may exceed 75 mmHg and the O2 saturation of arterial blood ranges from 85 percent to no less than 40 percent. The EEG shows slow activity in the delta or theta range, which is sometimes bilaterally synchronous.

The mechanism of the cerebral disorder is said to be CO2 narcosis, but the biochemical details are not all known. Normally the CSF is slightly acidic in comparison to the blood, and the Pco2 of the CSF is about 10 mmHg higher than that of the blood. With respiratory acidosis, the pH of the CSF falls (in the range of 7.15 to 7.25) and cerebral blood flow increases because of cerebral vasodilatation. However, the brain rapidly adapts to respiratory acidosis through the generation and secretion of bicarbonate by the choroid plexuses. Brain water also increases, mainly in the white matter. In animal models of hypercarbia, NH3 is elevated, which may explain the similarity of the syndrome to that of hyperammonemia (Herrera and Kazemi).

The most effective therapeutic measures are ventilation with a positive-pressure device, using oxygen if there is hypoxia; treatment of heart failure; phlebotomy to reduce the viscosity of the blood; and antibiotics to suppress pulmonary infection. Often these measures result in a surprising degree of improvement, which may be maintained for months or years. The danger of administering morphine, which depresses the respiratory center (now insensitive to CO2), and the danger of oxygen inhalation, which in these circumstances removes the major stimulus to the respiratory center, are now widely recognized; patients treated with oxygen have lapsed into coma.

Unlike pure hypoxic encephalopathy, prolonged coma due to hypercapnia is relatively rare and in our experience has not led to irreversible brain damage. Papilledema and jerky, intermittent lapses of sustained muscular contraction (asterixis) are important diagnostic features. The syndrome is apt to be mistaken for a brain tumor, confusional psychosis of other type, or a disease causing chorea or myoclonus. In the latter case, hypercapnia must be distinguished from other metabolic diseases presenting as chronic extrapyramidal syndromes, as described later in this chapter.

Etiology

The most common causes of hypoglycemic encephalopathy are (1) accidental or deliberate overdose of insulin or an oral diabetic agent; (2) ileal intussusception of the pancreas; (3) depletion of liver glycogen that occasionally follows a prolonged alcoholic binge, starvation, or some form of acute liver disease such as acute nonicteric hepatoencephalopathy of childhood (Reye syndrome); (4) glycogen storage disease of infancy; and (5) an idiopathic hypoglycemia
in the neonatal period and sometimes in infancy. Moderate degrees of hypoglycemia (50 mg/dL) may be observed with chronic renal insufficiency (Fisher et al.). In the past, hypoglycemic encephalopathy was not an infrequent complication of "insulin shock" therapy for schizophrenia. In functional hypersomnolence, as occurs in anoxia nervosa and in dietary faddism, the hypoglycemia is rarely of sufficient severity or duration to damage the CNS.

Clinical Features When the level of blood glucose has descended to about 30 mg/dL, the initial symptoms appear—nervousness, hunger, flushed face, sweating, headache, palpitation, trembling, and anxiety; these gradually give way to confusion and drowsiness and occasionally to excitement, overactivity, and bizarre behavior. Many of the early and mild symptoms relate to adrenal and sympathetic overactivity, and therefore some of the manifestations may be muted in diabetic patients with neuropathy. In the next stage, forced sucking, grasping, motor restlessness, muscular spasms, and decerebrate rigidity occur, in that sequence. Myoclonic twitching and convulsions develop in some patients but are by no means the rule. Rarely there are focal cerebral deficits, the pathogenesis of which remains unexplained. Hemiplegia, corrected by intravenous glucose, was observed in 3 of 125 patients who presented with symptomatic hypoglycemia (Malouf and Bruist).

Blood glucose levels of approximately 10 mg/dL are associated with deep coma, dilatation of pupils, pale skin, shallow respiration, slow pulse, and hypotonia of limb muscle—the so-called medullary phase of hypoglycemia. If glucose is administered before this level has been attained, the patient can be restored to normalcy, retracting the aforementioned steps in reverse order. However, once the "medullary phase" is reached, and particularly if it persists for a time before the hypoglycemia is corrected by intravenous glucose or spontaneously as a result of the gluconeogenic activities of the adrenal glands and liver, recovery is delayed for a period of days or weeks and may be incomplete.

The EEG is altered as the blood glucose falls, but the correlations are inexact. There is diffuse slowing in the theta or delta range. During recovery, sharp waves may appear and coincide in some cases with seizures.

A large dose of insulin, which produces intense hypoglycemia, even of relatively brief duration (30 to 60 min), is more dangerous than a series of less severe hypoglycemic episodes from smaller doses of insulin, possibly because the former impairs or exhausts essential enzymes—a condition that cannot then be overcome by large quantities of intravenous glucose.

The major clinical differences between hypoglycemic and hypoxic encephalopathy lie in the setting and the mode of evolution of the neurologic disorder. The effects of hypoglycemia usually unfold more slowly, over a period of 30 to 60 min, rather than in a few seconds or minutes. The recovery phase and the sequelae of the two conditions are quite similar. A severe and prolonged episode of hypoglycemia may result in permanent impairment of intellectual function as well as other neurologic residue, like those that follow severe anoxia. We have also observed states of protracted coma as well as relatively pure Korsakoff amnesias. However, one should not be hasty in prognosis, for we have observed slow improvement to continue for 1 to 2 years. Recurrent hypoglycemia, as with an islet cell tumor, may masquerade for some time as an episodic confusional psychosis or convulsive illness, and diagnosis then awaits the demonstration of low blood glucose or hypersomnolence in association with the neurologic symptoms.

Lesser degrees and more chronic forms of low blood glucose may produce two other distinct but not mutually exclusive syndromes, according to Marks and Rose, who have written an authoritative monograph on the subject. One of these syndromes, termed subacute hypoglycemia, is characterized by drowsiness and lethargy, diminution in psychomotor activity, deterioration of social behavior, and confusion. Oral or intravenous glucose will immediately alleviate the symptoms. In the other syndrome, termed chronic hypoglycemia, there is a gradual deterioration of intellectual functions, raising the question of dementia; in some reported instances, tremor, chorea, rigidity, cerebellar ataxia, and rarely signs of lower motor neuron involvement (hypoglycemic amyotrophy) are added. The latter feature has not been seen by the authors, who can only refer the reader to the report by Tom and Richardson.

These subacute and chronic forms of hypoglycemia have been observed in conjunction with islet cell hypertiroidism and islet cell tumors of the pancreas, carcinoma of the stomach, fibrous mesothelioma, carcinoma of the cecum, and hepatoma. Supposedly an insulin-like substance is elaborated by these nonpancreatic tumors.

Functional or reactive hypoglycemia is the most ambiguous of all syndromes related to low blood glucose. This condition is usually idiopathic but may precede the onset of diabetes mellitus. The rise in insulin in response to a carbohydrate meal is delayed but then causes an excessive fall in blood glucose, to 30 to 40 mg/dL. The symptoms are malaise, fatigue, nervousness, headache, tremor, and so on, which may be difficult to distinguish from anxious depression. Not surprisingly, the term functional hypoglycemia has been much abused, being applied indiscriminately to a variety of complaints that would now be called chronic fatigue syndrome. In fact, the syndrome of functional or reactive hypoglycemia is rare and its diagnosis requires the finding of an excessive reaction to insulin, a low blood glucose during the symptomatic period, and a salutary response to oral glucose. Treatment, which consists of a high-protein, low-carbohydrate diet, should be reserved for patients whose symptom complex correlates with pronounced hypoglycemia as documented by a 5-h glucose tolerance test.

Pathologically, in all forms of hypoglycemic encephalopathy, the major damage is to the cerebral cortex. Cortical nerve cells degenerate and are replaced by myelinic and glial tissue. The distribution of the damage is identical to that in hypoxic encephalopathy. This is similar to the following: the necrotic zone of the mural cortex is less vulnerable to hypoglycemia than to hypoxia.) Auer has described the ultrastructural changes in neurons resulting from experimental hypoglycemia; with increasing duration of hypoglycemia and EEG silence, there are mitochondrial changes, first in dendrites and then in nerve cell soma, followed by nuclear membrane disruption leading to cell death.

Treatment of all forms of hypoglycemia obviously consists of correction of the hypoglycemia at the earliest possible moment. It is not known whether hypothermia or other measures will increase the safety period in hypoglycemia or alter the outcome.

Hypoglycemia

Two syndromes have been defined, mainly in diabetics: (1) hyperglycemia with ketoadidosis and (2) hypomolar nonketotic hyperglycemia.

In diabetic acidosis the familiar picture is one of dehydration, fatigue, weakness, headache, abdominal pain, dryness of the mouth, stupor or coma, and Kussmaul type of breathing. Usually the condition has developed over a period of days in a patient known or proven to be diabetic. Insulin has been often omitted. The blood glucose level is found to be more than 400 mg/dL, the pH of the blood less than 7.20, and the bicarbonate less than 10 mg/dL. Ketone bodies and 2-hydroxybutyric acid are elevated in the blood and urine, and there is marked glycosuria. The prompt administration of insulin and repletion of intravascular volume correct the clinical and chemical abnormalities over a period of hours.

Of considerable interest is a small group of patients with diabetic ketoacidosis, such as those reported by Young and Bradley, in whom deepening coma and cerebral edema develop as the elevated blood level of glucose is corrected. This condition, which is indicated by rising CSF pressure, has been attributed by Prudkop to an accumulation of fructose and sorbitol in the brain. The latter substance, a polyl that is formed during hyperglycemia, crosses membranes slowly, but once it does so it is said to cause a shift of water into the brain and an intracerebral edema. However, according to Fishman, the increased polyls in the brain in hyperglycemia are not present in sufficient concentration to be important osmotically; they may induce other metabolic effects related to the encephalopathy. These are matters of conjecture, since the increase of polyls has never been found. The edema in this condition is probably due to reversal of the osmolality gradient from blood to brain, which occurs with rapid correction of hyperglycemia. The pathophysiology of the cerebral disorder in diabetic ketoadidosis is not fully understood. No consistent cellular pathology of the brain has been identified in the cases we have examined. Factors such as ketosis, tissue acidosis, hypotension, hypersomnolence, and hypothermia have not proved to be causative. Attempts at therapy by the administration of urea, mannitol, salt-poor albumin, and dexamethasone are usually unsuccessful, though recoveries are reported.

In hypermolar nonketotic hyperglycemia, the blood glucose is extremely high, over 600 mg/dL, but ketoadidosis does not develop or is mild. Osmolality is usually around 350 mosmol. There is also hyperosmolar and prerenal azotemia. Appreciation of the neurologic syndrome is generally credited to Wegierko, who published descriptions of it in 1956 and 1957. Most of the patients are elderly diabetics, but some were not previously known to have been diabetic. An infection, enteritis, pancreatitis, or a drug known to upset diabetic control (thiazides, penicillin, phenyltoin) leads to polyuria, fatigue, confusion, stupor, and coma. Often the syndrome arises in conjunction with the combined use of corticosteroids and phenytoin (which inhibits insulin release), for example, in elderly patients with brain tumors. The use of osmotic diuretics enhances the risk. If the patient is seen before coma supervenes, seizures and focal signs such as a hemiparesis, a hemisensory defect, or a homonymous visual field defect erroneously suggest the possibility of a stroke. The mortality rate has been as high as 40 percent. Fluids should be replaced cautiously, using isotonic saline and potassium. Correction of the markedly elevated blood glucose requires relatively small amounts of insulin, since these patients often do not have a high degree of insulin resistance.
Hepatic Stupor and Coma (Hepatic or Portal-Systemic Encephalopathy)

Chronic hepatic insufficiency with portosystemic shunting of blood is often punctuated by episodes of stupor, coma, and other neurologic symptoms—a state that is referred to as hepatic stupor, coma, or acute hepatic encephalopathy. This state complicates all varieties of liver disease. Less widely known is the fact that a surgical portal-systemic shunt (Eck fistula) is attended by the same clinical picture, in which case the liver itself may be little affected. Also, there are a number of hereditary hyperammonemias, usually occurring in infancy or childhood (see Chapter 37), that lead to episodic coma with or without seizures. In all these states, it is common for an excess of protein, derived from the diet or gastrointestinal hemorrhage, to induce or worsen the encephalopathy. Additional predisposing factors are hepatic hypokalemia, metabolic alkalosis, excessive diuresis, use of sedative hypnotic drugs, and constipation. Reye syndrome, a special type of acute nonicteric hepatic encephalopathy of children, is also associated with very high levels of ammonia in the blood (see further on in this chapter).

Clinical Features The clinical picture of subacute or chronic hepatic encephalopathy consists essentially of a derangement of consciousness, presenting first as mental confusion with decreased psychomotor activity, occasionally with hyperactivity, followed by progressive drowsiness, stupor, and coma. The confusional state, before coma supervenes, is frequently combined with a characteristic intermittency of sustained muscle contraction; this phenomenon, which was originally described in patients with hepatic stupor by Adams and Foley and called asterixis (from the Greek asterixis, a “fixed position”), is now recognized as a sign of various metabolic encephalopathies (page 107). It is conventionally demonstrated by having the patient hold his arms outstretched, but the same tremor can be elicited by any sustained posture, including that of the protruded tongue. A variable, fluctuating rigidity of the trunk and limbs, grimacing, suck and grasp reflexes, exaggeration or asymmetry of tendon reflexes, Babinski signs, and focal or generalized seizures round out the clinical picture.

The EEG is a sensitive and reliable indicator of impending coma, becoming abnormal during the earliest phases of the disordered mental state. The usual EEG abnormality consists of paroxysms of bilaterally synchronous slow or triphasic waves, in the delta range, which at first predominate frontally and are interspersed with alpha activity and later, as the coma deepens, displace all normal activity (Fig. 2-23; page 30). A small number of patients show only random high-voltage asynchronous slow waves.

This syndrome of hepatic encephalopathy is remarkably diverse in its clinical presentation. It usually evolves over a period of days to weeks and often terminates fatally; or, with appropriate treatment, the symptoms may regress completely or only partially and then fluctuate in severity for several weeks or months. Persistent hepatic coma of the latter type proves fatal in about half of the patients (Levy et al.). In many patients, the syndrome is relatively mild and does not evolve beyond the stage of mental dullness and confusion, with asterixis and EEG changes. In yet others, a subtle disorder of mood, personality, and intellect may be protracted over a period of many months or even years; this chronic but nevertheless reversible mental disturbance need not be associated with overt clinical signs of liver failure (mainly jaundice and ascites) or other neurologic signs. Characteristically in these patients an extensive portal-systemic collateral circulation can be demonstrated (chronic hepatic encephalopathy) and an association established between the mental disturbance and an intolerance to dietary protein and raised blood ammonia levels (Summerskill et al.).

Finally, there is a group of patients (most of whom have experienced repeated attacks of hepatic coma) in whom an irreversible mild dementia and a disorder of posture and movement (grimacing, tremor, dysarthria, ataxia of gait, choreoathetosis) gradually appear. This condition of chronic acquired hepatocerebral degeneration must be distinguished from other dementing and extrapyramidal syndromes (see further on). A few cases of isolated spastic-ataxic paraplegia (so-called hepatic myelopathy) have also been described (page 1329).

The concentrations of blood NH₃, particularly if measured repeatedly in arterial blood samples, usually are well in excess of 200 mg/dL, and the severity of the neurologic and EEG disorders is roughly parallel to the ammonium levels. With treatment, the fall in the NH₃ levels precedes clinical improvement. If the diagnosis remains uncertain, an intolerance to ammonia can be demonstrated by the administration of an oral dose of 6.0 g of NH₄Cl, which raises the blood NH₃ and sometimes produces mild symptoms of hepatic encephalopathy. In a normal person, this dosage does not alter the blood NH₃ concentrations.

Neuropathologic Changes The striking finding in patients who die in a state of hepatic coma is a diffuse increase in the number and size of the protoplasmic astrocytes in the deep layers of the cerebellar cortex, lenticular nucleus, thalamus, substantia nigra, cerebellar cortex, and red, dentate, and pontine nuclei, with little or no visible alteration in the nerve cells or other parenchymal elements. With periodic acid–Schiff (PAS) staining, the astrocytes are seen to contain characteristic glycogen inclusions. These abnormal glial cells are generally referred to as Alzheimer type II astrocytes, having been described originally in 1912 by von Hossli and Alzheimer in a patient with Westphal-Strümpell pseudosclerosis (familial hepatolenticular degeneration, or Wilson disease). These astrocytes have been studied electron microscopically in rats in surgically created portacaval shunts (Cavanagh; Norellberg); the astrocytes showed a number of striking abnormalities—swelling of their terminal processes, cytoplasmic vacuolation (distended sacs of rough endoplasmic reticulum), formation of folds in the basement membrane around capillaries, diminution in glycogen, and an increase in the number of mitochondria and in enzymes that catalyze ammonia. Also, some degeneration in myelinated nerve fibers in the neuropil and increase in the cytoplasm of oligodendrocytes were seen. In chronic cases, we have found neuronal loss in the deep layers of the cerebral and cerebellar cortex and in the lenticular nucleus as well as a vacuolization of tissue (possibly astrocyte vacuolization) resembling the lesions of Wilson disease.

The ubiquitously observed alterations occur to some degree in all patients who die of progressive liver failure, and the degree of this glial abnormality corresponds roughly to the intensity and duration of the neurologic disorder. Presumably the astrocytic changes affect the synaptic activities of the neurons. The clinical and EEG findings of hepatic encephalopathy as well as the clinicopathologic abnormality, are not specific for this state of metabolic disorder. Nevertheless, taken together in a setting of liver failure, these manifestations constitute a distinctive clinicopathologic entity.

Pathogenesis of Hepatic Encephalopathy The most plausible hypothesis relates hepatic coma to an abnormality of nitrogen metabolism, wherein ammonia (NH₃), which is formed in the bowel by the action of urease-containing organisms on dietary protein, is carried to the liver in the portal circulation but fails to be converted into urea, because of either hepatocellular disease, portal-systemic shunting of blood, or both. As a result, excess amounts of NH₃ reach the systemic circulation, where they interfere with cerebral metabolism in a way that is not yet fully understood. Certainly the ammonia theory best explains the basic neuropathologic change. Norellberg has proposed that the hypertrophy of the astrocytic cytoplasm and proliferation of the mitochondria and endoplasmic reticulum, as well as the increase in the astrogial glutamic dehydrogenase activity, reflect the heightened metabolic activity associated with ammonia detoxification. Removal of brain ammonia depends upon the formation of glycine, a reaction that is catalyzed by the ATP-dependent glutamate glutamine synthetase, which is localized in the astrocytes. It has been shown in experimental animals that hyperammonemia leads to a depletiof of ATP in midbrain reticular nuclei. Whether this is the primary cause of coma has not been resolved.

Numerous alternative theories have been suggested. One is that CNS function in cirrhotic patients is impaired by phenols or short-chain fatty acids (from the diet or from bacterial metabolism of carbohydrate). Another suggestion is that biogenic amines (e.g., octopamine), which arise in the gut and bypass the liver, act as false neurotransmitters and the putative putative biogenic amine hypothesis (Koeberle and Baldessarini) has presented evidence that some of the biogenic amines (methanethiol, methione), which are also generated in the gastrointestinal tract and removed by the liver, act in conjunction with NH₃ to produce hepatic encephalopathy. This theory and others have been the subject of reviews by Butterworth and coworkers, by Zieve, by Rothstein and Herlong, and by Jones and Basile, to which the reader is referred for detailed information.

For some time, it has been known that hepatic encephalopathy is associated with increased activity of the inhibitory transmitter GABA. It is also known that increased GABAergic neurotransmission may result from substances that inhibit the binding of endogenous benzodiazepines to their receptors (Basile et al.), and these antagonists have clinical and EEG effects similar to those observed in chronic hepatic encephalopathy. The actions of benzodiazepines are mediated by these receptor sites—hence the designation GABA-receptor benzodiazepine theory. The practicality of using benzodiazepine receptor antagonists (e.g., flumazenil) in the treatment of hepatic encephalopathy remains to be determined (see Mullenvay).

Until recently, the ammonia and the GABAergic-benzodiazepine hypotheses of the pathogenesis of hepatic encephalopathy have appeared to be unrelated and even mutually exclusive. However, there is a growing body of evidence (recently reviewed by Jones and Basile) that ammonia, even in the modestly elevated concentrations that occur in liver failure, probably enhances GABAergic neurotransmission—a concept that may unify the two hypotheses.

Also in recent years, manganese has emerged as a potential neurotoxin in the pathogenesis of hepatic encephalopathy (Kreiger et al.; Pomer-Layargues et al.). In patients with chronic liver diseases and with spontaneously or surgically induced portal-systemic shunts, manganese accumulates in the serum and in the brain, more specifically in the pallidum. This accumulation is readily discernible as a palilial signal hypointensity on T₁-weighted MRI. Following liver transplantation, there is
normalization of the MRI changes and the associated extrapyramidal symptoms. The effects of manganese chelation on such patients have not been studied and the possible mechanisms of accumulated manganese in the pathogenesis of hepatic encephalopathy are not known.

**Treatment** Despite the incompleteness of our understanding of the role of disordered ammonium metabolism in the genesis of hepatic coma, an awareness of this process has led to the few effective means of treating this disorder: restriction of dietary protein; reducing bowel flora by oral administration of neomycin or kanamycin, which suppresses the urease-producing organisms in the bowel; and the use of enemas. The mainstay of treatment has been the use of lactulose, an inert sugar that acidifies the colonic contents and greatly reduces bacterial activity. The sustained use of oral neomycin carries a risk of renal damage and ototoxicity and has therefore been relegated to a second line of therapy. The salutary effects of these therapeutic measures, the common attribute of which is the lowering of the blood 

Other methods of treatment, the value of which still remains to be established, include the use of bromocriptine, flumazenil, and keto-analogs of essential acid. Theoretically, the keto-analogs should provide a nitrogen-free source of essential amino acids (Maddrey et al), and bromocriptine, a dopamine agonist, should enhance dopaminergic transmission (Morgan et al). Administration of branched-chain amino acids may result in considerable improvement in mental status, but their effects have been variable and associated with an increased mortality (Naylor et al).

**Fulminant Hepatic Failure and Cerebral Edema** In acute hepatic failure, confusional, delirious, and comatose states also occur, but their mechanisms are still unknown. Blood 

**CT scanning** is an effective means of detecting cerebral edema in patients with fulminant hepatic failure, and the degree of cerebral swelling is roughly proportional to the severity of encephalopathy (Wy didn't provide a clear reference for this). Since patients with fulminant hepatic failure can survive liver transplantation with few or no neurologic deficits, it is important to recognize cerebral edema early, before the stages of stupor and coma and greatly increased intracranial pressure have been reached. Shock of transplantation, death in these cases may be prevented by lowering the intracranial pressure (as outlined by Lidoffsky et al) and by the use of cemic diuretics and hyperventilation, as detailed in Chap. 30. However, some survivors may be left with cerebral damage from raised intracranial pressure.

**Rye Syndrome (Rye-Johnson Syndrome)** As indicated above, this is a special type of nonicteric hepatic encephalopathy occurring in children and adolescents and characterized by acute brain swelling in association with fatty infiltration of the viscera, particularly of the liver. Although individual cases of this disorder had been described for many years, its recognition as a clinical-pathologic entity dates from 1963, when a large series was reported from Australia by Rye and colleagues and from the United States by Johnson and coworkers. The disorder tends to occur in outbreaks (286 cases were reported to the Centers for Disease Control during a 4-year period of 1967-1970). Mainly, these outbreaks were observed in association with influenza B virus and varicella infections, but a variety of other viral infections have been implicated (influenza A, echovirus, reovirus, rubella, rubella, herpes simplex, Epstein-Barr virus). In addition, the toxic or adjuvant effects of aspirin given during these infections seem to play a role in producing the disease. Only occasional instances of the Rye syndrome are observed now that the association with aspirin administration has become widely known and its use in the children with the infections has been interdicted.

Most patients are children, boys and girls being equally affected, but rare instances have been observed in infants (Hutlenkoch and Trauner) and in young adults. In most cases the encephalopathy is preceded for several days to a week by fever, symptoms of upper respiratory infection, and protracted vomiting. These symptoms are followed by the rapid evolution of stupor and coma, associated in many cases with focal and generalized seizures, signs of sympathic overactivity (tachypnea, tachycardia, mydriasis), decorticate and decerebrate rigidity, and loss of pupillary, corneal, and vestibulo-ocular reflexes. In infants, respiratory distress, tachypnea, and apnea are the most prominent features. The liver may be greatly enlarged, often extending to the pelvis and providing an important diagnostic clue as to the cause of the cerebral changes. Initially there is a metabolic acidosis, followed by a respiratory alkalosis (rising arterial pH and falling P CO2). The CSF is usually under increased pressure and is acellular; glucose values may be low, reflecting the hypoglycemia. The serum glutamic-oxaloacetic transaminase (SGOT), prothrombin time, and blood ammonia are increased, sometimes to an extreme degree. The EEG is characterized by diffuse, thyrhythmia activity, progressing to electrocerebral silence in patients who fail to survive.

The major pathologic findings are cerebral edema, with marked cerebral herniation, and infiltration of hepatocytes with fine droplets of fat (mainly triglycerides); the renal tubules, myocardium, skeletal muscles, pancreas, and spleen are infiltrated to a lesser extent. There are no inflammatory lesions in the brain, liver, or other organs. There is not full agreement as to the pathogenesis of this disorder.

**Prognosis and Treatment** In a series of children with blood ammonia levels greater than 500 mg/dL who were treated during the years 1967 to 1974, Shaywitz and colleagues reported a mortality of 60 percent. Once the child became comatose, death was almost inevitable. In more recent years, early diagnosis (elevations of SGOT, prothrombin time, and serum NH3) and initiation of treatment before the onset of coma has reduced the fatality rate to 5 to 10 percent. Treatment consists of the following measures: temperature control with a cooling blanket; nasotracheal intubation and controlled ventilation to maintain P CO2 above 20 mmHg; intravenous glucose covered by insulin to maintain blood glucose at 150 to 200 mg/dL; administration of neomycin enemas and lactulose; control of intracranial pressure by diuretics and hyperventilation, as detailed in Chap. 30; and the use of fluid and electrolyte balance (Trauner). Upon recovery, cerebral function returns to normal unless there had been deep and prolonged coma or protracted elevation of intracranial pressure.

**Uremic Encephalopathy**

Episodic confusion and stupor and other neurologic symptoms may accompany any form of severe renal disease—acute or chronic. The chronic symptoms attributable to uremia per se (first described by Addison in 1832) are best discerned in normotensive individuals in whom renal failure develops rapidly. Apathy, fatigue, inattentiveness, and irritability are usually the initial symptoms; later, there is confusion, disturbances of sensory perception, hallucinations, dysarthria, and asterixis. Sometimes this takes the form of a toxic psychosis, with hallucinations, delusions, insomnia, or catatonia (Marshall). Characteristically these symptoms fluctuate from day to day or even from hour to hour. In some patients, especially in those who become anuric, symptoms may come on rather abruptly and progress rapidly to a state of stupor and coma. In others, in whom uremia develops more gradually, mild visual hallucinations and a disorder of attention may persist for several weeks in a relatively hyperactive form. The EEG becomes diffusely slow and may remain so for several weeks after the institution of dialysis. The CSF pressure is normal and the protein is not elevated unless there is a uremic or diabetic neuropathy. In several reports, meningesis and a low-grade monocuclear pleocytosis is mentioned, but we have not found this.

In acute renal failure, claudification of the sensorium is practically always associated with a variety of motor phenomena, which usually occur early in the course of the encephalopathy, sometimes when the patient is still mentally clear. The patient begins to twitch and jerk and may convulse. The twitches involve parts of muscles, whole muscles, or limbs and are lightning-quick, arrhythmic, and asynchronous on the two sides of the body; they are incessant during both wakefulness and sleep. At times the movements resemble those of chorea or an arrhythmic tremor, and asterixis is readily evoked. The motor phenomena are often difficult to classify. The authors prefer to describe the condition as the *uremic twitch-convulsive syndrome*.

Because of the similarity of this syndrome to tetany, measurement should be made of serum calcium and magnesium—and, of course, hypocalcemia and hypomagnesemia do occur in uremia. But often the values for these ions are normal or near normal, and the administration of calcium and magnesium salts has little effect. The resemblance of uremic encephalopathy to hepatic and other metabolic encephalopathies has been stressed by Raskin and Fishman, yet we are more impressed with differences than with similarities. We have observed the twitch-convulsive syndrome in association with a variety of diseases such as widespread neurologic infections, diabetes, disorders of pyridoxine, and lupus erythematosus, in which the blood urea nitrogen was only modestly elevated; but always the factor of renal failure was ultimately discovered.

As the uremia worsens, the patient lapses into a quiet coma. Unless the accompanying metabolic acidosis is corrected, Kussmaul breathing appears and gives way to Cheyne-Stokes breathing and death.

It is important to keep in mind that encephalopathy and coma in the patient with renal failure may be due to disorders other than uremia itself. The altered excretion of medication leads to their accumulation, sometimes evoking excessive sedation even though serum concentrations are normal. Subdural and intracerebral hemorrhages...
may complicate uremia because of clotting defects and hypertension, and chronically azotemic patients are prone to infections, including meningitis.

Since uremia is so frequently associated with hypertension, a major problem also arises in distinguishing the cerebral effects of uremia from those of severe and accelerated hypertension. Volhard was the first to make this distinction; he introduced the term pseudo-uremia to designate the cerebral effects of malignant hypertension and to separate them from true uremia. The term hypertensive encephalopathy, by which pseudo-uremia is now known, was first used by Oppenheimer and Fishberg. The clinical picture of the latter disorder and its pathophysiology are discussed on page 903.

Opinions vary as to the biochemical basis of uremic encephalopathy and the twitch-convulsive syndrome. Restoration of renal function completely corrects the neurological disturbance, returning to a functional disorder of subcellular type. Whether caused by the retention of organic acids, elevation of phosphate in the CSF (claimed by Harrison et al.), or the action of urea or other toxins has never been settled. The data supporting the causative role of urea are ambiguous, as they are for other endogenous putative agents (see Bolton and Young and the review by Burn and Bates). However, it can be stated that urea itself is not the sole inductive agent, since its infusion does not produce the syndrome in man or animals.

It would appear that every level of the CNS is affected, from spinal cord to cerebrum. The authors have been unable to detect cellular changes in the brain or spinal cord other than a mild hyperplasia of protoplasmic astrocytes in some cases, but never of the degree observed in hepatic encephalopathy. Cerebral edema is notably absent. In fact, CT scans and MRI usually show an element of cerebral shrinkage, probably on the basis of hyposomolality. A peripheral neuropathy is also a common complication of uremia and is considered in Chap. 46.

In the treatment of uremic encephalopathy, the nature of the renal disease assumes paramount importance; if it is irreversible and progressive, the prognosis is poor without dialysis or renal transplantation. Improvement of encephalopathic symptoms may not be evident for a day or two after institution of dialysis. Convulsions, which occur in about one-third of cases, often preterminally, may respond to relatively low plasma concentrations of anticonvulsants, the reason being that serum albumin is depressed in uremia, increasing the unbound, therapeutically active portion. If there are severe associated metabolic disturbances, such as hyponatremia, the seizures may be difficult to control. One must be cautious in prescribing any of a large number of drugs in the face of renal failure, for inordinately high, toxic blood levels may result. Examples are aminoglycoside antibiotics (vestibular damage); furosemide (cochlear damage); and nitrofurantoin, tinidazole, and hydralazine (peripheral nerve damage).

**Dialysis “Disequilibrium Syndrome”**

This term refers to a group of symptoms that may occur during and following hemodialysis or peritoneal dialysis in association with some degree of cerebral edema. The symptoms include headaches, nausea, muscular cramps, nervous irritability, agitation, drowsiness, and convulsions. The headache may be bilateral and throbbing or resemble common migraine, develops in approximately 70 percent of patients, while the other symptoms are observed in 5 to 10 percent, usually in those undergoing rapid dialysis or in the early stages of a dialysis program. The symptoms tend to occur in the third or fourth hour of dialysis and subside after several hours. Sodium retention appears to be the cause of dialysis. Often these symptoms were attributed to the rapid lowering of serum urea, leaving the brain with a higher concentration of urea than the serum and resulting in a shift of water into the brain to equalize the osmotic gradient (reverse urea syndrome). Now it is believed that the shift of water into the brain is akin to water intoxication and is due to the inappropriate secretion of antidiuretic hormone.

The symptoms of subdural hematoma, which in some series have occurred in 3 to 4 percent of patients undergoing dialysis, may be mistakenly attributed to the disequilibrium syndrome.

**Dialysis Encephalopathy (Dialysis Dementia)**

This is a subacutely progressive syndrome, now virtually extinct, that complicated chronic hemodialysis. Characteristically the condition begins with a hesitant, stuttering dysarthria, dysphagia, and sometimes apraxia of speech, to which are added facial and then generalized myoclonus, focal and generalized seizures, personality and behavioral changes, and intellectual decline. The EEG is invariably abnormal, taking the form of paroxysmal and sometimes periodic sharp-wave or spike-and-wave activity (up to 500 mV and lasting 1 to 20 s) intermixed with abundant theta and delta activity. The CSF is normal except, occasionally, for increased protein.

At first the myoclonus and speech disorders are intermittent, occurring during or immediately after dialysis and lasting for only a few hours, but gradually they become more persistent and eventually permanent. Once established, the syndrome is usually slowly progressive over a 1- to 15-month period (average survival of 6 months in the 42 cases analyzed by Lederman and Henry).

The neuropathologic changes are subtle and consist of a mild degree of microcavitation of the superficial layers of the cerebral cortex. Although the changes are diffuse, they have been found, in one study, to be more severe in the left (dominant) hemisphere than in the right and more severe in the left frontotemporal operculum than in the surrounding cortex (Winkelman and Ricanati). The disproportionate affection of the left frontotemporal opercular cortex would explain the distinctive disorder of speech and language.

The current view of the pathogenesis of dialysis encephalopathy is that it represents a form of aluminum intoxication (Alfrey et al.), the aluminum being derived from the dialysate or from orally administered aluminum gels. In recent years, this disorder has disappeared, the result, no doubt, of the universal practice of purifying the water used in dialysis and thereby removing aluminum from the dialysate. The subject has been reviewed by Parkinson and coworkers.

**Complications of Renal Transplantation**

The risk, in immunosuppressed persons, of developing a primary lymphoma of the brain or progressive multifocal leukoencephalopathy has already been mentioned (pages 695 and 812). A different encephalopathy that is marked by widespread edema of the cerebral white matter, evident on the MRI and predominantly occipital, occurs after the administration of cyclosporine and other immunosuppressants. The pattern on MRI is not specific, being seen also in patients with hypertensive encephalopathy and other causes of systemic fungal infections are found at autopsy in about 45 percent of patients who have had renal transplants and long periods of immunosuppressive treatment; in about one-third of these patients, the CNS is involved. Cryptococcus, Listeria, Aspergillus, Candida, Nocardia, and Histoplasma are the usual organisms. Other CNS infections that have complicated transplantation are toxoplasmosis and cytomegalic inclusion disease.

In some nutritionally depleted uremic patients who are subjected to treatment that involves major shifts of plasma water and electrolytes, diseases unrelated to uremia may develop. In our necropsy material, we have found examples of Wernicke-Korsakoff disease and central pontine myelinolysis. A bleeding diathesis may result in subdural or cerebral hemorrhage.

**Encephalopathy Associated with Sepsis and Burns**

Bolton and Young have drawn attention to the frequent occurrence, in severely septic patients, of a drowsy or confusional state that is reversible but not explained by hepatic, pulmonary, or renal failure, electrolyte imbalance, hypotension, drug intoxication, or a primary lesion of the brain. According to their surveys, 70 percent of patients become disoriented and confused within hours of the onset of severe systemic infection; in a few cases, this state may progress to stupor and coma. Notably there are no signs of asterixis, myoclonus, or focal cerebral disorder, but paratonia is common, as is the later development of a polyneuropathy.

The encephalopathic state that occurs with severe systemic infection may also occur independently of sepsis, as a component of a syndrome of multiple organ failure and as a complication of widespread cutaneous burns (Akawala et al.).

It has been useful, in clinical work, to distinguish these encephalopathies of infection and multorgan failure from those due to isolated hepatic or renal disease. The lack of a biochemical marker and the confounding effects of hypotension during sepsis (septic shock) leave doubt as to pathogenesis. Altered phenylalanine metabolism and circulating cytokines have been proposed as causes, without firm evidence. Of interest in two of our fatal cases was the presence of brain purpura, but this has otherwise been an infrequent finding. The white matter of the cerebrum and cerebellum was speckled with myriad of pericapillary hemorrhages and zones of pericapillary necrosis. This pathologic reaction is nonspecific, having also been seen in some of our cases (10 in all) of viral pneumonia, heart failure with morphine overdose, and arsenical intoxication.

**Disorders of Sodium, Potassium, and Water Balance**

Drowsiness, confusion, stupor, and coma, in conjunction with seizures and sometimes with other neurologic deficits, may have as their basis a more or less pure abnormality of electrolyte or water balance. Only brief reference is made to some of these—such as hypocalcemia, hypercalcemia, hypophosphatemia, and
Hypomagnesemia—since they are considered in other parts of the text.

**Hypotension** Among the many causes of hypotension, the syndrome of inappropriate antidiuretic hormone secretion (SIADH) is of special importance, since it may complicate neurologic diseases of many types—head trauma, bacterial meningitis and encephalitis, cerebral infarction, subarachnoid hemorrhage, neoplasm, and Guillain-Barré disease. The diagnosis of SIADH should be suspected in any critically ill neurologic or neurological patient who excretes urine that is hypertonic relative to the plasma. As the hypotension develops, there is a decrease in alertness, which progresses through stages of confusion to coma, often with convulsions. As with many other metabolic derangements, the severity of the clinical effects is related to the rapidity of decline in serum Na. Lack of recognition of this state may allow the serum Na to fall to dangerously low levels, 100 meq/L or lower. One's first impulse is to administer NaCl intravenously, but this must be done cautiously, because in most of these patients the intravascular volume is already expanded and there is a risk of congestive heart failure. Most cases respond to the restriction of fluid intake—to 500 mL per 24 h if the serum Na is less than 120 meq/L and to 1000 mL per 24 h if less than 130 meq/L. Even when the Na reaches 130 meq/L, the fluid intake should not exceed 1500 mL per 24 h. In extreme cases of hypotension with stupor or seizures, infusion of NaCl is necessary. The amount of NaCl to be infused can be calculated from the current and the target levels of serum Na by assuming that the infused sodium load is distributed throughout the total body water content (0.6 × weight in kg).

\[
\text{Target Na} = \text{starting Na} \times 0.6 \times \text{weight (kg)}.
\]

The desired volume of normal saline can then be calculated by keeping in mind that its sodium concentration is 154 meq/L, and that of 3 percent (hypertonic) saline is 462 meq/L. If hypertonic saline is administered, it is usually necessary to simultaneously reduce intravascular volume with furosemide, beginning with a dose of 0.5 mg/kg intravenously, and to increase the dosage until a diuresis is obtained. Guidelines for the rapidity of correction of Na are elaborated further on in relation to central pontine myelinolysis (no more than 10 mmol/L in the first 24 h). Although the syndrome of SIADH is self-limiting, it may continue for weeks or months, depending on the type of associated brain disease.

It must be emphasized that not all patients with intracranial disorders who show hypotension and natriuresis have SIADH. In fact, in many of such patients, renal loss of salt is the cause of hypotension and, in contrast to SIADH, results in decreased blood volume. The process has been termed "cerebral salt wasting" (Neison et al.). Sodium loss in these circumstances is attributable to the production by the heart or brain of a potent polypeptide, atrial natriuretic factor. As discussed in Chap. 34, under "Subarachnoid Hemorrhage," the distinction between SIADH and cerebral salt wasting is of more than theoretical importance, insofar as fluid restriction to correct hypotension may be dangerous in patients with salt wasting, particularly in those with vasospasm after ruptured intracranial aneurysms.

Arief has emphasized the hazards of postoperative hypotension. He has reported a series of 15 patients, all of them women, in whom severe hypotension followed elective surgery. About 48 h after these patients had recovered from anesthesia, their serum Na fell to an average level of 106 meq/L, the urinary sodium was 68 mmol/L, and the urinary osmolality was 501 mosmol/kg. At this point, generalized seizures occurred, followed by respiratory arrest, requiring intubation. Of the 15 women, 5 died; there were no diagnostic pathologic findings, and no lesions of central pontine myelinolysis (see below) were found. Seven patients, whose serum Na was corrected slowly, improved over a period of several days but then developed a rapidly progressive diminution in alertness and increasing nausea, headache, and obtundation, followed by a recurrence of seizures and coma. These patients survived in a persistent vegetative state. We find the syndrome difficult to interpret. The initial hypotension was probably the result of SIADH. What happened later could have been the consequence of immediate and delayed hypoxia, but this is speculative.

An important consideration in the management of severe hypotension and hyperosmolality is the rapidity with which these abnormalities are corrected and the danger of provoking central pontine myelinolysis (CPM) and related brainstem, cerebellar, and cerebral lesions (extrapontine myelinolysis). These issues are considered below, in the section on CPM.

**Hypernatremia** Severe hypernatremia (Na >155 meq/L) and dehydration are observed in diabetes insipidus, the neurologic causes of which include head trauma with damage to the pituitary stalk (Chap. 27), nonketotic diabetic coma, protracted diarrhea in infants, and the deprivation of fluid intake in the stuporous patient. The last condition can be associated with a brain lesion that impairs consciousness. Exceptionally, in patients with chronic hydrocephalus, the hypothalamic thirst center is rendered inactive, and severe hypernatremia, stupor, and coma may follow a failure to drink. In hypernatremia from any cause, the brain volume is manifestly reduced in CT scans. Retraction of the cerebral cortex from the dura has been known to rupture a bridging vein and cause a subdural hematoma.

As is true for hypernatremia, the degree of CNS disturbance in hypernatremia is generally related to the rate at which the serum Na rises. Slowly rising values, to levels as high as 170 meq/L, are often well tolerated. Rapid elevations shrink the brain, especially in infants. Extremely high levels cause impairment of consciousness with asterixis, myoclonus, seizures, and choreiform movements. In addition, muscular weakness, rhabdomyolysis, and myoglobinuria have been reported.

It is to be noted that hypernatremia is usually accompanied by hypo-osmolality of the serum, and hypernatremia by hyperosmolality. However, there is no strict correlation between the degree of hypo- or hyperosmolality and neurologic dysfunction. Instead, the rapidity of change, as already emphasized, plays a major role. In hypernatremia associated with a brain lesion that impairs consciousness, the serum Na is often elevated with a brain lesion that impairs consciousness. Exceptionally, in patients with chronic hydrocephalus, the hypothalamic thirst center is rendered inactive, and severe hypernatremia, stupor, and coma may follow a failure to drink. In hypernatremia from any cause, the brain volume is manifestly reduced in CT scans. Retraction of the cerebral cortex from the dura has been known to rupture a bridging vein and cause a subdural hematoma.

Hypo- and Hyperkalemia

The main clinical effect of hyperkalemia (K, 2.0 meq/L or less) is generalized muscular weakness (see Chap. 48). A confusional state may also be added but is infrequent. Both conditions are readily corrected by adding K to intravenous fluid and infusing it at no more than 4 to 6 meq/h. Hyperkalemia (above 7 meq/L) also may manifest itself by generalized muscle weakness, although the main effects are changes in the electrocardiogram (ECG), possibly leading to cardiac arrest.

Other Metabolic Encephalopathies

Limitation of space permits only brief reference to other metabolic disturbances that may present as episodic confusion, stupor, or coma. The most important members of this group are summarized below.

**Hypercalcemia** This is defined as an elevation of the serum calcium concentration above 10.5 mg/dL. If the serum protein content is normal, Ca levels greater than 12 mg/dL are required to produce neurologic symptoms. However, with low serum albumin levels, an increased proportion of the serum Ca is in the unbound or ionized form (upon which the clinical effects depend), and symptoms may occur with serum Ca levels as low as 10 mg/dL.

In young persons, the most common cause of hypercalcemia is hyperparathyroidism (either primary or secondary); in older persons, osteolytic bone tumors, particularly metastatic carcinoma and multiple myeloma, are often causative. Less common causes are vitamin D intoxication, prolonged immobilization, hyperthyroidism, sarcoidosis, and decreased calcium excretion (renal failure).

Anorexia, nausea and vomiting, fatigue, and headache are usually the initial symptoms, followed by confusion (rarely a delirium) and drowsiness, progressing to stupor or coma in untreated patients. Diffuse myoclonus and rigidity occur occasionally, as do elevations of spinal fluid protein (up to 175 mg/100 mL). Convulsions occur uncommonly.

**Hypocalcemia** The usual manifestations of hypocalcemia are tetany and seizures. With severe and persistent hypocalcemia, altered mental status in the form of depression, confusion, dementia, or personality change can occur. Even coma may result, in which case there may be papilledema due to increased intracranial pressure. Aside from the raised pressure, the CSF shows no consistent abnormality. This increase in intracranial pressure may be manifest by headache and papilledema without altered mentation. Hyperparathyroidism is discussed further on.

Metabolic acidosis from any cause produces a typical syndrome of drowsiness, stupor, and coma, with dry skin and Kussmaul breathing. The CNS depression does not correlate with the concentration of ketones. Probably there are associated effects on neurotransmitters, consequent to the increase in osmolality and release of intracellular calcium.

In infants and children, acidosis may occur in the course of hyperammonemia, isovaleric acidemia, maple syrup urine disease, lactic and glutaric acidemia, hyperglycinemia, and other disorders, which are described in detail in Chap. 37. High-voltage slow activity predominates in the EEG, and correction of the acidosis or
elevated ammonia level restores CNS function to normal provided that coma was not prolonged or complicated by hypoxia or hypotension. In uncomplicated acidic coma, we have observed no recognizable neuropathologic change by light microscopy.

Encephalopathy due to Addison disease (adrenal insufficiency) may be attended by episodic confusion, stupor, or coma without special identifying features; it is usually precipitated in the addisonian patient by infection or surgical stress. Hemorrhagic destruction of the adrenals is another cause. Hypotension and diminished cerebral circulation and hypoglycemia are the most readily recognized metabolic abnormalities; measures that correct these conditions reverse the adrenal crisis in some instances.

Myxedema is well known to cause a mental dullness, drowsiness, and stupor. We have encountered several instances of an encephalopathy with myxedonous in patients with Hashimoto thyroiditis; some of these patients had nearly normal thyroid function studies, but they had high titers of antithyroglobulin antibodies; the encephalopathy in the latter case is thought to be on an autoimmune basis. These are discussed in a later part of the chapter.

The various neurologic syndrome that are consequent upon electrolytic disorders have been reviewed by Laureno.

Central Pontine Myelinolysis

In 1950, Adams and Victor observed a rapidly evolving quadriplegia and pseudobulbar palsy in a young alcoholic man who had entered the hospital 10 days earlier with symptoms of alcohol withdrawal. Postmortem examination several weeks later disclosed a large, symmetrical, essentially demyelinating lesion occupying the greater part of the basis pontis. Over the next 5 years, three additional cases (two alcoholic patients and one with scleroderma) were studied clinically and pathologically, and in 1959 these four cases were reported by Adams et al under the heading of central pontine myelinolysis (CPM). This term was chosen because it denotes both the specific anatomic localization of the disease and its essential pathologic attribute: the remarkably unsystematic dissolution of the sheaths of medullated fibers. Once attention was focused on this distinctive lesion, many other reports appeared. The exact incidence of this disease is not known, but in a series of 3548 consecutive autopsies in adults, the typical lesion was found in 9 cases, or 0.25 percent (Victor and Laureno).

Pathologic Features

One is compelled to define this disease in terms of its pathologic anatomy, because this stands as its most certain feature. Transverse sectioning of the fixed brainstem discloses a grayish discoloration and fine granularity in the center of the basis pontis. The lesion may be only a few millimeters in diameter, or it may occupy almost the entire basis pontis. There is always a rim of intact myelin between the lesion and the surface of the pons. Posteriorly it may reach and involve the medial tegmenti and, in the most advanced cases, other tegmental structures as well. Very rarely, the lesion encroaches on the midbrain, but inferiorly it does not extend as far as the medulla. Exceptionally the extensive pontine lesions may be associated with identical myelinolitic foci symmetrically distributed in the thalamus, subthalamic nucleus, striatum, internal capsule, amygdaloid nuclei, lateral geniculate body, white matter of the cerebellum folia, and deep layers of the cerebral cortex and subjacent white matter (“extrapontine myelinolysis”; Wright et al).

Microscopically, the fundamental abnormality consists of destruction of the medullated sheaths throughout the lesion, with relative sparing of the axis cylinders and intactness of the nerve cells of the pontine nuclei. These changes always begin and are most severe in the geometric center of the pons, where they may proceed to frank necrosis of tissue. Reactive phagocytes and glial cells are in evidence throughout the demyelinating focus, but no oligodendrocytes are seen. Signs of inflammation are conspicuously absent.

This constellation of pathologic findings provides easy differentiation of the lesion from infarction and the inflammatory demyelinizations of multiple sclerosis and postinfectious encephalomyelitis. Microscopically, the lesion resembles that of Marchiafava-Bignami disease (Chap. 41), in which it is rarely associated. Wernicke disease is not infrequently associated with CPM, but the lesions bear no resemblance to one another in terms of topography and histology.

Clinical Features

Central pontine myelinosis occurs only sporadically, with no hint of a genetic factor. The two sexes are affected equally, and the patients do not fall into any one age period. Whereas the cases first reported had occurred in adults, there are now many reports of the disease in children, particularly in those with severe burns (McKee et al).

The outstanding clinical characteristic of CPM is its invariable association with some other serious, often life-threatening disease. In more than half the cases, it has appeared in the late stages of chronic alcoholism, often in association with Wernicke disease and polyneuropathy. Among the other medical conditions and diseases with which CPM has been conjoined are chronic renal failure being treated with dialysis, hepatic failure, advanced lymphoma, carcinoma, cachexia from a variety of other causes, severe bacterial infections, dehydration and electrolyte disturbances, acute hemorrhagic pancreatitis, and pellagra.

In many patients with CPM there are no symptoms or signs that betray the pontine lesion, presumably because it is so small, extending only 2 to 3 mm on either side of the median raphe and involving only a small portion of the corticopontine or pontocerebellar fibers. In others, the presence of CPM is obscured by coma from a metabolic or other associated disease. Probably only a minority of cases, exemplified by the first patient whom we observed, are recognized during life. In this patient, the serious alcoholic with delirium tremens and pneumonia, there evolved, over a period of several days, a faciocapillary paralysis of all four limbs and an inability to chew, swallow, or speak (thus simulating occlusion of the basilar artery). Pupillary reflexes, movements of the eyes and lids, corneal reflexes, and facial sensation were spared. In some instances, however, conjugate eye movements are limited, and there may be nystagmus. With survival for several days, the tendon reflexes become more active, followed by spasticity and extensor posturing of the limbs on painful stimulation. Some patients are left in a state of mutism and paralysis with relative intactness of sensation and comprehension, i.e., the “locked-in syndrome.”

The capacity of CT scanning but especially MRI to visualize the pontine lesion has greatly increased the frequency of premortem diagnoses. The MRI discloses a characteristic “bat wing” lesion of the basis pontis in some cases (Fig. 40-2), although this change may become evident only several days after the onset of symptoms. Brainstem auditory evoked responses also disclose the lesions that encroach upon the pontine tegument.

Figure 40-2 T2-weighted MR image showing the typical lesion of central pontine myelinolysis in an alcoholic patient.

Variants of this syndrome are being encountered with increasing frequency. Two of our elderly patients, with confusion and stupor—but without signs of corticospinal or pseudobulbar palsy—recovered; however, they were left with a severe dystarthis and cerebellar ataxia lasting many months. By CT and MRI, no lesions were observed in the tegumentum of the brainstem and cerebellum. After 6 months, these patients’ nervous system function was essentially normal; originally both had serum Na levels of 99 meq/L, but information about the rate of restoration of serum Na was not available. Another of our patients developed a typical locked-in syndrome after the rapid correction of a serum sodium of 104 meq/L. He showed large symmetrical lesions of the frontal cortex and underlying white matter but no pontine lesion (by MRI).

Brainstem infarction due to basilar artery occlusion may be a source of confusion to the clinician. Sudden onset or step-like progression of the clinical state, asymmetry of long tract signs, and more extensive involvement of tegmental structures of the pons as well as the midbrain and thalamus are the distinguishing characteristics of vertebrobasilar thrombosis or embolism. Massive pontine demyelination in acute or chronic relapsing multiple sclerosis rarely produces a pure basis
Kernicterus syndrome. Other features of this disease provide the clues to correct diagnosis.

**Etiology and Pathogenesis**

Nutritional deficiency is a commonly invoked cause of CPM, because it is observed so frequently in chronic wasting diseases and particularly in malnourished alcoholics, often in association with Wernicke disease. Nevertheless, there are cases in which a nutritional factor cannot be incriminated. As mentioned in the section on hypotonia, the rapid correction of the serum sodium to normal or higher than normal levels plays an important role in the genesis of CPM. Significant hyponatremia, always less than 130 meq/L and usually much less, has been present in all our patients and in all the patients reported by Burcar and colleagues and by Karp and Laureno. The importance of serum sodium in the pathogenesis of this disease was demonstrated experimentally by Laurore. Dogs were made severely hypotonic (100 to 115 meq/L) by repeated injections of vasopressin and intraperitoneal infusions of water. The hyponatremia and profound weakness were both corrected by infusion of hypertonic (3%) saline, following which the dogs developed an rigid quadriparesis and showed, at autopsy, pontine and extrapontine lesions that were indistinguishable in their distribution and histologic features from those of the human disease. Hyponatremia alone or slowly corrected hyponatremia (<15 meq/L in the initial 24 h) did not produce the disease.

McKee and colleagues have adduced evidence that extreme serum hyperosmolality and not necessarily the rapid correction or overcorrection of hyponatremia is the important factor in the pathogenesis of CPM. They found the characteristic pontine and extrapontine lesions in 10 of 139 severely burned patients who were examined after death. Each of their patients with CPM had suffered a prolonged, nonterminal episode of severe serum hyperosmolality, which coincided temporally with the onset of the lesion, as judged by its histologic features. Hyponatremia was not present, and no other independent factors—such as hypotremia, hyperglycemia, or azotemia—correlated with the development of CPM.

Therapeutic guidelines for the correction of hyponatremia are still being considered. Karp and Laurore, on the basis of their experience and that of Sterness et al, have suggested that the hyponatremia be corrected by no more than 10 meq/L in the initial 24 h and by no more than 21 meq/L in the initial 48 h.

At the present time all one can say is that specific regions or zones of the brain, most often the center of the basis pontis, have a special susceptibility to some acute metabolic fault (possibly rapid correction or overcorrection of hyponatremia, possibly hyperosmolality), analogous perhaps to the selective vulnerability of the corpus callosum and anterior commissure in Marchiafava-Bignami disease (Chap. 41).

**METABOLIC DISEASES PRESENTING AS PROGRESSIVE EXTRAPYRAMIDAL SYNDROMES**

These syndromes are usually of mixed type—i.e., they include a number of basal ganglionic and cerebellar symptoms in various combinations and may emerge as part of an acquired chronic hepatic cerebellar degeneration or chronic hypoparathyroidism or as sequel to kernicterus or hypoxic or hypoglycemic encephalopathy. The basal ganglionic-cerebellar symptoms that result from severe anoxia and hypoglycemia have been described in the preceding section and in Chap. 4 and Chap. 5. Kernicterus is considered on page 1085, with the neurologic diseases of infancy and childhood, and calcification of the basal ganglia and cerebellum (due to chronic hypothyroid deficiency) on page 1032, with the inherited metabolic disorders, as well as further on in this chapter. It must be realized, however, that acquired hypoparathyroidism may also lead to calcification of the basal ganglia (see below, under “Metabolic Diseases Presenting as Cerebellar Ataxia”). We have observed choreiform movements in patients with hyperosmolar coma and with severe hyperpyrexemia, ascribed by Weiner and Klawans to a disturbance of dopamine metabolism.

**Chronic Acquired (Non-Wilsonian) Hepatocerebral Degeneration**

Patients who survive an episode or several episodes of hepatic coma are sometimes left with residual neurologic abnormalities, such as tremor of the head or arms, asterixis, grimacing, choreic movements and twitching of the limbs, dysarthria, ataxia of gait, or impairment of intellectual function; these symptoms may worsen, with repeated attacks of stupor and coma. In a few patients with chronic liver disease, permanent neurologic abnormalities become manifest in the absence of discrete episodes of hepatic coma. In either event, patients with these abnormalities deteriorate neurologically over a period of years. Examination of the brains of such patients discloses foci of destruction of nerve cells and other parenchymal elements in addition to a widespread transformation of astrocytes—changes that are very much the same as those of Wilson disease.

Probably the first to describe the acquired type of hepatic cerebellar degeneration was van Woorck (1914), whose report appeared only 2 years after Wilson's classic description of the familial form. A full account of the cases reported since that time as well as of our own extensive experience with this disorder is contained in the article by Vieray, Adams, and Cole, listed in the References.

**Clinical Features**

The first symptom may be a tremor of the outstretched arms, fleeting arrhythmic twitches of the face and limbs (resembling either myoclonus or chorea), or a mild unsteadiness of gait with action tremor. As the condition evolves over months or years, a rather characteristic dysarthria, ataxia, wide-based, unsteady gait, and choreoathetosis—mainly of the face, neck, and shoulders—are joined in a common syndrome. Mental function is slowly altered, taking the form of a simple dementia with a seeming lack of concern about the illness. A coarse, rhythmic tremor of the arms appearing with certain sustained postures, mild cogwheel rigidity, and diffuse EEG slowing are consistent with the diagnosis. Other less frequent signs are muscular rigidity, grasp reflexes, tremor in repose, nystagmus, asterixis, and action or intention myoclonus. In essence, each of the neurologic abnormalities that are observed in patients with acute hepatic encephalopathy are also part of chronic hepaticocerebral degeneration, the only difference being that the abnormalities are evanescent in the former and irreversible and progressive in the latter.

As a rule, all measurable hepatic functions are altered, but the chronic neurologic disorder correlates best with an elevation of serum ammonia (usually greater than 200 ng/dL). Unlike Wilson disease, where the cirrhosis usually remains occult for a long time, there is no question about its presence in the acquired syndrome; jaundice, ascites, and encephalopathy are present in most of the acquired cases. Wilson disease, which enters into the differential diagnosis, is usually not difficult to differentiate on clinical grounds, although the distinction in some cases requires the critical evidence of familial occurrence, Kayser-Fleischer rings (never found in the acquired type), and certain biochemical abnormalities (diminished serum ceruloplasmin, elevated serum copper, and urinary copper excretion—see page 1026).

**Pathology**

The chronic cerebellar symptoms, like the transient ones, may occur with all varieties of chronic liver disease. The cerebral lesion is localized more regularly in the cortex than is the case in Wilson disease. In some specimens an irregular gray line of necrosis or gliosis can be observed throughout both hemispheres, and the lenticular nuclei may appear shrunken and discolored. These lesions resemble hypoxic ones and may be concentrated in the vascular border zones, but they tend to spare the hippocampus, globus pallidus, and deep foci of the cerebellar cortex—the sites of predilection in anoxic encephalopathy. Microscopically, a widespread hyperplasia of protoplasmic astrocytes is visible in the deep layers of the cerebral cortex and in the cerebellar cortex as well as in thalamic and lenticular nuclei and other nuclear structures of the brainstem. In the necrotic zones, the medullated fibers and nerve cells are destroyed, with marginal fibrous gliosis; at the corticomedullary junction, in the stratum (particularly in the superior pole of the putamen), and in the cerebellar white matter, polymicrocavitation may be prominent. Protoplasmic astrocytic nuclei contain PAS-positive glycogen granules. Some nerve cells appear swollen and chromatolyzed, taking the form, we believe, of the so-called Opiaski cells usually associated with Wilson disease. The similarity of the neuropathologic lesions in the familial and acquired forms of hepaticocerebral disease is striking.

**Pathogenesis**

It is evident that a close relationship exists between the acute, transient form of hepatic encephalopathy (hepatic coma) and the chronic, largely irreversible hepatic cerebellar syndrome, frequently one blends imperceptibly into the other. This relationship is reflected in the pathologic findings as well; the astrocystic hyperplasia and PAS-positive inclusions are identical in both forms of the disease, and the distribution of the destructive lesions follows closely the distribution of the astrocystic change. Also, both disorders are characterized by hyperammonemia, episodic in one and persistent in the other. Reducing the serum ammonia by the measures that are effective in acute hepatic encephalopathy will cause a recession of many of the chronic neurologic abnormalities, not completely but to an extent sufficient to permit the patient to function better.

It appears that the parenchymal damage in the chronic disease simply represents the most severe degree of a pathologic process that in its mildest form is reflected in an astrocystic hyperplasia alone.

**Kernicterus**

Kernicterus, formerly a common cause of congenital choreoathetosis, has now been virtually eliminated. It is discussed on page 1085.
Hypoparathyroidism

This condition and pseudohypoparathyroidism (page 1032) were mentioned in relation to the hereditary metabolic disorders. In the past, the usual cause of hypoparathyroidism was surgical removal of the parathyroid glands during subtotal thyroidectomy, although there were always idiopathic cases as well. With the more widespread use of radiation and drug therapy for thyroid disease, the number of surgically created cases has become small in proportion to nonsurgical ones. The latter may occur in pure form, presumably as an agenesis of the parathyroid glands with unmeasurable levels of parathyroid hormone in the blood, or as part of the DiGeorge syndrome of agenesis of the thymus and parathyroid glands, organs that are embryologically derived from the third and fourth branchial arches. Hypoparathyroidism is also part of a familial syndrome, pachydermoperiostosis, and adrenal function is also affected. Other causes are intestinal malabsorption, pancreatic insufficiency, and vitamin D deficiency. In all instances the low levels of parathormone and normal responses to injected hormone permit the recognition of a primary defect of the parathyroid glands and distinguish it from all other conditions in which there is hypocalcemia and hyperphosphatemia.

The clinical manifestations, mainly attributable to the effects of hypocalcemia, are tetany, paresthesias, muscle cramps, laryngeal spasm, and convulsions. Children with this disease may be irritable and show personality changes. In adults with chronic hypocalcemia, calcium deposits occur in the basal ganglia, dentate nuclei, and cerebellar cortex. In such patients we have observed unilateral tremor, a restless choreoathetotic hand, bilateral rigidity, slowness of movement and flexed posture resembling Parkinson disease, and ataxia of the limbs and gait—in various combinations. Interestingly, the multiple skeletal and developmental abnormalities that characterize both pseudo- and pseudo-hypoparathyroidism (short stature, round face, short neck, stocky body build, shortening of metacarpal and metatarsal bones and phalanges from premature epiphyseal closure) are rarely seen in pure hypoparathyroidism.

A similar deposition of ferrocoll in the walls of small blood vessels of the lenticular and dentate nuclei and to a lesser extent in other parts of the brain is a common finding and is similar to that observed in normal older individuals but more severe. It also occurs in animals. Occasionally it reaches a degree of severity that destroys striatal or dentate neurons. In such cases, films of the skull and particularly CT scans will reveal the deposits. Cases of this type have been reported for years (page 1032). The cause of the deposits is unknown. Apparently some protein in the capillary walls has an avidity for both calcium and iron.

**METABOLIC DISEASES PRESENTING AS PSYCHOSIS AND DEMENTIA**

Cerebellar Ataxia Associated with Myxedema

The association of myxedema and cerebellar ataxia has been mentioned sporadically in medical writings since the latter part of the nineteenth century. Interest in this problem was revived in more recent years by Jellinek and Kelly, who described 6 such cases. All of them showed an ataxia of gait; in addition, some degree of ataxia of the arms and dexterity were present in 4 instances, and nystagmus in 2. Cremers and coworkers have reported a similar clinical experience, based on a study of 24 patients with either primary or secondary hypothyroidism.

There have been only a few reports of the pathologic changes, and these are far from satisfactory. The myxedematous patient described by Price and Netsky had also been a serious alcoholic, and the clinical signs (ataxia of gait and of the legs) and pathologic changes (loss of Purkinje cells and gliosis of the molecular layer, most pronounced in the vermis) cannot be attributed to those due to alcoholism and malnutrition. Scattered throughout the nervous system of their case were unusual glycogen-containing bodies, similar but not identical to corpora amylacea. These structures, designated myxedema bodies by Price and Netsky, were also observed in the cerebellar white matter of a second case of myxedema; there were no other neuropathologic changes, however, and this patient had shown no ataxia during life. It is difficult to know whether these peculiar bodies have anything to do with myxedema. If they do, it should be possible to demonstrate them in more than two cases. We have not seen them in one carefully studied case of myxedema, nor have they been described by others. Thyroid medication corrects the defect in motor coordination, raising doubt as to whether it could be based on a visible structural lesion.

Other metabolic disorders, some heritable, in which ataxia may be a leading manifestation include Whipple disease ([Chap. 33]), GM, gangliosidosis, sprue (discussed below), and a large number of neonatal and infantile aminoacidopathies. The various causes of cerebellar ataxia, including these, are summarized in **Table 5-1** (page 97).

**Effects of Hyperthermia on the Cerebellum**

The damaging effects of hyperthermia, like those of anoxia, involve the brain diffusely. In the case of hyperthermia, however, the changes are disproportionately severe in the cerebellum. The acute manifestations of profound hyperthermia are coma and convulsions, frequently complicated by shock and renal failure. Patients who survive the initial stage of the illness frequently show signs of widespread cerebral affection, such as confusion and pseudobulbar and spastic paralysis. These abnormalities tend to resolve gradually, leaving the patient with a more or less pure disorder of cerebellar function.

The most extensive account of the pathologic effects of hyperthermia is that of Malamud and colleagues. These authors studied 125 fatal cases of heat stroke, but their observations are probably applicable to hyperthermia of other types. In patients who survived less than 24 h, the changes consisted mainly of a loss of some of the Purkinje cells and swelling, pyknosis, and disintegration of those that remained. In cases surviving beyond 24 h, there was almost complete degeneration of the Purkinje cells and dendrites throughout the cerebellar cortex. The changes in the cerebellar cortex were equally pronounced in the hemispheres and vermis. The unanswered question is whether high temperature alone is an adequate cause or must be combined with hypoxia and ischemia. It is of interest that we have not seen this syndrome in patients with infective fevers, malignant hyperthermia, or the malignant neuroleptic syndrome—either the neuropathologic changes or the clinical cerebellar syndrome in survivors.

Cerebellar Syndromes Associated with Celiac-Sprue and Jejunoileal Bypass

A progressive cerebellar ataxia of gait and limbs, sometimes with polymyoclonus in association with a gluten-sensitive enteropathy, has been the subject of several reports. The underlying lesion is a villus atrophy of the intestinal mucosa, consistent with celiac disease of children and sprue in adults. The neurologic disorder may appear several years after onset of the enteropathy and, in addition to ataxia, usually includes signs of peripheral neuropathy and, in some cases, myelopathy and encephalopathy (dementia). According to Finelli et al, neurologic abnormalities occur in approximately 10 percent of cases of adult celiac-sprue. This subject has been reviewed by Bhatia et al and recently by Hadjivassiliou et al. The latter authors emphasize the frequent occurrence of ataxia in patients with gluten sensitivity (indicated by circulating antibodies to gliadin) but without overt signs of bowel disease. There is also a strong association (in more than 90 percent of patients) with the HLA DQB class II genotype. The few cases that have come to autopsy have shown severe cerebellar atrophy, a finding that may also be disclosed by MRI. Hadjivassiliou et al observed lymphocytic infiltration and perivascular cuffing in the cerebellar cortex and peripheral nerves in one autopsy case but not in another, changes that led the group to represent immunologic injury to these parts. The main differential diagnostic considerations are paraneoplastic cerebellar degeneration and Whipple disease.

Vitamin E deficiency may induce a similar syndrome with features of spinocerebellar dysfunction (see page 1224).

**Jejunoileal bypass operation**, in addition to causing a chronic arthropathy, neuropathy, and vasculitic skin lesions, may give rise to an episodic confusion and cerebellar ataxia associated with a lactic acidosis and abnormalities of pyruvate metabolism. Overfeeding and fasting are provocative factors ([Dhalquist et al]).

**METABOLIC DISEASE PRESENTING AS PSYCHOSIS AND DEMENTIA**

The point has been made that milder forms of diseases that cause episodic stupor and coma, if persistent, may present as states of protracted confusion, difficult to distinguish from the demencias. Chronic hepatic encephalopathy and the syndromes of chronic hypoglycemia, chronic hypercalcemia (in multiple myeloma, metastatic carcinoma, or hyperparathyroidism), and dally may be included in this category. Unlike the common types of dementia described in [Chap. 21], the acquired metabolic diseases are nearly always accompanied by drowsiness, inattentiveness, and reduced alertness; i.e., by a clouding of the sensorium and inaccurate perceptions and interpretations—attributes that usually allow an encephalopathic confusion state to be distinguished from a dementia. If the onset of the illness is abrupt rather than gradual and of brief duration and if therapy reverses the condition, restoring full mental clarity, the conclusion is justified that one is dealing with a confusional state, but at any one time in the active phase of the disease the clinical state may resemble dementia.
In general hospitals, an episodic confusional state lasting days and weeks in the course of a medical illness or following an operation should always raise the suspicion of one of the aforementioned metabolic states. Usually, however, all of them can be excluded, and one falls back on a rather unsatisfactory interpretation—that a combination of drugs, fever, toxemia, and unspecifiable metabolic disorders is responsible. The “septic encephalopathy” described earlier in the chapter falls into this category.

In the endemic encephalopathies, which are described below, the clinical phenomena may be even more abstruse, although they often take the form of a unique psychosis. Confusional states may be combined with agitation, hallucinations, delusions, anxiety, and depression, and the time span of the illness may be in terms of weeks and months rather than days. Certain aspects of the endemic psychoses are discussed further on page 1641.

Cushing Disease and Corticosteroid Psychoses

Derangements of mental function that followed administration of adrenocorticotropic hormone (ACTH) and then of corticosteroids have become the prototypes of iatrogenic psychoses. The same disturbances of mental function may accompany Cushing disease (page 715).

Our experience with this neuropsychiatric condition was derived originally from observations of patients receiving ACTH and later from patients receiving prednisone for a variety of neurologic and medical metabolic diseases. With low doses there is usually no psychiatric effect other than a sense of well-being and decreased fatigability. At higher doses (60 to 100 mg/day of prednisone), approximately 10 to 15 percent of patients become overly active, emotionally labile, and unable to sleep. Unless the dose is promptly reduced, there follows a progressive shift in mood, usually toward euphoria and hypomania—but sometimes toward depression and then insensitivity, distractibility, and mild confusion. The EEG becomes less well modulated and slower frequencies appear. A minority of patients experience frank hallucinations and delusions, giving the illness a truly psychotic stamp and raising the suspicion of schizophrenia or manic-depressive disease. In nearly all instances, however, this mixture of confusion and mood change, in association with disordered cognitive function, distinguishes the iatrogenic corticosteroid psychosis. Withdrawal of medication relieves the symptoms, but full recovery may take several days to a few weeks, at which time, as with all confusional states and deliria, the patient has only a fragmentary recollection of events that occurred during the illness.

The neurologic basis of this condition is poorly understood. Its attribution to premorbid personality traits or a disposition to psychiatric illness is plausible but lacks convincing documentation. Part of the difficulty is the lack of knowledge of the role of these endocrine agents in normal cerebral metabolism. We have only incomplete knowledge, for example, as to how they act to reduce the volume of the edematous cerebral tissue around a tumor or to shrink the brain. Critical studies of cellular or subcellular metabolism and morphologic changes are lacking. “Cerebral atrophy” (ventricular enlargement and sulcal widening) has been shown radiologically in patients with Cushing disease and after a prolonged period of corticosteroid therapy, but the basis of this change also is unexplained (Momose et al).

In most cases, withdrawal of steroids has led to reversal of symptoms and reduction in ventricular size, documented by repeated CT scans.

In patients with Cushing disease due to adrenal or pituitary tumors, mental changes suggestive of dementia and enlarged ventricles are not unusual. Here again there is a peculiar combination of mood changes and impaired cognitive function. A frank psychosis may occur. This condition is described more completely in Chap. 57, and the attending polymorphia, in Chap. 51.

Thyroid Encephalopathies

Hyperthyroidism The neurology of thyrotoxicosis has proved to be particularly elusive. Allusions to psychosis are frequent in the medical literature, and some thyrotoxic patients have been observed with mental confusion, seizures, manic or depressive attacks, and delusions. Tremor is almost universal, and chorea occurs occasionally in various combinations with muscular weakness and atrophy, periodic paralysis, and myasthenia. In descriptions of the chorea, it is often not clear whether it was chorea, tremor, myoclonus, or just flickeliness that was observed. Treatment of the hyperthyroidism gradually restores the mental state to normal, leaving one with no explanation of what had happened to the CNS.

Thyroid crisis or “storm” refers to a fulminating increase in the symptoms and signs of thyrotoxicosis—extreme restlessness, tachycardia, fever, vomiting, and diarrhea—leading to delirium or coma. In the past, this was a not uncommon postoperative event in patients poorly prepared for thyroid surgery. Now it is seen mainly in patients with inadequately treated or untreated thyrotoxicosis complicated by serious medical or surgical illness.

Hashimoto Encephalopathy Shaw and colleagues have described an encephalopathy consisting of confusion, altered consciousness, and prominent myoclonus, sometimes relapsing, in patients with Hashimoto disease (“Hashimoto encephalopathy”). Curiously, most have had normal thyroid function. There are, however, high titers of several antithyroid antibodies, including antibodies against thyroid peroxidase and thyroglobulin. Seizures—including myoclonic and rarely nonconvulsive status epilepticus—hemiparesis, ataxia, psychosis, and unusual tremors have been reported in individual cases. Often there are others in the family with autoimmune diseases. It has been the myoclonic aspect of the encephalopathy, a feature of all of our cases, that has led to consideration of this diagnosis. We have encountered incomplete knowledge, for example, as to how they act to reduce the volume of the edematous cerebral tissue around a tumor or to shrink the brain. Critical studies of cellular or subcellular metabolism and morphologic changes are lacking. “Cerebral atrophy” (ventricular enlargement and sulcal widening) has been shown radiologically in patients with Cushing disease and after a prolonged period of corticosteroid therapy, but the basis of this change also is unexplained (Momose et al).

Hypothyroidism As a rule, the myxedematous patient is slow to react and psychomotor activity is reduced; but only in exceptional cases have we noted a significant change in cerebral function. When such a change has been observed, we have been more impressed with drowsiness, inattentiveness, and apathy. In two personally observed cases, the somnolence was so extreme that the patients could not stay awake long enough to be fed or examined. They were in a state of hypothermic stupor but exhibited no other neurologic abnormality. The extreme somnolence can be reversed within a few days by thyroid medication.

Hypothyroidism is associated with a number of distinctive myopathic disturbances, which are discussed in Chap. 51. The ataxia and peripheral neuropathy that are sometimes observed in patients with myxedema are described in this chapter (above) and in Chap. 46, respectively.

Cretinism and Neonatal Myxedema This form of severe hypothyroidism, occurring during intrauterine life (hypothyroidism in mother and fetus) or postnatally as a hereditary or acquired thyroid disease, is probably the most frequent and potentially preventable and correctable metabolic mental defect in the world. A perspective on its relative frequency among neonatal metabolic disorders is given in Table 37.1. Although the condition is most common in goitrous regions where there is a lack of iodine, it may also be due to any of several genetically determined defects in thyroid synthesis that have come to light in recent years (Vassart et al). In areas of endemic cretinism, additional factors may be operative, such as the widespread ingestion of cassava, which contains a toxic goitrogen that inhibits the uptake of iodine by the thyroid.

As a rule, the symptoms and signs of congenital thyroid deficiency are not recognizable at birth but become apparent only after a few weeks; more often the diagnosis is first made between the sixth and twelfth months of life. Psychologic jaundice tends to be severe and prolonged (up to 3 months), and this, along with widening of the posterior fontanelle and molting of the skin, should raise suspicion of the disease.

In general, two types of early life hypothyroidism are recognized—sporadic and endemic. The sporadic type occurs occasionally in developed countries (less than once in 4000 births) and is consequent upon a congenital metabolic or anatomic disorder of the thyroid gland. At birth, the gland is either absent or represented by a minute mass of tissue from which endemic cretinism, additional factors may be operative, such as the widespread ingestion of cassava, which contains a toxic goitrogen that inhibits the uptake of iodine by the thyroid.

In the endocrine encephalopathies, which are described below, the clinical phenomena may be even more abstruse, although they often take the form of a unique psychosis. Confusional states may be combined with agitation, hallucinations, delusions, anxiety, and depression, and the time span of the illness may be in terms of weeks and months rather than days. Certain aspects of the endemic psychoses are discussed further on page 1641.

Endemic cretinism is most common in developing countries, with an estimated incidence in these areas of 5 to 15 percent. DeLong and colleagues, on the basis of epidemiologic surveys in Ecuador, Zaire, and western China, have distinguished two forms of endemic cretinism—neurologic and myxedematous. The occurrence of the two different types is governed by the timing, duration, and severity of the iodine deficiency (Thilly et al).

The neurologic form of endemic cretinism is characterized by varying degrees of deaf-mutism or lesser degrees of hearing loss, dysarthria, proximal limb and truncal...
rigid-spastic motor disorder involving mainly the lower extremities, and mental deficiency of a characteristic type. In the most severely affected, there is also strabismus, kyphoscoliosis, underdevelopment of leg muscles, and frontal lobe release signs. Bone age, head size, and height are normal and there are none of the coarse facial features of the myxedematous form. In the so-called myxedematous form of endemic cretinism, short stature, microophaly, coarse facial features, and retarded psychomotor development are the main features. There is no deafness or spastic rigidity of the limbs. In typical instances, the face is pale and puffy; the skin dry; the hair coarse, scantly, and dry; the eyelids thickened; the heavy lips parted by the elongated tongue; the forehead low; and the base of the nose broad. There are fat pads above the clavicles and in the axillae. The abdomen is protuberant, often with an umbilical hernia, and the head is small—a physical appearance that prompted William Boyd to remark: “What was intended to be created in the image of God has turned out to be the pariah of nature, all for the want of a little thyroid.”

DeLong and others attribute neurologic cretinism to a lack of available iodine in the mother and fetus during the second and third trimesters of pregnancy; neither mother nor fetus elaborate thyroxin. The first and part of the second trimester developmental period, which does not require iodine or thyroxin, passes normally and the general morphology of the brain is normal. It is during the second trimester, when the cochleas and the neuronal population of the cerebral cortex and basal ganglia are forming, that these structures suffer irreparable damage. The effects of this midfetal hypothyroidism and iodine deficiency cannot be corrected by giving thyroxin at birth and thereafter. It can be prevented only by providing iodine therapy to the mother before and during the first trimester of pregnancy (Cao et al.)

The myxedematous form of cretinism is more likely to occur from lack of thyroid hormone in the late second and the third trimesters.

The mental defect ranges from apathy and absence of social interaction to an alert, cooperative state, but a backwardness in higher-order thinking and verbal facility is always evident. Retentive memory and apprehension are commensurate with overall intellectual competence as judged by the level of mental associations and capacity for abstract thought. The status of the thyroid gland varies; among neurologic cretins, about half are goitrous or have palpable glands; in the rest, the glands are atrophic; practically all the myxedematous cretins are athyreotic. Although typical examples of neurologic and myxedematous hypothyroidism are readily distinguished, both types may exist in the same endemic area and the stigmata of both forms may be recognized in the same individual. The QRS complex of the electrocardiogram is of low voltage; the EEG is slower than normal, with less alpha activity; the CSF contains an excess of protein (50 to 150 mg/dL); and the serum T3 and T4, protein-bound iodine, and radioactive iodine uptake are all subnormal. Serum cholesterol is increased (300 to 600 mg/dL).

At autopsy the brain of neurologic cretinism, though small, is normally formed, with all central and brainstem structures and cortical sulcation intact. A reduction in number of nerve cells was described by Marinesco, especially in the fifth cortical layer, but others have not confirmed this finding. The use of Golgi and other silver techniques has shown decreased interneuronal distances (packing density is increased, as in the immature cortex) and a deficiency of neuropil. The latter change is due to a poverty of dendritic branchings and crossings, and presumably there is a decrease of the synaptic surfaces of cells (Eavan). Thyroid hormone appears to be essential, not for neuronal formation and migration but for dendritico-axonic development and organization.

There is fairly substantial evidence that the administration of iodinated oil to hypothyroid women before and during the first trimester of pregnancy spares sporadic and endemic cretinism. Treatment begun during the second trimester protects the fetal brain to a varying degree. Treatment that is started after the beginning of the third trimester does not improve the neurologic status, although head growth and statural development may improve slightly (Cao et al.). In sporadic cretinism, if the condition is recognized early, say at birth, and treated consistently with potent thyroid hormones, statural and mental development can be stimulated to normal or near-normal levels. Extent of recovery depends on the severity and duration of intrauterine hypothyroidism, i.e., its duration before treatment was begun and the adequacy of therapy. In most patients, some degree of mental deficiency persists throughout life.

**Pancreatic Encephalopathy**

This term was introduced by Rothermich and von Haam in 1941 to describe what they considered to be a fairly uniform clinical state in patients with acute abdominal symptoms referable to pancreatic disease, mainly pancreaticitis. The encephalopathy, as they described it, consists of an agitated, confused state, sometimes with hallucinations and clouding of consciousness, dysartria, and changing rigidity of the limbs—all of which fluctuate over a period of hours or days. Coma and quadriplegia have also been reported. At autopsy, a variety of lesions have been described; two cases have had central pontine myelinolysis and others have had small foci of necrosis and edema, petechial hemorrhages, and “demyelination” scattered through the cerebrum, brainstem, and cerebellum. These have been uncritically attributed to the action of released lipases and proteases from the action of pancreatic enzymes (see review of this subject by Sharf and Levy). The term pancreatic encephalopathy has also been applied to a depressive illness which seems to occur with disproportionate frequency before the symptoms of a pancreatic tumor become apparent.

The status of this entity, in the authors’ opinion, is uncertain. Pallis and Lewis also express reservations and suggest that before such a diagnosis can be seriously entertained in a patient with acute pancreatitis, one must exclude delirium tremens, shock, renal failure, hypoglycemia, diabetic acidosis, hyperosmolality, and hypocalcemia or hypercalcemia—any one of which may complicate the underlying disease. Other cases conform to the encephalopathy of multigain failure discussed earlier. Several patients in our care who were thought originally to have pancreatic encephalopathy proved to have sequential strokes from marantic endocarditis.

**CHAPTER REFERENCES**

Among nutritional disorders, those of the nervous system occupy a position of special interest and importance. The early studies of beriberi, at the turn of the century, were largely responsible for the discovery of thiamine, and consequently for the modern concept of deficiency disease. Despite the notable achievements in the science of nutrition that followed the discovery of vitamins, diseases due to nutritional deficiency—and particularly those of the nervous system—continue to represent a worldwide health problem of serious proportions. In Far Eastern communities, where the diet consists mainly of highly milled rice, there is still a significant incidence of beriberi. In other underdeveloped countries, deficiency diseases are endemic, the result of chronic dietary deprivation. And the ultimate effects on the nervous system of mass starvation, involving entire nations of the African continent, is alarming to contemplate.

It comes as a surprise to many physicians that deficiency diseases are also common in the United States and other parts of the western world. To a large extent this is attributable to the prevalence of alcoholism. Relatively less common causes are dietary faddism and impaired absorption of dietary nutrients (which occurs in patients with celiac sprue, pernicious anemia, or surgical exclusion of portions of the gastrointestinal tract—for treatment of obesity or other reasons). Finally, there are the deficiencies induced by the use of vitamin antagonists or certain drugs, such as isonicotinic acid hydrazide (INH), which is used in the treatment of tuberculosis and interferes with the enzymatic function of pyridoxine.

General Considerations

The term deficiency is used throughout this chapter in its strictest sense, to designate disorders that result from the lack of an essential nutrient(s) in the diet or from a conditioning factor that increases the need for these nutrients. The most important of these nutrients are the vitamins, more specifically, members of the B group—thiamine, nicotinic acid, pyridoxine, pantothenic acid, riboflavin, folic acid, and cobalamin (vitamin B12). Most deficiency diseases cannot be related to the lack of a single vitamin (subacute combined degeneration of the cord, due to vitamin B12 deficiency, is a notable exception). Usually the effects of several vitamin deficiencies can be recognized. This statement should not obscure the fact that particular manifestations of deficiency disease (e.g., the ocular palsies of Wernicke disease) are indeed related to a deficiency of a specific nutrient, nor should it diminish the need to identify such relationships.

Nutritional diseases of the nervous system are not simply a matter of vitamin deprivation, however. Practically always, the general signs of undernutrition, such as circulatory abnormalities and loss of subcutaneous fat and muscle bulk, are associated. Furthermore, a total lack of vitamins, as in starvation, is rarely associated with the classic deficiency syndromes of beriberi or pellagra; a certain amount of food is necessary to produce them. An excessive intake of carbohydrate relative to the supply of thiamine favors the development of a thiamine deficiency state. All deficiency diseases, including those of the nervous system, are influenced by factors such as exercise, growth, pregnancy, and infection, which increase the need for essential nutrients, and by disorders of the liver and the gastrointestinal tract, which may interfere with the synthesis and absorption of these nutrients.

As already mentioned, alcoholism is an important factor in the causation of nutritional diseases of the nervous system. Alcohol acts mainly by displacing food in the diet but also by adding carbohydrate calories (alcohol is burned almost entirely as carbohydrate), thus increasing the need for thiamine. There is some evidence as well that alcohol impairs the absorption of thiamine and other vitamins from the gastrointestinal tract.

In infants and young children, a reduction of protein and caloric intake (so-called protein-calorie malnutrition, or PCM) has a devastating effect upon body growth. Whether or not PCM also hinders the growth of the brain, with consequent effects upon intellectual and behavioral development, cannot be answered as readily. The data bearing on this matter are the last part of the chapter.

Deficiency diseases of the nervous system may occur in pure form and are so described in the following pages. But more often, the symptoms of other deficiencies are added, i.e., the deficiency diseases occur in various combinations. Characteristic also of the nutritional diseases is the involvement of both the central and peripheral nervous systems, an attribute shared only with certain hereditary metabolic disorders.

The following deficiency diseases are discussed in this chapter:

1. Wernicke disease and Korsakoff psychosis
2. Nutritional polyneuropathy (neuropathic beriberi)
3. Deficiency amblyopia (nutritional optic neuropathy; "tobacco-alcohol" ambioplia)
4. Pellagra (with some remarks on spinal spastic ataxia, and nicotinic acid deficiency encephalopathy)
5. The syndrome of amblyopia, painful neuropathy, and orogenital dermatitis ("Strachan syndrome")
6. Subacute combined degeneration of the spinal cord (vitamin B12 deficiency)
7. Neurologic disorders due to a deficiency of pyridoxine and possibly other B vitamins (pantothenic acid, riboflavin, folic acid)
8. Vitamin E deficiency

In addition, attention is drawn to several distinctive neurologic disorders in which nutritional deficiency may play a role, although this has not been proved: (1) “alcoholic” cerebellar degeneration, (2) central pontine and extrapontine myelinolysis, and (3) primary degeneration of the corpus callosum (Marchialfava-Bignami disease). Also, some comments are made about PCM, the neurologic disorders consequent upon intestinal malabsorption, and the rare, hereditary vitamin-responsive diseases. Deficiencies of trace elements, because of their rarity, are not discussed; only iodine deficiency (cretinism) is of much importance in humans, and it is discussed in the chapter on acquired metabolic disease. Deficiencies of other elements have been reviewed by Fowden and colleagues.

The Wernicke-Korsakoff Syndrome

Wernicke disease and the Korsakoff amnesic state are common neurologic disorders that have been recognized since the 1880s. Wernicke disease (originally called polioencephalitis hemorrhagica superiori) is characterized by nystagmus, abducens and conjugate gaze palsies, ataxia of gait, and mental confusion. These symptoms develop acutely or subacutely and may occur singly or, more often, in various combinations. Wernicke disease is due to nutritional deficiency, more specifically to a deficiency of thiamine, and is observed mainly, though far from exclusively, in alcoholics.

The Korsakoff amnesic state (Korsakoff psychosis) refers to a unique mental disorder in which retentive memory is impaired out of proportion to other cognitive functions in an otherwise alert and responsive patient. This amnesic disorder, like Wernicke disease, is most often associated with alcoholism and malnutrition, but it...
may be a symptom of various other diseases that have their basis in lesions of the medial thalamus or the inframedial portions of the temporal lobes, such as infarction in the territory of the temporal lobe branches of the posterior cerebral arteries, hippocampal damage after cardiac arrest, third ventricular tumors, or herpes simplex encephalitis. A Korsakoff type of memory disturbance may also follow lesions that involve the basal septal nuclei of the frontal lobe. Transient impairments of retentive memory of the Korsakoff type may be the salient manifestations of temporal lobe epilepsy, concussive head injury, and a unique disorder known as transient global amnesia. A persistent abnormality of this sort may be the most prominent feature of anoxic encephalopathy and of Alzheimer disease. The anatomic basis of the Korsakoff syndrome is discussed further in Chap. 21.

In the alcoholic, nutritionally deficient patient, the Korsakoff amnesic state is usually associated with Wernicke disease. Stated another way, Korsakoff psychosis is the psychic manifestation of Wernicke disease. For this reason and others elaborated below, the term Wernicke disease or Wernicke encephalopathy should be applied to a symptom complex of ophthalmoplegias, nystagmus, ataxia, and an acute aphasic-confusional state. If an enduring defect in learning and memory is added, the symptom complex is appropriately designated as the Wernicke-Korsakoff syndrome.

**Historical Note** In 1881, Carl Wernicke first described an illness of sudden onset characterized by paralysis of eye movements, ataxia of gait, and mental confusion. Swelling of the optic discs and retinal hemorrhages were also said to be present. His observations were made in 3 patients, of whom 2 were alcoholics and 1 was a young woman with persistent vomiting following the ingestion of sulfuric acid. In each of these patients there was progressive stupor and coma, culminating in death. The amnesic state described by Wernicke was primarily affecting the gait, but also the third and fourth ventricles and aqueduct of Sylvius; he considered these changes to be inflammatory in nature and confined to the gray matter, hence his designation "polioencephalitis hemorrhagica superioris." In the belief that Gâyet described an identical disorder in 1875, the term Gâyet-Wernicke is used frequently by French authors. Such a designation is hardly justified insofar as the clinical signs and pathologic change in Gâyet's patient differed from those of Wernicke's patients in all essential details.

In a similar vein, a number of early writers, beginning with Magnus Huss in 1852, made casual reference to a disturbance of memory in the course of chronic alcoholism. However, the first comprehensive account of this disorder was given by the Russian psychiatrist S. S. Korsakoff in a series of articles published between 1897 and 1898 (for English translation and commentary, see reference by Victor and Yakovlev). Korsakoff stressed the relationship between "neuritis" (a term used at that time for all types of peripheral nerve disease) and the characteristic disorder of memory, which he believed to be "two facets of the same disease" and which he called "psychosis polyneuritica." But he also made the points, generally disregarded by subsequent authors, that neuritis need not accompany the characteristic amnesic syndrome and that both disorders could affect nonalcoholic as well as alcoholic patients. His clinical descriptions were remarkably complete and have hardly been surpassed to the present day.

It is of interest that the relationship between Wernicke disease and Korsakoff polyneuritic psychosis was appreciated neither by Wernicke nor by Korsakoff. Murawieff, in 1897, stated that a single cause was responsible for both. The intimate clinical relationship was established by Bonhoeffer in 1904, who stated that in all cases of Wernicke disease he found neuritis and an amnesic psychosis. Confirmation of this relationship on pathologic grounds came many years later, for further details, see the monograph by Victor et al.

**Clinical Features** The incidence of the Wernicke-Korsakoff syndrome cannot be stated with precision, but it has, until recently, been a common disorder, judging from our experience. At the Cleveland Metropolitan General Hospital, for example, in a consecutive series of 3548 autopsies in adults (for the period 1963 to 1976), the pathognomonic lesions were found in 77 cases (2.2 percent). The disease affects males only slightly more frequently than females, and the age of onset is fairly evenly distributed between 30 and 70 years. In the past two decades, the incidence of the Wernicke-Korsakoff syndrome has fallen significantly in the alcoholic population. However, it is being recognized with increasing frequency among nonalcoholic patients in a variety of clinical settings, mainly iatrogenic ones.

The triad of clinical features described by Wernicke—ophthalmoplegia, ataxia, and disturbances of memory and consciousness—is still diagnostically useful provided that the diagnosis is suspected and the signs are carefully sought. Often the disease begins with ataxia, followed in a few days or weeks by mental confusion; or there may be the more or less simultaneous onset of ataxia, nystagmus, and ophthalmoplegia, with or without confusion. Less often, one component of this triad may be the sole manifestation of the disease. A description of each of the major manifestations follows.

**Oculomotor Abnormalities** The diagnosis of Wernicke disease is made most readily on the basis of the ocular signs. These consist of (1) nystagmus that is both horizontal and vertical, (2) weakness or paralysis of the lateral rectus muscles, and (3) weakness or paralysis of conjugate gaze. Usually there is some combination of these abnormalities (see Chap. 14).

Next to nystagmus, the most frequent ocular abnormality is lateral rectus weakness, which is bilateral but not necessarily symmetrical and is accompanied by diplopia and internuclear ophthalmoplegia. With complete paralysis of the lateral rectus muscles, nystagmus is initially absent in the abducting eyes, but it becomes evident as the weakness improves. The palsy of conjugate gaze varies from merely a nystagmus on extreme gaze to a complete loss of oculo motor movement in that direction. This applies to both horizontal and vertical movements, abnormalities of the former being somewhat more frequent. Paralysis of downward gaze is an unusual manifestation, but internuclear ophthalmoplegia is common. In advanced stages of the disease there may be a complete loss of oculo motor movements, and the pupils, which are usually spared, may become miotic and nonreacting. Plosis, small retinal hemorrhages, involvement of the near-far focusing mechanism, and evidence of optic neuropathy occur occasionally, but we have never observed papilledema in this disease. Although the aforementioned ocular signs are highly characteristic of Wernicke disease, disappearance of nystagmus and an improvement in ophthalmoplegias within hours or a day or two of the administration of thiamine will confirm the diagnosis.

**Ataxia** Essentially the ataxia is one of stance and gait, and in the acute stage of the disease it may be so severe that the patient cannot stand or walk without support. Lesser degrees are characterized by a wide-based stance and a slow, uncertain, short-stepped gait; the mildest degrees are apparent only in tandem walking. In contrast to the gross disorder of locomotion is the relative infrequency of a limb ataxia and intention tremor; when present, they are more likely to be elicited by heel-to-knee than by finger-to-nose testing. Scanning speech is present only rarely.

**Disturbances of Consciousness and Mentation** These are present in some form in all but 10 percent of patients. Four types of deranged mentation and anterograde amnesia may take place; for example, with repeated trials, the patient may learn mirror writing or to negotiate a maze, despite no recollection of ever having learned these tasks.

As indicated in Chap. 21, the core of the amnesic disorder is a defect in learning (anterograde amnesia) and a loss of past memories (retrograde amnesia). The defect in learning (memorization) can be remarkably severe. The patient may be incapable, for example, of committing to memory three simple facts (such as the examiner's name, the date, and the time of day); despite countless attempts; the patient can repeat each fact as it is presented, indicating that he understands what is wanted of him and that "registration" is intact; but by the time the third fact is repeated, the first may have been forgotten. However, certain subtle learning may take place; for example, with repeated trials, the patient may learn mirror writing or to negotiate a maze, despite no recollection of ever having learned these tasks.
Anterograde amnesia is always coupled with a disturbance of past or remote memory (retrograde amnesia). The latter disorder is usually severe in degree, though rarely complete, and covers a period that antedates the onset of the illness by several years. Characteristically, a few isolated events and information from the past are retained, but these are related without regard for the intervals that separated them or for their proper temporal sequence. Usually the patient "telescopes" events, sometimes the opposite. This aspect of the memory disorder becomes prominent as the initial (global confusional) stage of the illness subsides and some improvement in memory function occurs; this may account for certain instances of confabulation (see below).

It is probably true that memories of the recent past are more severely impaired than those of the remote past (Ribot's rule); language, computation, knowledge acquired in school, and all habitual actions are preserved. This is not to say that all remote memories are intact. These are not as readily tested as more recent memories, and the two are therefore difficult to compare. It is our impression that there are gaps and inaccuracies in memories of the distant past in practically all cases of the Korsakoff amnesic state and serious impairments in many of them.

It should be emphasized that the cognitive impairment of the Korsakoff patient cannot be explained in terms of memory loss alone, even though this is the most critical functional loss. Psychologic testing discloses that certain cognitive and perceptual functions that depend little or not at all on retentive memory are also impaired. The most consistent failure is with the digit symbol task and, to a lesser degree, with arithmetic and block design. Also, as a rule, the Korsakoff patient has no insight into his illness and is characterized apathetic and inert, lacking in spontaneous initiative and indifferent to everything and everybody around him. However, the patient has a relatively normal capacity to reason with data immediately before him.

Confabulation is generally considered to be a specific feature of Korsakoff psychosis. The validity of this view depends largely on how one defines confabulation, and there is no uniformity of opinion on this point. Our observations do not support the oft-repeated statement that the Korsakoff patient fills the gaps in his memory with confabulation. In the sense that gaps in memory exist and that whatever the patient supplies in place of the correct answers fills these gaps, the statement is incontrovertible. It is hardly explanatory, however. The implication that confabulation is a deliberate attempt to hide the memory defect, out of embarrassment or for other reasons, is probably not correct. In fact, the opposite seems to pertain: as the patient improves and become more aware of a defect in memory, the tendency to confabulate becomes less.

In our experience, confabulation is associated with two phases of the Wernicke-Korsakoff syndrome: the initial phase, in which profound general confusion dominates the illness; and the convalescent phase, in which the patient recalls fragments of past experience in a distorted fashion. Events that were separated by long intervals are juxtaposed or related out of sequence, so that the narrative has an implausible or fictional aspect. Whether one designates the latter defect as confabulation or as a particular defect of retentive memory is academic. In the chronic, stable state of the disease, confabulation is usually absent. These and other aspects of confabulation are discussed more fully in the monograph by Victor and colleagues.

**Other Clinical Abnormalities**

Signs of peripheral neuropathy are found in more than 80 percent of patients with the Wernicke-Korsakoff syndrome. In most of them the neuropathic disease is mild and does not account for the disorder of gait, but it may be so severe that stance and gait cannot be tested. In a small number, refinery neuropathy is added. Despite the frequency of peripheral neuropathy, overt signs of beriberi heart disease are rare. However, indications of disordered cardiovascular function such as lachrymosis, exertional dyspnea, postural hypotension, and minor electrocardiographic abnormalities are frequent; occasionally, the patient dies suddenly, following only slight exertion. These observations may show an elevation of cardiac output associated with low peripheral vascular resistance—abnormalities that revert to normal after the administration of thiamine. Postural hypotension and syncope are common findings in Wernicke disease and are probably due to impaired function of the autonomic nervous system, more specifically to a defect in the sympathetic outflow (Birchfield). There may be mild hypothyroidism. Patients with the Korsakoff amnesic state may have a demonstrably impaired olfactory discrimination. This deficit, like the notable aphaty that is present in most Wernicke patients, is probably attributable to a lesion of the mediodorsal nucleus of the thalamus and its connections and not to a lesion of the peripheral olfactory system (Mair et al).

**Ancillary Laboratory Findings**

Vestibular function, as measured by the response to standard ice-water caloric tests, is universally impaired in the acute stage of Wernicke disease (Gher). Vertigo is not a complaint, however. To this abnormality of function, which is bilateral and more or less symmetrical, the term vestibular paresis has been applied. It probably accounts for the decreased mobility of the eyes in the initial stage of the illness. The CSF in uncomplicated cases of the Wernicke-Korsakoff syndrome is normal or shows only a modest elevation of the protein content. Protein values above 100 mg/dl or a pleocytosis should suggest the presence of a complicating illness—subdural hematoma and meningeal infection being the most common.

Blood pyruvate is elevated in untreated cases of Wernicke disease, but blood transketolase activity is a more accurate index of the thiamine deficiency. Transketolase, one of the enzymes of the hexose monophosphate shunt, requires thiamine pyrophosphate (TPP) as a cofactor. In normal adult subjects, transketolase values (expressed as sedoheptulose-7-phosphate produced per milliliter per hour) range from 90 to 140 mg and the TPP effect from 0 to 10 percent, depending upon the degree of vitamin supplementation. Before specific treatment with thiamine, patients with Wernicke disease show a marked reduction in their transketolase activity (as low as one-tenth of normal values) and a striking TPP effect (up to 50 percent). Restoration of these values toward normal occurs within a few hours of the administration of thiamine, and completely normal values are usually attained within 24 h.

An important abnormality of transketolase has been described by Blass and Gibson. They found that transketolase in cultured fibroblasts from four alcoholics with Wernicke-Korsakoff disease bound TPP less avidly than did the transketolase from control lines. Presumably this defect in transketolase would be insignificant if the diet were adequate but would be deleterious if the diet were low in thiamine. These findings, which have been corroborated by Mukherjee and colleagues, suggest a hereditary factor in the genesis of Wernicke-Korsakoff disease and possibly may explain why only a small proportion of nutritionally deficient alcoholics develop this disease.

Only about half the patients with Wernicke-Korsakoff disease show electroencephalographic (EEG) abnormalities, consisting of diffuse mild to moderate slow activity. Total cerebral blood flow and cerebral oxygen and glucose consumption may be greatly reduced in the acute stages of the disease, and these defects may still be present after several weeks of treatment (Shimoyco et al). These observations indicate that significant reductions in brain metabolism need not be reflected in EEG abnormalities or in depression of the state of consciousness and that the latter is more a function of the location of the lesion than of the overall degree of metabolic defect.

The acute lesions of the Wernicke-Korsakoff syndrome, both the medial thalamic and periaqueductal ones, can be demonstrated by magnetic resonance imaging (Donnal et al, Gallucci et al). This procedure is particularly useful in patients in whom stupor or coma has supervened or in whom ocular and ataxic signs are otherwise inconstant (Victor, 1990).

**Course of the Illness**

The mortality rate in the acute phase of Wernicke disease was 17 percent in our series of patients. Mainly the fatalities were attributable to hepatic failure and to infection (pneumonia, pulmonary tuberculosis, and septicemia being the most common). Some deaths were undoubtedly due to the effects of thiamine deficiency that had reached an irreversible stage.

Most patients respond in a fairly predictable manner to the administration of thiamine, as detailed further on. The most dramatic improvement is in the ocular palsies, as already mentioned. Recovery begins often within hours after the administration of thiamine and practically always within several days. This effect is so constant that a failure of the ocular palsies to respond to thiamine should call doubts about the diagnosis of Wernicke disease. Sixth nerve palsies, ptosis, and vertical gaze palsies recover completely within a week or two in most cases, but vertical nystagmus may sometimes persist for several months. Horizontal gaze palsies recover completely as a rule, but in 60 percent of cases a fine horizontal nystagmus remains as a permanent sequela. In this respect, horizontal nystagmus is unique among the ocular signs.

In comparison with the ocular signs, improvement of ataxia is somewhat delayed. About 40 percent of patients recover completely from ataxia. The remainder recover incompletely or not at all and are left with a slow, shuffling, wide-based gait and inability to walk tandem. The residual gait disturbances and horizontal nystagmus provide a means of identifying obscure and chronic cases of dementia as alcoholic-nutritional in origin. Vestibular function improves at about the same rate as the ataxia of gait, and recovery is usually but not always complete.

The early symptoms of apathy, drowsiness, and global confusion invariably recede, and as they do so the defect in memory and learning stands out more clearly. The memory disorder, once established, recovers completely or almost completely in only 20 percent of patients. The remainder are left with varying degrees of permanent disability.
It is apparent from the foregoing account that Wernicke disease and Korsakoff psychosis are not separate diseases but that the changing ocular and ataxic signs and the transformation of the global confusional state into an amnesic syndrome are simply successive stages in a single disease process. Of 186 patients in our series who presented with Wernicke disease and survived the acute illness, 157 (84 percent) showed this sequence of clinical events. As a corollary, a survey of alcoholic patients with Korsakoff psychosis in a state mental hospital disclosed that in most the illness had begun with the symptoms of Wernicke disease, and that about 60 percent of them still showed the ocular and/or cerebellar stigmata of Wernicke disease many years after the onset.

Neuropathologic Findings and Clinical-Pathologic Correlation

Patients who die in the acute stages of Wernicke disease show symmetrical lesions in the paraventricular regions of the thalamus and hypothalamus, mammillary bodies, periaqueductal region of the midbrain, floor of the fourth ventricle (particularly in the regions of the dorsal motor nuclei of the vagus and vestibular nuclei), and superior cerebellar vermis. Lesions are consistently found in the mammillary bodies and less consistently in other areas. The microscopic changes are characterized by varying degrees of necrosis of periventricular structures. Within the area of necrosis, nerve cells are lost, but usually some remain; some of these are damaged, but others are intact. Myelinated fibers are more affected than neurons. These changes are accompanied by a prominence of the blood vessels, although in some cases there appears to be a primary endothelial proliferation. In the areas of parenchymal damage there is astrocytic and microglial proliferation. Discrete hemorrhages were found in only 20 percent of our cases, and many of them appeared to be agonal in nature. The cerebellar changes consist of a degeneration of all layers of the cortex, particularly of the Purkinje cells; usually this lesion is confined to the superior vermis of the cerebellum; ataxia of individual movements of the legs is attributable to an extension of the lesion into the anterior parts of the anterior lobes. Hypothymria, which occurs sometimes as a presenting feature of Wernicke disease, is probably attributable to lesions in the posterior and posterolateral nuclei of the hypothalamus (experimentally placed lesions in these parts have been shown to cause hypothermia or poikilothermia in monkeys).

The topography of the neuropathologic changes in patients who die in the chronic stages of the disease, when the amnesic symptoms predominate, is much the same as the changes in the acute stages of Wernicke disease. Apart from the expected differences in age of the glial and vascular reactions, the only important difference has to do with the involvement or lack of involvement of the medial dorsal and anterior nuclei of the thalamus. The medial parts of these nuclei were consistently involved in our patients who had shown the Wernicke amnesic state during life; they were not involved in patients who had had no persistent amnesic symptoms. The mammillary bodies were affected in all of the patients, both those with the amnesic defect and those without. These observations suggest that the lesions responsible for the memory disorder are those of the thalami, predominantly of the medial dorsal nuclei (and their connections with the medial temporal lobes and amygdaloid nuclei, i.e., a thalamic amnesic state), and not those of the mammillary bodies, as is frequently stated. It is also notable that the hippocampal formations, the site of damage in many other types of Korsakoff memory loss, are intact.

Treatment of the Wernicke-Korsakoff Syndrome

Wernicke disease constitutes a medical emergency, and its recognition (or even the suspicion of its presence) demands the immediate administration of thiamine. The prompt use of thiamine prevents progression of the disease and reverses those lesions that have not yet progressed to the point of fixed structural change. In patients who show only ocular signs and ataxia, the administration of thiamine is crucial in preventing the development of an irreversible amnesic state.

Although 2 to 3 mg of thiamine may be sufficient to modify the ocular signs, much larger doses are needed to sustain improvement and replenish the depleted thiamine stores—50 to 100 mg intravenously and 50 mg intramuscularly—the latter dose being repeated each day until the patient resumes a normal diet.

It should be standard practice in emergency departments to administer 50 to 100 mg of thiamine simultaneously with intravenous fluids that contain glucose in order to prevent precipitating Wernicke disease. It is also good practice to give B vitamins to all alcoholic patients. The chronic alcoholic (or the nonalcoholic with persistent vomiting) exhausts his body stores of thiamine in a matter of 7 or 8 weeks, at which time the administration of glucose may serve to precipitate Wernicke disease or cause an early form of the disease to progress rapidly. The further management of Wernicke disease involves the use of a balanced diet and all the B vitamins, since the patient is usually deficient in more than thiamine alone.

A problem in management may arise once the patient has recovered from Wernicke disease and the amnesic psychosis becomes prominent. As indicated above, only a minority of such patients (less than 20 percent in our series) recover; moreover, the onset of recovery in such patients may be delayed for several weeks or even months, and then it proceeds very slowly over a period of many months. The extent to which the amnesic symptoms will recover cannot be predicted accurately during the acute stages of the illness; one must guard against the premature commitment of the patient to a mental hospital. Interestingly, the alcoholic Korsakoff patient, once more or less recovered, seldom demands alcohol but will drink it if it is offered.

Infantile Wernicke-beriberi Disease

This term designates an acute and frequently fatal disease of infants, which until recently was very common in rice-eating communities of the Far East. It affects only breast-fed infants, usually in the second to the fifth months of life. Acute cardiac symptoms dominate the clinical picture, but neurologic symptoms (aphonia, strabismus, nystagmus, spasmodic contraction of facial muscles, and convulsions) have been described in many cases. This syndrome can be reversed dramatically by the administration of thiamine, so that some authors prefer to call it acute thiamine deficiency in infants. In the few neuropathologic studies that have been made of this disorder, changes like those of Wernicke disease in the adult have been described.

Infantile beriberi bears no consistent relationship to beriberi in the mother. Infants of mothers with overt signs of beriberi may be quite normal. Conversely, mothers of infants with beriberi may themselves be free of the disease. The levels of thiamine in the breast milk of such mothers have not been determined, however. The absence of beriberi in the mothers of affected infants suggests that infantile beriberi might be due to a toxic factor in breast milk, but such a factor, if it exists, has never been isolated.

Rarely, the clinical manifestations of beriberi in infancy represent an inherited (autosomal recessive) thiamine-dependent state, responding to the continued administration of massive doses of thiamine (Mandel et al; see also Table 41-2).

NUTRITIONAL POLYNEUROPATHY (NEUROPATHIC BERIBERI)

Most physicians in the western world have only a dim notion about beriberi, which they recall as an ill-defined, predominantly cardiac disorder occurring among the rice-eating people of the Orient. In fact, beriberi is a distinct clinical entity that is not confined to any particular part of the world. Essentially it is a disease of the heart.
and of the peripheral nerves (which may be affected separately), with or without edema, the latter feature providing the basis for the classic division into “wet” and “dry” forms. The cardiac manifestations range from tachycardia and exertional dyspnea to acute and rapidly fatal heart failure. This last is the most dramatic manifestation of beriberi, but it is uncommon. Here we are concerned with the affection of the peripheral nerves, or neuropathic beriberi, as it is designated.

That beriberi is essentially a degenerative disorder of the peripheral nerves was established in the late nineteenth century by the classic studies of the Dutch investigators Eijkman, Pekelharing and Winkler, and Grijns. Only after beriberi gained acceptance as a nutritional disease (this followed Funk’s discovery of vitamins in 1911) was it suspected that the neuropathy of alcoholics was also nutritional in origin. The similarity between beriberi and alcoholic neuropathy was commented upon by several authors, but it was Shattuck, in 1928, who first seriously discussed the relationship of the two disorders. He suggested that “polynurolitis of chronic alcoholism was caused chiefly by failure to take or assimilate food containing a sufficient quantity of vitamin B . . . and might properly be regarded as true beriberi.” Convincing evidence that “alcoholic neuritis” is not due to the neurotoxic effect of alcohol was supplied by Strauss. He allowed 10 patients to continue their daily consumption of whiskey while they consumed a well-balanced diet supplemented with yeast and vitamin B concentrates; the peripheral nerve symptoms improved in every case. Our own observations support Strauss’s contention that alcoholic polyneuropathy is essentially a nutritional disease.

Clinical Features
The symptomatology of nutritional polyneuropathy is diverse. In fact, many patients are asymptomatic, and evidence of peripheral nerve affection is found only on clinical or electromyographic examination. In the latter circumstance the neuropathic signs are mild in degree, consisting of thinness and tenderness of the leg muscles, loss or depression of the Achilles reflexes and perhaps of the patellar reflexes, and at times a patchy blunting of pain and touch sensation over the feet and shins.

The majority of patients, however, are symptomatic—weakness, paresthesias, and pain being the usual complaints. The symptoms are madidus in onset and slowly progressive, but occasionally they seem to evolve or to worsen rapidly, over a matter of days. The initial symptoms are usually referred to the distal portions of the limbs and progress proximally if the illness remains untreated. The lower limbs are always affected earlier and more severely than the upper ones. Most often some aspect of motor disability constitutes the chief complaint, but in about one-quarter of the patients the main complaints are pain and paresthesias. The discomfort takes several forms: a dull, constant ache in the feet or legs; sharp and lancinating pains, momentary in duration, like those of labes dorsals; sensations of cramping or tightness in the muscles of the feet and calves; or band-like feelings around the legs. Coldness of the feet is a common complaint but is purely subjective. Far more distressing are feelings of heat or “burning” affecting mainly the soles, less frequently the dorsal aspects of the feet. The dysesthesias fluctuate in severity and characteristically are worsened by contactual stimuli, sometimes to the point where the patient cannot walk or bear the touch of bedclothes, despite the relative preservation of motor power. The term burning feet has been applied to this syndrome, but it is not particularly apt, since the patient also complains of other types of paresthesia and pain, and these symptoms may involve the hands as well as the feet.

Examination discloses varying degrees of motor, sensory, and reflex loss. As the symptoms suggest, the signs are symmetrical, usually more severe in distal than in proximal portions of the limbs, and often confined to the legs. The disproportionate affection of motor power may be striking, taking the form of a foot and wrist drop; but even in these patients the proximal muscles are usually affected as well (indicated by difficulty in arising from a squatting position). In other patients, all the leg muscles are affected more or less equally, and in a few, weakness appears to be most severe in the proximal muscles. Absolute paralysis of the legs is observed only rarely; immobility due to contractures at the knees and ankles is a more common occurrence. Tenderness of muscles on deep pressure is a highly characteristic finding, elicited most readily in the muscles of the feet and calves. Deep tendon reflexes in the legs are almost always lost, even when weakness is slight in degree. In the arms, tendon reflexes are sometimes retained despite a loss of strength in the hands. In a small number of patients, particularly those in whom pain and dysesthesias are prominent and motor loss is slight, the reflexes at knee and ankle may be retained or even of greater than average briskness.

Excessive sweating of the soles and dorsal aspects of the feet and of the volar surfaces of the hands and fingers is a common manifestation of alcohol-induced nutritional neuropathy. Postural hypotension is sometimes associated. These symptoms are indicative of involvement of the peripheral sympathetic nerve fibers.

Sensory loss or impairment may involve all the modalities, although one may be affected out of proportion to the others. One cannot predict from the patient’s symptoms which mode of sensation might be affected disproportionately. In patients with impairment of superficial sensation (i.e., touch, pain, and temperature), the border between impaired and normal sensation is not sharp but shades off gradually over a considerable vertical extent of the limbs.

Patients in whom pain is the outstanding symptom do not constitute a distinct group in terms of their neurologic signs. Pain and dysesthesias may be prominent in patients with either severe or slight degrees of motor, reflex, and sensory loss. The term hyperesthesic is used commonly to designate the exquisitely painful form of neuropathy but is not well chosen; as pointed out on page 145, one is usually able, by using finely graded stimuli, to demonstrate an elevated threshold to painful, thermal, and tactile stimuli in the “hyperesthesic” zone. Once the stimulus is perceived, however, it has a painful and diffuse, unpleasant quality (hyperpathia). Tactile evocation of pain or burning is an example of allodynia.

In most patients with nutritional polyneuropathy, only the limbs are involved; the abdominal, thoracic, and bulbar muscles are usually spared. In the most advanced instances of neuropathy, hoarseness and weakness of the voice and dysphagia due to affection of the vagus nerves may be added to the clinical picture.

Some idea of the incidence of the motor, reflex, and sensory abnormalities and the combinations in which they occur can be obtained from Table 41-1, which is based on our study of 189 nutritionally depleted alcoholic patients. Noteworthy is the fact that only 66 (35 percent) of the 189 patients showed the clinical picture of polyneuropathy in its entirety—i.e., a symmetrical impairment or loss of tendon reflexes, sensation, and motor power affecting legs more than the arms and the distal more than the proximal segments of the limbs. The remaining patients in the 189 cases, the motor-reflex-sensory signs occurred in various combinations, as indicated in Table 41-1.

Stasis edema and pigmentation, glossiness, and thinness of the skin of the lower legs and feet are common findings in patients with severe forms of neuropathy. Major dystrophic changes, in the form of perforating plantar ulcers and painless destruction of the bones and joints of the feet (ulcero-osteolytic neuropathy; “Charcot foot”) have been described but are rare. Repeated trauma to insensitive parts and superimposed infection are thought to be responsible for the neuropathic arthropathy.

The CSF is usually normal, although a modest elevation of protein content is found in a small number of cases. Electromyographic (EMG) findings include mild to moderate degrees of slowing of motor and sensory conduction and a marked reduction of the amplitudes of sensory action potentials; the motor conduction velocities in distal segments of the nerves may be reduced, while conduction in proximal segments is normal. Denervated muscles show fibrillation potentials.

Pathologic Features
The essential pathologic change is one of axonal degeneration, with destruction of both axon and myelin sheath. Segmental demyelination may also occur, but only in a small proportion of fibers. This change may be difficult to discern in myelin-stained sections of whole nerve trunks, but it can be observed in teased nerve fibers stained with osmium. The most pronounced changes are observed in the distal parts of the longest and largest myelinated fibers in the crural and, to a lesser extent, brachial nerves. In advanced cases the degenerative changes extend into the anterior and posterior nerve roots. The vagus and phrenic nerves and paravertebral sympathetic trunks may be affected in advanced cases.
Anterior horn and dorsal root ganglion cells undergo chromatolysis, indicating axonal damage. Degenerative changes in the posterior columns are seen in some cases and are probably secondary to the changes in the dorsal spinal roots.

Pathophysiology The nutritional factor(s) responsible for the neuropathy of alcoholism and beriberi have not been defined precisely. Because of the difficulties in producing peripheral neuropathy in Mammalia by means of a thiamine-deficient diet, several investigators in the past questioned the idea that thiamine is the antineuritic vitamin. Very few of the animal experiments undertaken to settle this point are satisfactory from a nutritional and pathologic point of view. Nevertheless, several studies in birds and humans do indeed indicate that uncomplicated thiamine deficiency may result in peripheral nerve disease. The necessity of either accepting or rejecting the specific role of thiamine became less urgent when it was demonstrated, in both animals and humans, that a deficiency of pyridoxine or of pantothenic acid could also result in degeneration of the peripheral nerves (see Swank and Adams).

The question of whether polyneuropathy in the alcoholic patient might be due to the direct toxic effects of alcohol and not to a nutritional deficiency has been raised from time to time (see, for example, Denny-Brown and Belye and Buchthal). The evidence for this view is not compelling, either on clinical or on experimental grounds (see reference to Strauss, in introductory section on nutritional neuropathy). The interested reader will find a detailed critique of this subject in the chapters by Victor and by Windem in the second and third editions, respectively, of Peripheral Neuropathy, edited by Dyck and coworkers.

Treatment and Prognosis The first consideration is to supply adequate nutrition in the form of a balanced diet supplemented with B vitamins. Equally important is to make certain that the patient follows the prescribed diet. If persistent vomiting or other gastrointestinal complications prevent the patient from eating, then parenteral feeding becomes necessary; the vitamins may be given intramuscularly or added to intravenous fluids.

Where pain and sensitivity of the feet are the major complaints, the pressure of bedclothes may be avoided by placing a cradle support over the legs. Aching of the limbs may be related to their immobility, in which case they should be moved passively on frequent occasions. Aspirin or acetaminophen is usually sufficient to control hyperesthesia; occasionally codeine in doses of 15 to 30 mg must be added. Obviously, opiates and addicting synthetic analgesics should be avoided. Some of our patients with severe burning pain (similar to causalgia) in the feet have been helped by blocking the lumbar sympathetic ganglia or by epidural injection of analgesics. The response to phenytoin and carbamazepine (Tegretol) has been inconsistent. Adrenergic blocking medication has been of little value.

The regeneration of peripheral nerves, which may take many months, will be of no avail if the muscles have been allowed to undergo contracture and the joints to become fixed. The patient's legs should be supported against the footboard, in order to prevent shortening of the heel cords. In cases of severe paralysis, molded splints should be applied to the arms, hands, legs, and feet during periods of rest. Pressure on the heels and elbows can be avoided by padding the splints and by turning the patient frequently or by asking the patient to do so. As soon as the patient's general condition permits, the limbs must be passively moved through a full range of movement several times daily. As function returns, more vigorous physiotherapeutic measures can be undertaken.

Recovery from nutritional neuropathy is a slow process. In the mildest cases there may be a considerable restoration of motor function in a few weeks. In severe forms of the disease, several months may pass before the patient is able to walk unaided. The slowness of recovery creates a special problem for the alcoholic patient, in whom the great danger to continued recovery is the resumption of drinking. Suitable arrangements must therefore be made for close supervision during the long and tedious convalescence.

Deficiency Amblyopia (Nutritional Optic Neuropathy)

("Tobacco-Alcohol Amblyopia"); See also Chap. 13

These terms refer to a characteristic form of visual impairment that results from nutritional deficiency. The defect in vision is due not to an abnormality of the cornea or other parts of the refractive mechanism but to a lesion of the optic nerve, more or less confined to the region of the papillomacular bundle.

Typically, the patient complains of dimness or blurring of vision for near and distant objects, evolving gradually over a period of several days or weeks. Examination discloses a reduction in visual acuity due to the presence of central or centrocecal scotomata, which are larger for colored than for white test objects. Pallor of the temporal portion of the optic disc is observed in some cases. These abnormalities are bilateral and roughly symmetrical and, if untreated, may progress to blindness and irreversible optic atrophy. With nutritious diet and vitamin supplements, improvement occurs in all but the most chronic cases, the degree of recovery depending upon the severity of the amblyopia and particularly upon its duration before therapy is instituted.

Although the precise deficiency responsible cannot be named, the nutritional basis of this disorder was established beyond doubt during World War II and the Korean War, when innumerable instances were observed in prisoners of war who had been confined for prolonged periods under conditions of severe dietary deprivation. Fisher described the optic nerve lesions in 4 such patients who had died of unrelated causes between 8 and 10 years after the onset of amblyopia. The optic nerves in each case showed a loss of myelin and axis cylinders restricted to the region of the papillomacular fibers. Of the 4 cases, 3 also showed demyelination of the posterior columns of the spinal cord, no doubt an expression of the associated sensory polyneuropathy.

In the western world, a visual disorder indistinguishable clinically and pathologically from that observed in prisoners of war is observed infrequently, mainly among undernourished alcoholics. For many years this has been referred to as tobacco-alcohol amblyopia, with the implication that the visual loss is due to the toxic effects of alcohol, tobacco, or both. Actually, the evidence is overwhelming that so-called tobacco-alcohol amblyopia is due to nutritional deficiency. A specific nutrient has not been identified, however. There is evidence in humans and in animals that under certain conditions a deficiency of one or more of the B vitamins—thiamine, vitamin B₁₂, and perhaps riboflavin—may cause degenerative changes in the optic nerves, a situation that persists in the peripheral nerves as well.

In the 1960s, a popular theory held that the combined effects of vitamin B₁₂ deficiency and chronic poisoning by cyanide (generated in tobacco smoke) were responsible for "tobacco-alcohol amblyopia." Vitamin B₁₂ deficiency is a rare but undoubted cause of optic neuropathy (page 286), but the notion that cyanide or other substances in tobacco smoke have a damaging effect upon the optic nerves is supported neither by logic nor by experimental data (see reviews of Pots and of Victor). Clinically, instances of Leber's hereditary optic atrophy may be mistaken for "tobacco-alcohol amblyopia"—an error that should no longer be made because the former disorder can now be identified with certainty by mitochondrial DNA testing.

The most recent outbreaks of nutritional optic neuropathy occurred in Cuba during 1991–1993 and in Tanzania. In both outbreaks the optic neuropathy was frequently associated with peripheral neuropathy, for which reason they are considered further on, with the Strachan syndrome.

Pellagra

In the early 1900s, pellagra attained epidemic proportions in the southern United States and in the alcoholic population of large urban centers. Since 1940, the prevalence of pellagra has diminished greatly because of the general practice of enriching bread with niacin. Nevertheless, among the vegetarian, maize-eating people of underdeveloped countries and among the black population of South Africa, pellagra is still a common disease (Bomh et al, Shah et al, Ronthal and Adler). In developed countries, pellagra is practically confined to alcoholics (Ishii and Nishihara, Spivak and Jackson, Serdaru et al).

In its fully developed form, pellagra affects the skin, alimentary tract, and hematopoietic and nervous systems. The early symptoms may be mistaken for those of a neurosis. Insomnia, fatigue, nervousness, irritability, and feelings of depression are common complaints; examination may disclose mental dullness, apathy, and an impaired sense of memory. Sometimes an acute confusional psychosis dominates the clinical picture. Untreated, these symptoms progress to a dementia. Pellagra may not only produce insanity but occasionally result from it, by virtue of the anorexia and refusal of food that accompany certain mental illnesses. The spinal cord manifestations have not been clearly described; in general, the signs are referable to both the posterior and lateral columns, predominantly the former. Signs of peripheral nerve affection are relatively less common and are indistinguishable from those of neuropathic beriberi.

Pathologic Changes These are most readily discerned in the large cells of the motor cortex, the cells of Betz and are seen to a lesser extent in the smaller pyramidal cells of the cortex, the large cells of the basal ganglia, the cells of the cranial motor and dentate nuclei, and the anterior horn cells of the spinal cord. The affected cells appear swollen and rounded, with eccentric nuclei and loss of the Nissl bodies (frequently referred to as "axonal reaction"). In the pathologic material of Hauw et al, and associates, the chromatolytic changes were most pronounced in the brainstem nuclei (upper reticular and pontine) and not in the Betz cells. They concluded that...
The hematologic effects of vitamin B deficiency are widespread and can involve multiple systems. Vitamin B deficiency can affect the hematopoietic system, leading to anemia, particularly megaloblastic anemia, which is characterized by large, immature red blood cells. This anemia is often referred to as "pernicious anemia" because it can be caused by a deficiency of vitamin B12 (cobalamin).

In the context of vitamin B deficiency, megaloblastic anemia occurs due to the inability of the bone marrow to produce mature red blood cells efficiently. The anemia is typically macrocytic, meaning the red blood cells are larger than normal. This is because the bone marrow cells are not able to complete their development due to a lack of vitamin B12, which is necessary for DNA synthesis.

The clinical features of megaloblastic anemia include pallor, fatigue, weakness, and sometimes difficulty with fine motor coordination (ataxia). In severe cases, coma may occur if the anemia becomes life-threatening.

The hematologic manifestations of vitamin B deficiency are distinct as they result from the specific metabolic role of these vitamins in the production of normal red blood cells.
lack of vitamin B$_2$ but from the failure to transfer minute amounts of this nutrient across the intestinal mucosa—"starvation in the midst of plenty," as Castle aptly put it. This failure derives from the chronic absence of an intrinsic factor, which is secreted (along with hydrochloric acid) by the parietal cells of the gastric mucosa and which transports cobalamin (extrinsic factor in the diet) to the ileum, where it is absorbed into the portal system. This is referred to as a **conditioned deficiency**, since it is conditional upon the lack of an intrinsic factor.

The hematologic and neurologic manifestations of vitamin B$_2$ deficiency occasionally complicate other malabsorptive disorders: celiac sprue; extensive gastric or ileal resections; overgrowth of intestinal bacteria in "blind loops," anastomoses, diverticula, and other conditions resulting in intestinal stasis; and infestation with cobalamin-metabolizing fish tapeworm (Diphyllolothrium latum). Rare instances of vitamin B$_2$ deficiency are observed in lactovegetarians, in infants nursed by mothers deficient in vitamin B$_2$, and as a result of nitrous oxide poisoning. Finally, vitamin B$_2$ deficiency may be due to a rare genetic defect of methylmalonyl coenzyme A (CoA) mutase (Table 41.2).

**Clinical Manifestations** Symptoms of nervous system disease occur in the majority of patients with pernicious anemia. The patient first notices general weakness and paresthesias consisting of tingling, "pins and needles" feelings, or other vaguely described sensations. The paresthesias involve the hands and feet, more often the former, and tend to be constant and steadily progressive and the source of much distress. As the illness progresses, the gait becomes unsteady and stiffness and weakness of the legs, especially of the legs, develop. If the disease remains untreated, an ataxic paraplegia evolves, with variable degrees of spasticity and contracture.

Early in the course of the illness, when only paresthesias are present, there may be no objective signs. Later, examination discloses a disorder of the posterior and lateral columns of the spinal cord, predominantly of the former. Loss of vibration sense is by far the most consistent sign; it is more pronounced in the feet and legs than in the hands and arms and frequently extends over the trunk. Position sense is usually impaired as well. The motor signs, usually limited to the legs, include a mild symmetric loss of strength in proximal limb muscles, spasticity, changes in tendon reflexes, clonus, and extensor plantar responses. At first the paleolar and Achilles reflexes are found to be diminished as frequently as they are increased, and they may even be absent. With treatment the reflexes may return to normal or become hyperactive. The gait at first is predominantly ataxic, later ataxic and spastic.

Loss of superficial sensation below a segmental level on the trunk may occur in isolated instances, implicating the spinothalamic tracts, but such a finding should always suggest the possibility of some other disease of the spinal cord. The defect of cutaneous sensation may take the form of impaired tactile, pain, and thermal sensation over the limbs in a distal distribution, implicating the peripheral nerves; but such findings are also relatively uncommon. The Hermitte phenomenon (paresthesias down the spine or across the shoulders induced by rapid flexion of the neck) is a not uncommon finding if sought.

The nervous system involvement in subacute combined degeneration is roughly symmetrical, and sensory disturbances precede the motor ones; predominantly motor involvement from the beginning and a definite asymmetry of motor or sensory findings maintained over a period of weeks or months should always cast doubt on the diagnosis.

Mental signs are frequent, ranging from irritability, apathy, somnolence, suspiciousness, and emotional instability to a marked confusional or depressive psychosis or intellectual deterioration. Lindenbaum and coworkers have reported cases in which neuropsychiatric symptoms, responsive to vitamin B$_2$, were present without spinal cord or peripheral nerve abnormalities. In our clinical material, symptoms of dementia have not been frequent and always followed the spinal cord disorder. **Visual impairment** due to optic neuropathy may occasionally be the earliest or sole manifestation of pernicious anemia; examination discloses roughly symmetrical centrocecal scotomata and optic atrophy in the most advanced cases (page 263). The fact that visual evoked potentials may be abnormal in vitamin B$_2$-deficient patients without clinical signs of visual impairment suggests that the visual pathways may be affected more often than is evident from the neurologic examination alone. A small number of patients have symptoms of autonomic dysfunction, including urinary sphincteric symptoms and impotence.

The CSF is usually normal; in some cases there is a moderate increase in protein. The EMG shows slowing of sensory conduction or reduced-amplitude sensory potentials. Almost always, according to Hemmer and colleagues, somatosensory evoked potentials show delayed conduction or absent responses; these changes are known to recover with treatment. Quite remarkable, as these authors report, is the finding on MRI of a T2 signal change that demarcates the posterior columns of the cord (Fig. 41-1).

**Neuropathologic Changes** The pathologic process takes the form of a diffuse though uneven degeneration of white matter of the spinal cord and occasionally of the brain. The earliest histologic event is a swelling of myelin sheaths, characterized by the formation of intramyelinic vacuoles and separation of myelin lamellae. This is followed by a coalescence of small foci of tissue destruction into larger ones, imparting a vacuolated, sieve-like appearance to the tissue—a change also seen in the white matter of the spinal cord or peripheral nerve abnormalities. In our clinical material, symptoms of dementia have not been frequent and always followed the spinal cord disorder. **Visual impairment** due to optic neuropathy may occasionally be the earliest or sole manifestation of pernicious anemia; examination discloses roughly symmetrical centrocecal scotomata and optic atrophy in the most advanced cases (page 263). The fact that visual evoked potentials may be abnormal in vitamin B$_2$-deficient patients without clinical signs of visual impairment suggests that the visual pathways may be affected more often than is evident from the neurologic examination alone. A small number of patients have symptoms of autonomic dysfunction, including urinary sphincteric symptoms and impotence.

The CSF is usually normal; in some cases there is a moderate increase in protein. The EMG shows slowing of sensory conduction or reduced-amplitude sensory potentials. Almost always, according to Hemmer and colleagues, somatosensory evoked potentials show delayed conduction or absent responses; these changes are known to recover with treatment. Quite remarkable, as these authors report, is the finding on MRI of a T2 signal change that demarcates the posterior columns of the cord (Fig. 41-1).

Figure 41-1 Sagittal spinal MRI, T2-weighted image in subacute combined degeneration showing signal changes in the posterior columns. The patient had markedly reduced vibration and position sense and a Romberg sign; the tendon reflexes were preserved and there were no corticospinal tract or peripheral nerve signs. (Courtesy of Dr. James Corbett.)
superficial sensation and loss of tendon reflexes that occur in some patients are best explained by involvement of peripheral nerves and are reflected in nerve conduction studies (see further on, under "Diagnosis").

Pathogenesis 
Methylcobalamin is an essential cofactor in the conversion of homocysteine to methionine. An impairment of this reaction due to a deficiency of cobalamin leads to a failure of DNA synthesis, accounting for the hematologic abnormalities and particularly for the production of megaloblasts. However, since neurons do not divide, this sequence of chemical events does not explain the central nervous system abnormalities. One of the better-understood functions of vitamin B12 is its role as a coenzyme in the methylmalonyl CoA–mutase reaction. In this reaction, which is a key step in propionate metabolism, methylmalonyl CoA is transformed to succinyl CoA, which subsequently enters the Krebs cycle. A lack or failure of the cobalamin-dependent enzyme methylmalonyl CoA mutase leads to the accumulation of methylmalonyl CoA and its precursor, propionyl CoA. According to this theory, propionyl CoA displaces succinyl CoA, which is the usual primer for the synthesis of even-chain fatty acids and results in the anomalous insertion of odd-chain fatty acids into membrane lipids, such as are found in myelin sheaths. Conceivably this biochemical abnormality underlies the lesions of myelinated fibers that characterize this disease. However, Carmel and associates have described a hereditary form of cobalamin deficiency in which the methylmalonyl CoA mutase activity was normal, despite the presence of typical neurologic abnormalities in their view, the primary failure is one of methylation of homocysteine to methionine, i.e., a failure of the methionine synthetase reaction, for which the coenzyme methylcobalamin is necessary.

Evidence for the latter view comes also from the observations that prolonged administration of nitrous oxide (N2O) may produce not only megaloblastic changes in the marrow (Anness et al) but also a sensorimotor polyneuropathy, often combined with signs of involvement of the posterior and lateral columns of the spinal cord (Lazzeri). Probably N2O produces its effects by inactivating the methylcobalamin-dependent enzyme methionine synthetase. These and other hypotheses are discussed by Jandi, Carmel and colleagues, and Beck.

The role of folate deficiency in the genesis of SCD is even less certain. One mistake has been to treat pernicious anemia by giving folic acid; this corrects the anemia but may worsen or even evoke the spinal cord lesions. There are, nevertheless, a few reported examples of cerebral and spinal cord lesions indistinguishable from those due to vitamin B12 deficiency in patients with defective folate metabolism—both in adults with acquired deficiency (Pincus) and in children with an inborn metabolic error (Clayton et al).

Diagnosis 
The main differential diagnostic considerations are cervical spondylitis (page 1332), multiple sclerosis of the cervical cord (page 963), rickets, etc. as the female carrier state of adrenoleukodystrophy (adrenomyeloneuropathy, page 1035), and combined system disease (page 1328). The chief obstacle to early diagnosis is the lack of parallelism that may exist between the hematologic and neurologic signs, occurring particularly in patients who have taken dietary or medicinal folate. Anemia may be absent, sometimes for many months, in patients who have not taken folate. In a retrospective study of 141 patients with neuropsychiatric abnormalities due to cobalamin deficiency, there were 19 patients in whom both the hematocrit and mean cell volume were normal (Lindenbaum et al); in these patients, subtle morphologic abnormalities—hypersynapted polymorphonuclear leukocytes and megaloblastosis in bone marrow smears—were almost always found if carefully sought.

Achlorhydria is almost invariably present in patients with pernicious anemia; its presence can be detected by measuring the serum gastrin level. Antibodies to gastric parietal cells are also present in as many as 90 percent of patients with cobalamin deficiency, but this test often yields false-positive results. The finding of serum antibodies against intrinsic factor is diagnostically specific, but unfortunately they are found in only 50 percent of cases.

Serum cobalamin should be measured whenever the diagnosis of vitamin B12 deficiency is in question. Microbiologic assay (using Euglena gracilis) is the most accurate way to measure vitamin B12, but the method is time-consuming and cumbersome and has been largely replaced by a commercial radioisotope assay (the inexpensive chemiluminescence assay is slightly less dependable). With the radioassay, serum levels of less than 100 pg/ml are usually associated with neurologic symptoms and signs of vitamin B12 deficiency. Levels below 200 pg/ml unassociated with symptoms call for further investigation of cobalamin deficiency. Even serum levels of 200 to 300 pg/ml may be associated (in 5 to 10 percent of cases) with cobalamin deficiency. It must be emphasized that the serum cobalamin level is not a measure of total body cobalamin. In a patient who stops absorbing ingested cobalamin, the serum levels may long remain in the normal range despite decreasing tissue reserves. In patients who have received vitamin B12 parenterally, the two-stage Schilling test is a reliable indicator of cobalamin deficiency, since it uncovers a defect in absorption of the vitamin. Low cobalamin levels with or without the clinical signs of deficiency may occur in patients with atrophic gastritis or at subtotal gastrectomy. The malabsorption in such cases is thought to be due to a failure to extract cobalamin from food rather than a failure of the intrinsic-factor mechanism ("food-cobalamin malabsorption"); since the absorption of free cobalamin is normal, the Schilling test is unimpaired (Carmel). High serum concentrations of cobalamin metabolites—methylmalonic acid (normal range, 73 to 271 nmol/l) and homocysteine (normal range 5.4 to 16.2 nmol/l) are probably the most reliable indicators of an intracellular cobalamin deficiency and can be used to establish the diagnosis (Allen et al; Lindenbaum et al).

Nerve conduction tests have varied in vitamin B12–deficient patients. Early in the course of SCD, nerve conduction may be normal, but in our experience most patients with neurologic symptoms have slowing of distal sensory conduction; others have found reduced amplitudes and minor signs of denervation, suggestive of axonal change. In patients with normal peripheral nerve studies, the somatosensory evoked potentials show abnormalities that are attributable to central conduction delays, implicating the posterior columns as the cause of the sensory symptoms (Fine and Hallet). In advanced cases, motor conduction and late responses may be affected to a slight degree. These ambiguities reflect the inconsistent and poorly understood role of the peripheral neuropathic component in this disease.

Treatment 
The diagnosis of subacute combined degeneration demands the administration of vitamin B12 and the continuation of treatment for the rest of the patient's lifetime. Initially the patient should be given 1000 mg of cyanocobalamin or hydroxycobalamin intramuscularly each day. Thereafter this dose is repeated weekly for a lifetime. Initially the patient should be given 1000 mg of cyanocobalamin or hydroxycobalamin intramuscularly each day. Thereafter this dose is repeated weekly for a lifetime. In some patients who have received vitamin B12 parenterally, the two-stage Schilling test is a reliable indicator of cobalamin deficiency, since it uncovers a defect in absorption of the vitamin. Low cobalamin levels with or without the clinical signs of deficiency may occur in patients with atrophic gastritis or at subtotal gastrectomy. The malabsorption in such cases is thought to be due to a failure to extract cobalamin from food rather than a failure of the intrinsic-factor mechanism ("food-cobalamin malabsorption"); since the absorption of free cobalamin is normal, the Schilling test is unimpaired (Carmel). High serum concentrations of cobalamin metabolites—methylmalonic acid (normal range, 73 to 271 nmol/l) and homocysteine (normal range 5.4 to 16.2 nmol/l) are probably the most reliable indicators of an intracellular cobalamin deficiency and can be used to establish the diagnosis (Allen et al; Lindenbaum et al).

The most important factor influencing the response to treatment is the duration of symptoms before treatment is begun; age, sex, and the degree of anemia are relatively unimportant factors. The greatest improvement occurs in those patients whose disturbance of gait has been present for less than 3 months, and recovery may be complete if therapy is instituted within a few weeks after the onset of symptoms. In practically all instances, there is some degree of improvement after treatment, although sometimes, in cases of longest duration, the best that can be accomplished is an arrest of progression. All neurologic symptoms and signs may improve, mostly during the first 3 to 6 months of therapy, and then, at a slower tempo, during the ensuing year or even longer.

Other Neurologic Disorders due to B Vitamin Deficiencies

Pyridoxine (Vitamin B6) Deficiency 
A special type of nutritional polyneuropathy is encountered in tuberculous patients as a complication of treatment with isonicotinic acid hydrazide (INH, Isoniazid). In the recent past, a similar neuropathy was observed in hypertensive patients treated with hydralazine.

The occurrence of a neuropathy due to INH was recognized in the early 1950s, soon after the introduction of this drug for the treatment of tuberculosis. The neuropathy was characterized by paresthesias and burning pain of the feet and legs, followed by weakness of these parts and loss of ankle reflexes. Rarely, with continued use of the drug, the hands were affected as well. The nature of INH-induced neuropathy was clarified by Biehl and Viller. They found that the administration of isoniazid results in a marked excretion of pyridoxine, and that the administration of pyridoxine in conjunction with INH prevents the development of neuropathy. As a result of this simple preventive measure, very few examples of INH-induced neuropathy are now observed. Hydralazine, closely related in structure to INH, causes the formation of pyridoxal-isoniazid complexes (hydrzones), which makes pyridoxal (the main form of vitamin B6) unavailable to the tissues. The neuropathy responds favorably to discontinuation of the drug and the administration of pyridoxine.

Pyridoxine deficiency in animals and humans also causes seizures. This was first observed in swine by Swank and Adams and later in infants who were maintained on a milk formula lacking in pyridoxine.

Paradoxically, the consumption of large amounts of pyridoxine (by food and vitamin faddists) may also cause a peripheral neuropathy (Schaumburg et al; Albin et al). There is no weakness; the symptoms, including ataxia, are purely sensory and can be quite disabling. Improvement is the rule when the drug is withdrawn. This disorder is probably due to the direct toxic effect of pyridoxine on dorsal root ganglion cells.

Pantothenic Acid Deficiency 
A predominantly sensory neuropathy has also been induced, again in swine, by Swank and Adams and later in humans by a deficiency of pantothenic acid (a constituent of coenzyme A), as reported by Bean et al. In some patients the administration of pantothenic acid has allegedly reversed the
pathologic changes consist of a degeneration of all the neurocellular elements of the cerebellar cortex, but particularly of the Purkinje cells; they are restricted to the anterior and superior aspects of the vermis and, in advanced cases, to the anterior parts of the anterior lobes. Serum creatine phosphokinase was normal in these individuals, but carnitine was reduced. The oral administration of 200 mg of riboflavin and 4 g of carnitine per day relieved the symptoms. We have had no experience with such cases.

In summary, polyneuropathy may be caused by a deficiency of at least four B vitamins—thiamine, pyridoxine, pantothenic acid, and vitamin B12. That a deficiency of riboflavin causes lesions of the central or peripheral nervous system has not been proved. Despite the frequency of folate deficiency and its hematologic effects, its role in the pathogenesis of nervous system disease has not been established beyond doubt (see reviews by Crelin et al. and by Carney).

The polyneuropathy that occasionally complicates the chronic administration of phenytoin has been attributed, on uncertain grounds, to folate deficiency. Botez and colleagues have described a group of 10 patients with sensorimotor polyneuropathy (4 also had spinal cord disease) presumably due to intestinal malabsorption; all of the patients improved over several months while receiving large doses of folic acid. This experience is unique, however. The possible role of folate deficiency in the pathogenesis of spinal cord disease has been mentioned above in relation to vitamin B12 deficiency, and its putative role in psychiatric disease has been discussed by Carney.

Disorders Due to Deficiencies of Fat-Soluble Vitamins

Vitamin E Deficiency A rare neurologic disorder of childhood, consisting essentially of spinocerebellar degeneration in association with polyneuropathy and pigmentary retinopathy, has been attributed to a deficiency of vitamin E consequent upon prolonged intestinal fat malabsorption (Muller et al. Satya-Murti et al.). The same mechanism has been proposed to explain the neurologic disorders that sometimes complicate abetalipoproteinemia (page 1021), fibrocystic disease (Soldi et al.), celiac-sprue disease (page 1198), and extensive intestinal resections (Harding et al.). Vitamin E deficiency has also been observed in young children with chronic cholestatic hepatobiliary disease (Rosensoum & et al.). Ataxia, loss of tendon reflexes, ophthalmoparesis, proximal muscle weakness with elevated serum creatine kinase, and decreased sensation are the usual manifestations. These symptoms are referable to parts of the nervous system and musculature that are found to be diseased in animals deprived of vitamin E—degeneration of Clark's columns, spinocerebellar tracts, posterior columns, nuclei of Goll and Burdach, and sensory roots (Welsh et al.). Local differences in the natural concentration of vitamin E in various parts of the nervous system and musculature may account for the distribution of the lesions. In affected children, neurologic function improves after long-term daily supplementation with high doses of vitamin E.

In recent years there have been several reports of an inherited form of spinocerebellar degeneration attributable to vitamin E deficiency (“familial isolated vitamin E deficiency”). In these patients, absorption and transport of vitamin E to the liver is normal, but hepatic incorporation of a-tocopherol (the active form of vitamin E) into very low density lipoproteins is defective (Traber et al.). The a-tocopherol transfer protein, which normally is needed for this transport, is thought to be abnormal in these patients and the cause of spinocerebellar disease. The abnormality has been traced to a mutation in the gene for the a-tocopherol transfer protein, located on chromosome 8q (Gotoda et al.). In a sense this is a vitamin deficiency conditioned by genetic mutation.

Vitamins A and D Disorders due to a lack or excess of these fat-soluble vitamins are seen occasionally. Vitamin A deficiency sometimes occurs with malabsorption syndromes, causing impairment of vision. Excess of vitamin A in children may result in the syndrome of pseudotumor cerebri (page 667). Vitamin D deficiency is usually associated with hypoparathyroidism or a malabsorption state and leads to proximal muscle weakness and rickets.

DISEASES OF THE NERVOUS SYSTEM OF PROBABLE BUT UNPROVEN NUTRITIONAL ORIGIN

The disorders comprised by this category, as the above title indicates, have only an uncertain causal relationship to nutritional deficiency. They are found mainly in alcoholics, but their relationship to alcohol is probably not fundamental, since each of them has also been observed in nonalcoholic patients. The belief that these disorders in origin is based on certain indirect evidence: (1) Usually a prolonged period of undernutrition, associated with a significant loss of weight, precedes the neurologic illness. In such cases as are associated with alcoholism, the amount of alcohol consumed need not be large, but the dietary deprivation is always severe. (2) Examination at the onset of the illness frequently discloses general physical evidence of undernutrition as well as the presence of neurologic disorders of known nutritional etiology. (3) Certain attributes of the neuropathologic changes—namely their subacute evolution, symmetry, and constancy of localization—are precisely the features that characterize neurologic disorders of known nutritional etiology. (4) The same syndromes are observed occasionally in nonalcoholics under conditions of dietary depletion. (5) There is at least a partial response to correction of the nutritional impairment.

"Alcoholic" Cerebellar Degeneration

This term refers to a common and uniform type of cerebellar degeneration in alcoholics. Its incidence is about twice that of Wernicke disease, but, unlike the latter, it is considerably more frequent in men than in women. It is characterized clinically by a wide-based stance and gait, varying degrees of instability of the trunk, and ataxia of the legs, the arms being affected to a lesser extent and often not at all. Nystagmus and dysarthria are infrequent signs. In addition to an ataxic (intention) tremor, there may be a tremor of the fingers or hands resembling one of the two types of parkinsonian tremor but appearing only when the limbs are placed in certain sustained postures. Maurit and coworkers have demonstrated that the instability of the trunk in these cases consists of a specific 3-Hz rhythmic swaying in the anteroposterior direction; by contrast, patients with lesions of the cerebellar hemispheres show only slight postural instability without directional preponderance.

In most cases, the cerebellar syndrome evolves over a period of several weeks or months, after which it remains unchanged for many years. In others, it develops more rapidly or more slowly, but in these cases also the disease eventually stabilizes. Occasionally, the cerebellar disorder progresses in a saltatory manner, the symptoms worsening in relation to a severe infectious illness or an attack of delirium tremens.

The pathologic changes consist of a degeneration of all the neurocellular elements of the cerebellar cortex, but particularly of the Purkinje cells; they are restricted to the anterior and superior aspects of the vermis and, in advanced cases, to the anterior parts of the anterior lobes. The cerebellar atrophy is readily visualized by computed tomography (CT) and MRI.

Figure 41-2 CT scan from a 60-year-old alcoholic patient showing prominence of midline cerebellar sulci. A broad-based gait and ataxia of the legs had been present for many years. Death was from myocardial infarction. The cerebellum, cut in the midsagittal plane (below), shows folial atrophy of the anterior-superior vermis, characteristic of alcoholic cerebellar degeneration.

Two particular forms of this syndrome have not been emphasized sufficiently. In one, the clinical abnormalities are limited to an instability of station and gait, individual movements of the limbs being unaffected. The pathologic changes in such cases are restricted to the anterolateral portions of the vermis. A second type...
is acute and transient in nature. Here, except for their reversibility, the cerebellar symptoms are identical to those that characterize the chronic, fixed form of the disease. In this transitory type, the derangement is only one of function ("biochemical lesion") and has probably not progressed to the point of fixed structural changes. These forms of cerebellar disease, and particularly the restricted and reversible varieties, cannot be distinguished from the cerebellar manifestations of Wernicke disease either on pathologic or on clinical grounds. It is our opinion that the cerebellar ataxia of Wernicke disease and that referred to as alcoholic cerebellar degeneration are one and the same disease process, the former term being applicable when the cerebellar abnormalities are associated with ocular and mental signs and the latter when the cerebellar syndrome stands alone. Alcoholic cerebellar degeneration is in all likelihood due to nutritional deficiency and not to the toxic effects of alcohol or other causes, for reasons already indicated. Insofar as the cerebellar ataxia usually improves to some extent under the influence of thiamine alone (see above, under "Wernicke-Korsakoff Syndrome"), it is likely that a deficiency of this vitamin is responsible for the cerebellar lesion.

**Marchiafava-Bignami Disease (Primary Degeneration of the Corpus Callosum)**

In 1903, the Italian pathologists Marchiafava and Bignami described a unique alteration of the corpus callosum in three alcoholic patients. In each case, coronal sectioning of the fixed brain disclosed a pink-gray discoloration of the central portion of the corpus callosum throughout the longitudinal extent of this structure. Microscopically, the lesion proved to be confined to the middle lamina (which makes up about two-thirds of the thickness of the corpus callosum), in which there was a loss of myelin with relative preservation of the axis cylinders; macrophages were abundant in the altered zone, and astrocytic proliferation followed. The clinical observations in these patients were few and incomplete. In 1907, Bignami described a case in which the corpus callosum lesion was accompanied by a similar lesion in the central portion of the anterior commissure. These early reports were followed by a spate of articles that confirmed and amplified the original clinical and pathologic findings. By 1922 about 40 cases of this disorder had been described in the Italian literature (Minzucini). With one exception, all the reported cases were in males, and all of these men were insatiable drinkers. They drank red wine for the most part but other forms of liquor also. Beginning in 1936, with the report of King and Mehan, the disease came to be recognized throughout the world, and the notions that it had a predilection for drinkers of red wine and a special racial predisposition or geographic restriction were abandoned.

**Pathologic Features** Marchiafava-Bignami disease is more readily defined by its pathologic than by its clinical features. The principal alteration is in the middle portion of the corpus callosum, which on gross examination appears somewhat rarefied and sunken or gray-yellow in color, depending on its age. In the anterior portion of the corpus callosum, the lesion tends to be more severe in the midline than in its lateral parts; in the splenium, however, the opposite may pertain. The most chronic lesion takes the form of a centrally placed gray cleft or cavity, with collapse of the surrounding tissue and reduction in thickness of the corpus callosum. Microscopically, corresponding to the gross lesions, one observes clearly demarcated zones of demyelination, with variable involvement of the axis cylinders and an abundance of fatty macrophages with gliosis at the margins. Inflammatory changes are absent.

Infrequently, lesions of a similar nature are found in the central portions of the anterior and posterior commissures and the brachia pontis. These zones of myelin destruction are always surrounded by a rim of intact white matter. The predilection of this disease process for commissural fiber systems has been stressed, but it is clear, too, that some of these fibers, especially the interhemispheric fibers, are involved in the columns of Gok and in the fornix, the splenium of the corpus callosum, and the septal commissures. Involvement of the corpus callosum and the corresponding zones of both hemispheres, involving the centrum semiovale and extending, in some cases, into the adjacent convolutional white matter. As a rule, the internal capsule and corona radiata, subcortical arcuate fibers, and cerebellum are spared. In several cases, the lesions of deficiency amilobyia (see above) have been observed, and in others, the lesions of Wernicke disease.

Many of the reported cases, as first pointed out by Jequier and Wildi, have involved cortical lesions of a special type: the neurons in the third layer of the frontal and temporal lobe cortices had disappeared and were replaced by a fibrous gliosis. Morel, who first described this cortical laminar sclerosis, did not observe its association with Marchiafava-Bignami disease. However, when Jequier and Adams reviewed his original cases (unpublished), all had Marchiafava-Bignami disease. In a subsequent report by Delay and colleagues comprising 14 cases of cortical laminar sclerosis, the cortical lesion was also consistently associated with a corpus callosum lesion. We believe the cortical lesions to be secondary to the callosal degeneration.

**Clinical Features** The disease affects persons in middle and late adult life. With few exceptions, the patients have been males and severe chronic alcoholics. The clinical features of the illness are otherwise quite variable, and a clear-cut syndrome of uniform type has not emerged. Many patients have presented in a state of terminal stupor or coma, precluding a detailed neurologic assessment. In others, the clinical picture was dominated by the manifestations of chronic inebriation and alcohol withdrawal—tremor, seizures, hallucinosis, and delirium tremens. In some of these patients, following the subsidence of the withdrawal symptoms, no signs of neurologic disease could be elicited, even in the end stage of the disease, which lasted for several days to weeks. In yet another group, a progressive dementia has been described, evolving slowly over a 3- to 6-year period before death. Emotional disorders leading to acts of violence, marked apathy, moral perversions, and sexual misdemeanors have been noted in these patients; dysarthria, slowing and unsteadiness of movement, transient spastic lariamenl incontinence, hemiparesis, and apractic or aphasic disorders were superimposed. The last stage of the disease is characterized by physical decline, seizures, stupor, and coma. An impressive feature of these varied neurologic deficits in some patients has been their tendency toward remission when nutrition was restored.

In two cases that have come to our attention, the clinical manifestations were essentially those of bilateral frontal lobe disease: motor and mental slowness; apathy; psychomotor retardation; spasticity; deficits of orientation; and a slow, halting, wide-based gait. In both of these cases, the neurologic abnormalities evolved over a period of about 2 months, and both patients recovered from these symptoms within a few weeks of hospitalization. Death occurred several years later as a result of liver disease and subdural hematoma, respectively. In each case, autopsy disclosed an old lesion typical of Marchiafava-Bignami disease confined to the central portion of the most anterior parts of the corpus callosum, but one had to look closely to see the gray line of gliosis.

In view of the great variability of the clinical picture and the obscurity in many patients of subtle mental and neurologic abnormalities by the effects of chronic inebriation and other alcoholic neurologic disorders, the diagnosis of Marchiafava-Bignami disease is understandably difficult. In fact, it is rarely made during life. The occurrence, in a chronic alcoholic, of a frontal lobe syndrome or a symptom complex that points to a diagnosis of frontal or corpus callosum tumor but in whom the symptoms remit should suggest the diagnosis of Marchiafava-Bignami disease. The CT scan and MRI have disclosed some unsuspected instances of this disease (see also Kawamura et al)

**Pathogenesis and Etiology** Originally, Marchiafava-Bignami disease was attributed to the toxic effects of alcohol, but this is an unlikely explanation in view of the prevalence of alcoholism and the rarity of corpus callosum degeneration. Further, the distinctive callosal lesions have not been observed with other neurotoxins. Very rarely, undoubted examples of Marchiafava-Bignami disease have occurred in abstainers, so that alcohol cannot be an indispensable factor. A nutritional etiology has been invoked, for the reasons given earlier, but the deficient factor has not been defined. The mechanisms involved in the selective necrosis of particular areas of the corpus callosum require elucidation. Perhaps mechanical factors, such as the increased CSF pressure in Marchiafava-Bignami disease, like central pontine myelinolysis (which it resembles histologically), will have to be considered in a chapter other than one on nutritional disease.

**Protein calorie Malnutrition (PCM) and Mental Retardation**

The reader might gather from the foregoing descriptions that the nervous system is rarely affected by nutritional deficiency except when subjected to the influence of chronic alcoholism and other alcoholic neurologic disorders, the alcoholic cerebellar disease either on pathologic or on clinical grounds. It is our opinion that the cerebellar ataxia of Wernicke disease and that referred to as alcoholic cerebellar degeneration are one and the same disease process, the former term being applicable when the cerebellar abnormalities are associated with ocular and mental signs and the latter when the cerebellar syndrome stands alone. Alcoholic cerebellar degeneration is in all likelihood due to nutritional deficiency and not to the toxic effects of alcohol or other causes, for reasons already indicated. Insofar as the cerebellar ataxia usually improves to some extent under the influence of thiamine alone (see above, under "Wernicke-Korsakoff Syndrome"), it is likely that a deficiency of this vitamin is responsible for the cerebellar lesion.

The clinical signs of polyneuropathy or subacute combined degeneration of the cord are lacking in children with PCM. However, electrophysiologic testing...
may cause a reduction in motor nerve conduction velocity and abnormalities of sensory conduction (Chopra et al). In children with severe degrees of PCM, it is said that there may be evidence, in sural nerve biopsies, of retarded myelination (presence of only the small myelinated fibers) and segmental demyelination.

Of great interest is whether the children who are rescued from these states of undernutrition by proper feeding are left with an underdeveloped or damaged brain. This subject has been studied extensively in many species of animals, as well as in humans, by clinical, biochemical, and neuropathologic methods. The literature is too large to review here, but excellent critiques have been provided by Winick, Birch and coworkers, Latham, and Dodge and colleagues.

In contrast to the devastating effect of PCM upon body growth, brain weight is only slightly reduced. Nevertheless, on the basis of experiments in dogs, pigs, and rats, it is evident that prenatal and early postnatal malnutrition retards cellular proliferation in the brain. All cells are affected, including oligodendroglia, with a proportional reduction in myelin. Also, the process of dendritic branching may be retarded by early malnutrition. A limited number of studies in humans suggest that PCM has a similar effect upon the brain during the first 8 months of life. In animals, varying degrees of recovery from the effects of early malnutrition are possible if normal nutrition is reestablished during the vulnerable periods. Presumably this is true for humans as well, although proof is difficult to obtain. In every series of severely undernourished infants and young children who have been observed for a period of many years, a variable proportion has been left scholastically incompetent and mentally backward to a modest degree; the majority recover, however (Galler). Unfortunately, the neurologic and intellectual consequences of PCM have defied accurate assessment because of the difficulty of isolating the effects of severe malnutrition from those of infection, social deprivation, genetic faults, and other factors. The relative importance of these various factors is still under study.

**Nutritional Deficiencies Secondary to Diseases of the Gastrointestinal Tract**

The vitamins that are known to be essential to the normal functioning of the central and peripheral nervous systems cannot be synthesized by the human organism. Each is ingested as an essential part of the normal diet and absorbed in certain regions of the gastrointestinal tract. Impairment or failure of absorption due to diseases of the gastrointestinal tract gives rise to several malabsorption syndromes. In these diseases, the site of the block in transport from the intestinal lumen varies; it may be at the surface of the enterocytes or at their interface with the lymphatic channels and portal capillaries.

Table 41-3, which is modified from Pallis and Lewis, lists the malabsorptive diseases and their relationships to the intestinal abnormalities. Of all these diseases, celiac sprue (gluten enteropathy) is the most common. The neurologic complications of this disorder, in our experience, have always taken the form of a symmetrical sensory polyneuropathy. However, other complications have been described, notably a progressive cerebellar syndrome with cortical, dentatal, and olivary cell loss (Finelli et al; see also Chap. 40). The cerebellar changes may be coupled with a symmetrical demyelination of the posterior columns, producing a spinocerebellar disorder similar to that of vitamin E deficiency (Cooke and Smith). In the latter case, however, vitamin E supplementation has no consistent effect. Hallert and colleagues have described a high incidence of depression and other psychiatric disturbances in adult patients with celiac sprue. Unexplained seizures are also said to occur.

**Table 41-3** Mechanisms whereby malabsorption may be related to neurologic disease

Polynynepathy and subacute combined degeneration of the spinal cord manifesting themselves many years after gastrectomy are encountered only rarely.

An important effect of fat malabsorption is a deficiency of vitamin E, which, in turn, may give rise to neurologic symptoms, particularly in young children. This topic is discussed in an earlier part of this chapter.

The neurology of gastrointestinal disease has been reviewed recently by Perkin and Murray-Lyon.

**Inherited Vitamin-Responsive Neurologic Diseases (See Also Chap. 37)**

Although humans lack the capacity to synthesize essential vitamin molecules, they are nonetheless able to use them in a series of complex chemical reactions involved in intestinal absorption, transport in the plasma, entry into the organelles of many organs, activation of the vitamin into coenzyme, and finally their interaction with certain specific apoenzyme proteins. This compels consideration of another aspect of nutrition wherein one or more of these steps in vitamin utilization may be defective because of a genetic abnormality. Under these circumstances, the signs of vitamin deficiency result not from vitamin deficiency in the diet but from a genetically deranged control mechanism. In some instances the defect is only quantitative, and by loading the organism with a great excess of the vitamin in question the biochemical abnormality can be overcome. The special type of vitamin E deficiency that results from an inherited inability to incorporate the vitamin into lipoproteins also falls into this category—the diseases of which, being of hereditary type, have already been described in Chap. 37. "The Inherited Metabolic Diseases of the Nervous System." Rosenberg has listed the most important of these hereditary vitamin-responsive diseases, which we have simplified for the reader interested in this subject in Table 41-2.

**Treatment of Alcohol Addiction**

Inter temperance in the use of alcohol creates many problems in modern society, the importance of which can be judged by the repeated emphasis they receive in contemporary writings, both literary and scientific. These problems may be divided into three categories: psychologic, medical, and sociologic. The main psychologic problem is why a person drinks excessively, often with full knowledge that such action will result in physical injury and even death. The medical problem embraces all aspects of alcoholic habitation as well as the diseases that result from the abuse of alcohol. The sociologic problem consists of the effects of sustained drinking on the patient’s work, family, and community. Some idea of the enormity of these problems can be gleaned from figures supplied by the Secretary of Health and Human Services—which reveal that up to 40 percent of medical and surgical patients have alcohol-related problems and that these patients account for 15 percent of all health care costs (which in 1995 were estimated at 150 billion dollars).

These several problems engendered by excessive drinking cannot be separated from one another; the physician must therefore be conversant with all aspects of this subject. He may be asked to help the patient to overcome his drinking problem or to diagnose and treat the numerous diseases to which such a patient is subject; often he must admit the patient to a “detoxification” unit or a general hospital or to a psychiatric facility, according to the nature of the clinical disorder; and, last, he may be required to enlist the aid of social agencies when their services are needed by either the patient or the patient’s family.

**Primary alcoholism** has been defined as both a chronic disease and a disorder of behavior, characterized in either context by chronic, repetitive, excessive drinking to an extent that interferes with the drinker’s health, interpersonal relations, or means of livelihood. Reduced to pharmacologic terms, it is addiction to alcohol.

Secondary alcoholism refers to excessive drinking in the context of another major psychiatric illness—e.g., manic-depressive disease. The term alcoholism, unqualified, refers to the primary variety.

The causation of alcoholism remains obscure, although environmental, cultural, and genetic factors are clearly implicated in certain groups of patients. No single personality type has been shown to predict reliably who will become addicted to alcohol and who will not, similarly, no particular aspect of alcohol metabolism has been found to account for the development of addiction, although the possibility of a diminished “first-pass” metabolism of alcohol remains.

Some persons drink excessively and become alcoholics in response to some profoundly disturbing personal or family problem, but many do not. Alcoholism may develop in response to a depressive illness, more so in women than in men, but far more often is depression a consequence of drinking. Social and cultural influences are undoubtedly important in the genesis of alcoholism, as evidenced, for example, by the markedly high incidence of alcoholism and drinking problems in the American Indian and Eskimo populations and by the disparity in the prevalence of alcoholism, within a single community, between the Irish and the Jews. However, no ethnic or racial group and no social or economic class is exempt. Moreover, no particular pattern of child rearing or cultural attitude is universally effective in facilitating or protecting against the development of alcoholism. The writings of Schuckit and of Mello, listed in the references, provide critical overviews of the many etiologic theories.

The importance of genetic factors in the causation of alcoholism is being increasingly recognized. Goodwin and coworkers studied 55 Danish men whose biologic parents were alcoholic and 55 control subjects whose biologic parents were not alcoholic. All of the subjects had been adopted before the age of 5 weeks and had no knowledge of their biologic parentage. Twenty percent of the offspring of biologic alcoholic parents, but only 5 percent of the control subjects, had become alcoholics by the age of 25 to 29 years. A Swedish adoption study (Bohman) and one in the United States (Cadoret et al) have corroborated these findings. Family studies have disclosed a three- to fourfold increased risk for alcoholism in sons and daughters of alcoholics, and twin studies have shown a twofold higher concordance rate for alcoholism in monozygotic than in dizygotic pairs. Details of these studies can be found in the comprehensive reviews of the genetics of alcoholism by Grove and Cadoret and by Schuckit. The search goes on for a biologic trait, or marker, that would identify those who are genetically vulnerable to the development of alcoholism, but to date none has proved to be sufficiently practical or sensitive to identify all such persons (Reich).

As to the frequency of alcoholism, the survey by Grant et al of more than 43,000 households is still an epidemiologic benchmark. They estimated that in 1988, some 15.3 million Americans (8.6 percent of persons 18 years or older) were either alcohol abusers or alcohol-dependent. Of this number, 4.1 million were women. In addition, there were approximately 4.6 million problem drinkers among adolescents (about 20 percent of the persons in this age group). Several more recent surveys have suggested a rate of alcohol dependence of 3 to 5.5 percent of adults, Schuckit has estimated that the lifetime risk for alcoholism is at least 10 percent for men and 3 to 5 percent for women. A minimum of 3 percent of deaths in the United States can be attributed to alcohol-related causes. Alcohol intoxication is responsible for approximately 45 percent of fatal motor vehicle accidents and 22 percent of boating accidents. It requires little imagination to conceive the havoc wrought by alcohol in terms of decreased productivity, increased incidence of suicide, accidents, crime, mental and physical disease, and disruption of family life.

**PHARMACOLOGIC AND PHYSIOLOGIC CONSIDERATIONS**

Ethyl alcohol, or ethanol, is the active ingredient in beer, wine, whiskey, gin, brandy, and other less common alcoholic beverages. In addition, the stronger spirits contain enathic ethers, which provide flavor but have no important pharmacologic properties, and impurities such as amyl alcohol (fuely oil) and acetaldehyde, which act like alcohol but are more toxic. Contrary to popular opinion, the content of B vitamins in American beer and other liquors is so low as to have little nutritional value (Davidson).

**Absorption, Distribution, and Metabolism of Alcohol**

Alcohol is absorbed unaltered from the gastrointestinal tract, about 25 percent from the stomach and the rest from the upper small intestine. Its presence may be detected in the blood within 5 min after ingestion, and the maximum concentration is reached in 30 to 90 min. The ingestion of milk and fatty foods impedes and water facilitates its absorption. The rate of absorption increases after gastrectomy; in such cases maximum blood alcohol concentrations are higher and are attained faster than in persons with intact stomachs. In habituated persons, the blood alcohol concentration rises somewhat from the upper small intestine. Its presence may be detected in the blood within 5 min after ingestion, and the maximum concentration is reached in 30 to 90 min. The

Alcohol is carried chiefly in the plasma and enters the various organs of the body—such as the cerebrospinal fluid (CSF), urine, and pulmonary alveolar air—in concentrations that bear a constant relationship to the concentration in the blood. Alcohol is metabolized chiefly by oxidation, less than 10 percent being excreted unchanged in the urine, perspiration, and breath. The energy liberated by the oxidation of alcohol (7 kcal/g) can be utilized as completely as that derived from the metabolism of other carbohydrates. However, calories from alcohol are empty of nutrients such as proteins and vitamins and cannot be used in the repair of damaged tissue. Therefore, unless the chronic drinker takes an adequate amount of protein (which he frequently fails to do), muscle bulk is lost and other tissues are subject to damage.

All ingested alcohol except that metabolized by alcohol dehydrogenase in the stomach wall is carried by the portal system to the liver. Here several enzyme systems (located in different subcellular compartments of the hepatocyte) can independently oxidize alcohol to acetaldehyde. The most important of these systems, accounting for 80 to 90 percent of ethanol oxidation in vivo, are alcohol dehydrogenase (ADH) and its coenzymes; they are found in the soluble fraction of the hepatocyte and utilize nicotinamide adenine dinucleotide (NAD) as the coactor. This reaction leads to the formation of acetaldehyde and the reduction of NAD to NADH. A second pathway involves catalase, which is located in the peroxisomes and mitochondria; a third utilizes the “microsomal ethanol oxidizing system” (MEOS), located mainly in the smooth endoplasmic reticulum. Although this enzyme is capable of metabolizing up to 20 percent of alcohol absorbed from the gut, it seems to be of little importance in the ethanol metabolism of the mammalian liver. Aminotransferases of the liver have been implicated in the production of acetaldehyde by the conversion of aspartic acid to oxaloacetic acid.

The metabolism of aldehydes proceeds by two major pathways. Acetaldehyde is oxidized to acetic acid by liver microsomal enzymes and by mitochondria. The latter reaction is the major pathway for the metabolism of acetaldehyde in the liver, and it is blocked by various drugs such as diazepam and alcohol itself.

Acetaldehyde is further oxidized to acetic acid by mitochondrial enzymes. This reaction is catalyzed by aldehyde dehydrogenase, which is found in the liver and in other tissues as well. This enzyme is inhibited by acetaldehyde, and its activity is decreased in patients with alcoholic liver disease. The inhibition of this enzyme is therapeutically important in the treatment of acute alcohol poisoning, for it reduces the formation of acetaldehyde and decreases the level of serum acetic acid. Acetaldehyde is also oxidized to acetic acid by the liver microsomal enzymes, although this pathway is not important in the metabolism of alcohol.

Acetaldehyde is oxidized to acetic acid by liver microsomal enzymes and by mitochondria. This reaction is catalyzed by aldehyde dehydrogenase, which is found in the liver and in other tissues as well. This enzyme is inhibited by acetaldehyde, and its activity is decreased in patients with alcoholic liver disease. The inhibition of this enzyme is therapeutically important in the treatment of acute alcohol poisoning, for it reduces the formation of acetaldehyde and decreases the level of serum acetic acid. Acetaldehyde is also oxidized to acetic acid by the liver microsomal enzymes, although this pathway is not important in the metabolism of alcohol.

The formation of acetaldehyde by alcohol dehydrogenase is an important step in the metabolism of alcohol. Acetaldehyde is a toxic substance that can cause liver damage and other problems. It is converted to acetic acid by the liver microsomal enzymes and by mitochondria. This reaction is catalyzed by aldehyde dehydrogenase, which is found in the liver and in other tissues as well. This enzyme is inhibited by acetaldehyde, and its activity is decreased in patients with alcoholic liver disease. The inhibition of this enzyme is therapeutically important in the treatment of acute alcohol poisoning, for it reduces the formation of acetaldehyde and decreases the level of serum acetic acid. Acetaldehyde is also oxidized to acetic acid by the liver microsomal enzymes, although this pathway is not important in the metabolism of alcohol.
the microsomes of the endoplasmic reticulum. The MEOS, which is dependent upon reduced nicotinamide adenine dinucleotide phosphate (NADPH), does not account for much of the alcohol metabolized in normal circumstances, but it may be responsible for the increased rate of alcohol metabolism observed in chronic alcoholics.

The aforementioned shift in the NADH/NAD ratio results in a number of metabolic derangements in carbohydrate and lipid metabolism. The synthesis of glucose declines and there is a conversion of lactate to pyruvic acid. However, a significant lowering of blood glucose will occur only if the hepatic glycogen stores are depleted—as a result of fasting, for example. The levels of serum lactate will be increased occasionally, to the point of lactic acidosis. In certain circumstances alcohol can interfere with the peripheral utilization of glucose, resulting in hyperglycemia. Also, as a result of the changed NADH/NAD ratio, there occurs a depression in the conversion of the fatty acids, the excess of which are converted to triglycerides. This leads, in turn, to a fatty liver. Such changes are related to alcohol per se and are independent of malnutrition.

The details of the process by which acetaldehyde is metabolized are still not settled. Most likely it is converted by aldehyde dehydrogenase to acetate. Acetaldehyde has a number of unique biochemical effects that are not produced by alcohol alone. Persons who flush easily after ingestion of alcohol (Chinese, Japanese, and other Asians) differ from “nonflushers” with respect to the metabolism of acetaldehyde rather than to the metabolism of alcohol. The flushing reaction has been traced to a deficiency of aldehyde dehydrogenase activity (Harada et al). The low rate of alcoholism among Asians is said to be related to the flushing reaction (which is, in effect, a severe reaction to alcohol in nonflushers). But such a case, since North American Indians, a group with a high incidence of alcoholism, show the same reaction. There are no valid data to support the claim that acetaldehyde, rather than ethanol itself, is the major intoxicating and adding agent in alcoholism.

For all practical purposes, it may be accepted that once the effects of alcohol has ended and an equilibrium has been established with the tissues, ethanol is oxidized at a constant rate, independent of its concentration in the blood (about 150 mg alcohol per kilogram of body weight per hour, or about 1 oz of 90-proof whisky per hour). Actually, slightly more alcohol is metabolized per hour when the initial concentrations are very high, and repeated ingestion of alcohol may facilitate its metabolism, but these increments are of little clinical significance. Neither do agents such as amino acids, insulin, and fructose have any practical value in enhancing ethanol metabolism. On the other hand, the rate of oxidation of acetaldehyde does depend on its concentration in the tissues. This fact is of importance in connection with the drug disulfiram (Antabuse), which acts by raising the tissue concentration necessary for the metabolism of a certain amount of acetaldehyde per unit of time. The patient taking both disulfiram and alcohol will accumulate an inordinate amount of acetaldehyde, resulting in nausea, vomiting, and hypotension, sometimes so pronounced in degree as to be fatal. This pharmacologic principle underlies the treatment of alcoholism with disulfiram. Certain other drugs—namely the sulfonylureas, metronidazole, and furazolidone—have effects like those of disulfiram but are less potent.

The fraction of ingested alcohol that survives first-pass oxidation in the stomach wall and the liver equilibrates rapidly with all bodily fluids and tissues and affects their function to a degree that is governed by the alcohol blood concentration. Only the effects on the nervous system concern us in this chapter. Complete accounts of the nonneurologic effects can be found in the monographs edited by Lieber and by Mendelson and Mello.

**Pharmacologic Effects**

Alcohol acts directly on neuronal membranes in a manner akin to that of the general anesthetics. These agents, as well as barbiturates and benzodiazepines, are lipid-soluble and are thought to produce their effects by dissolving in the cell membranes (in direct relation to the degree of their lipid solubility). This process has a disordering effect on other membrane structures, particularly proteins. With continued ingestion of alcohol, the neuronal membranes rigidify and become resistant to the fluidizing effect of alcohol (Chin and Goldstein; Harris et al).

It is unlikely, however, that these changes in the physical properties of cell membranes are in themselves sufficient to alter cell function. Probably of greater importance are the effects of alcohol on membrane receptor systems, which regulate ion channels, particularly the chloride and calcium channels. One likely site that relates to the acute intoxicating effects of alcohol is a receptor for the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) and its associated chloride-ion channel. Benzodiazepine antagonists appear to block the potentiation by alcohol of GABA-induced chloride flux. Like the GABA-chloride channel, the N-methyl-d-aspartate (NMDA) receptors, which transduce signals carried by glutamate (the major excitatory transmitter in brain), are sensitive to extremely low concentrations of alcohol. It is also clear that alcohol selectively potentiates serotonin 5-HT3 receptor-ion currents, and the activity of this receptor has been implicated in alcohol- and drug-seeking behavior and addiction.

The effect of chronic administration of alcohol is to increase the number of neuronal calcium channels in the cell membrane; moreover, calcium channel blockers, given during chronic administration, prevent both the increase in neuronal calcium channels and the development of tolerance to alcohol (Polin and Little). The significance of these findings has been demonstrated by Little and colleagues, who showed that calcium channel blockers, given to chronically intoxicated animals after withdrawal, prevent withdrawal convulsions.

The molecular mechanisms involved in the genesis of alcohol intoxication and tolerance are obviously far more complex than the foregoing remarks would indicate (see reviews by Charness and by Samson and Harris). There is now a vast literature on this subject, much of it contradictory. A unified concept of the role of neurotransmitters and their receptors and modulators in the production of alcohol intoxication and tolerance has yet to emerge. The role of internal cellular messengers, which have attracted much attention in the field of addiction, is also currently under investigation.

**Physiologic Effects**

Alcohol functions not as a central nervous system (CNS) stimulant but as a depressant. Some of the early toxic effects of alcohol, such as garrulousness, aggressiveness, excessive activity, and increased electrical excitability of the cerebral cortex—all of them suggestive of cerebral stimulation—are thought to be due to the inhibition of certain substochiometric structures (possibly the high brainstem reticular formation) that ordinarily moderate cerebrocortical activity. Subsequent impairment of tendon reflexes, the transitory escape of spinal motor neurons from higher inhibitory centers. With increasing amounts of alcohol, however, the depressant action spreads to involve the cortical as well as other brainstem and spinal neurons.

All manner of motor functions—whether the simple maintenance of a standing posture, the control of speech and eye movements, or highly organized and complex motor skills—are adversely affected by alcohol. The movements involved in these acts are not only slower than normal but also more inaccurate and random in character and therefore less well adapted to the accomplishment of specific ends.

Alcohol also impairs the efficiency of mental function by interfering with the speed of perception and the ability to persist in mental processing. The learning process is impaired, the retention of information is lessened, and the acquisition of new skills is reduced. The subject is less versatile in directing thought along new lines appropriate to the problem at hand. Finally, alcohol impairs the faculties of judgment and character and therefore less well adapted to the accomplishment of specific ends.

A scale relating various degrees of functional impairment to blood alcohol levels in nonhabituated persons was constructed many years ago by Miles. At a blood alcohol level of 30 mg/dL, a mild euphoria was detectable, and at 50 mg/dL, a mild incoordination. At 100 mg/dL, ataxia was obvious; at 200 mg/dL, there was confusion and a reduced level of mental activity; at 300 mg/dL, the subjects were stuporous; and a level of 400 mg/dL—accompanied by deep anesthesia—was potentially fatal. These figures are valid provided that the alcohol content in the blood rises steadily over a 2-h period.

**Tolerance** should be emphasized that a scale such as the one described above has virtually no value in the chronic alcoholic patient, for it does not take into account the adaptation of the organism to alcohol, i.e., the phenomenon of tolerance. It is common knowledge that a habituated person can drink more and show fewer effects than the moderate drinker or abstainer. This phenomenon accounts for the surprisingly large amounts of alcohol that the chronic drinker can consume without experiencing significant signs of drunkenness. Sober-appearing alcoholics may have blood alcohol levels of 400 to 500 mg/dL. The aspect of tolerance must always be considered in judging the significance of a single estimation of the blood alcohol concentration as an index of functional capacity.

The nervous system is capable of adapting to alcohol after a very short exposure. Thus, if the alcohol concentration in the blood is raised very slowly, few symptoms appear, even at quite high levels. Contrariwise, the degree of intoxication is more severe when the blood alcohol level peaks rapidly. As mentioned earlier, the important factor in this rapid adaptability is not so much the height of the blood alcohol concentration as the length of time the alcohol has been present in the body. If the concentration of alcohol that causes blood levels to be high is held constant, the blood alcohol concentration falls gradually and clinical evidence of intoxication disappears. The cause of this fall in alcohol concentration is not clear.

The mechanisms that underlie tolerance and addiction are just beginning to be understood. There is little evidence that an enhanced rate of alcohol metabolism can adequately account for the degree of tolerance observed in alcoholics. An increased degree of neuronal adaptation to alcohol is a more likely explanation. As mentioned earlier, the main factors that are operative in this adaptation are the increasing resistance of neuronal membranes to the "fluidizing" effects of alcohol and...
The usual manifestations of alcohol intoxication are so commonplace that they require little elaboration. They consist of varying degrees of exhilaration and excitement, loss of restraint, irregularity of behavior, incoherence, and slurred speech, incoordination of movement and gait, irritability, drowsiness, and, in advanced cases, stupor and coma. There are several complicated types of alcohol intoxication, which are considered below.

**Pathologic Intoxication** Despite what has been said above, on rare occasions, alcohol has an excitatory rather than a sedative effect. This reaction has been referred to in the past as pathologic, or complicated, intoxication and as acute alcoholic encephalopathy. Since all forms of intoxication are pathologic, atypical intoxication or idiosyncratic alcohol intoxication are more appropriate designations. Nevertheless, the term pathologic intoxication is still widely used. The boundaries of this syndrome have never been clearly drawn. In the past, variant forms of delirium tremens and epileptic phenomena as well as psychopathologic and criminal behavior were occasionally included. Now the term is generally used to designate an outburst of blind fury with assaultive and destructive behavior. Often the patient is subdued only with difficulty. The attack terminates with deep sleep, which occurs spontaneously or in response to parenteral sedation; on awakening, the patient has no memory of the episode. Lesser degrees are also known wherein the patient, after several drinks, repeatedly commits gross social indiscretions. Allegedly this reaction may follow the ingestion of a small amount of alcohol, but in our experience the amount has always been substantial. Unlike the usual forms of alcohol intoxication and withdrawal, the atypical form has not been produced in experimental subjects, and the diagnosis depends upon the aforementioned arbitrary anecdotatal criteria.

Pathologic intoxication has been ascribed to many factors, the common ones being constitutional differences in the susceptibility to alcohol (idiosyncratic reaction to alcohol), pre-existent cranioencephalic trauma or other brain disease, and an underlying "hysterical or epileptic temperament or sociopathy." There are no meaningful data to support any of these beliefs. However, an analogy may be drawn between pathologic intoxication and the paradoxical reaction that occasionally follows the administration of barbiturates or other sedative drugs.

The diagnosis of pathologic or idiosyncratic intoxication could conceivably have important legal implications. Because of long-held public and legal attitudes, a person suffering from alcoholism or the usual forms of drunkenness is considered to be responsible for the consequences of his drinking, whereas a person with pathologic intoxication might be considered insane at the time and therefore not responsible. The main disorders to be distinguished from pathologic intoxication are temporal lobe seizures that occasionally take the form of outbursts of rage and violence and the explosive episodes of violence that characterize the behavior of certain sociopaths. The diagnosis in these cases may be difficult and depends on eliciting the other manifestations of temporal lobe epilepsy or sociopathy.

**Alcoholic "Blackouts"** In the language of the alcoholic, the term blackout refers to an interval of time, during a period of severe intoxication, for which the patient, when sober, has no memory—even though the state of consciousness, as observed by others, was not grossly altered during that interval. However, a systematic assessment of mental function during the amnesic period has usually not been made. A few observations indicate that it is short-term (retentive) memory, rather than immediate or long-term memory, that is impaired; this feature and the subsequent amnesia for the episode are somewhat reminiscent of the disorder known as transient global amnesia (page 457).

The nature and significance of such episodes are unclear. It is widely held that the occurrence of blackouts is an early and serious indicator of the development of alcohol addiction. In our experience, blackouts may occur at any time in the course of alcoholism, even during the first drinking experience, and they certainly have happened in persons who never became alcoholics. The salient facts are that there is a degree of intoxication which interferes with the registration of events and the formation of memories during the period of intoxication, and that the amount of alcohol consumed in moderate social drinking will rarely produce this effect.

**Alcoholic Stupor and Coma** As has been indicated, the symptoms of alcoholic intoxication are the result of the depressant action of alcohol on cerebral and spinal neurons. In this respect alcohol acts on nerve cells in a manner akin to the general anesthetics. Unlike the latter, however, the margin between the dose of alcohol that produces surgical anesthesia and that which dangerously depresses respiration is a narrow one, a fact that adds an element of urgency to the diagnosis and treatment of alcoholic narcosis. One must also be alert to the possibility that barbiturates or other sedative-hypnotic drugs may have potentiated the depressant effects of alcohol.

The signs of alcohol intoxication are distinctive and most forms present no problem in diagnosis or management. On the other hand, coma due to alcohol may present difficulties in differential diagnosis. It should be stressed that the diagnosis of alcoholic coma is made not merely on the basis of a flushed face, stupor, and the odor of alcohol but only after the careful exclusion of all other causes of coma (page 383).

**Treatment of Alcohol Intoxication** Mild to moderate degrees of intoxication require no special treatment. Certain time-honored forms of stimulation—such as a cold shower, strong coffee, forced activity, or induction of vomiting—may be helpful, but there is no evidence that any of them influences the rate of disappearance of alcohol from the blood. Alcoholic stupor is also a relatively brief, self-limited state; if the vital signs are normal, no special therapeutic measures are necessary. **Pathologic intoxication:** may require the use of restraints and the parenteral administration of diazepam (5 to 10 mg) or haloperidol (2 to 5 mg), repeated once after 30 to 40 min if necessary.

Coma due to alcohol intoxication represents a medical emergency. The main object of treatment is to prevent respiratory depression and the complications it engenders. The management of the comatose patient is described in **Chap. 17.** One would like to lower the blood alcohol level as rapidly as possible, but the administration of fructose or of insulin and glucose for this purpose is of little practical value. Analeptic drugs such as amphetamine and various mixtures of caffeine and other analeptics are not antagonistic to alcohol and are safe as long as they are used in doses which do not hasten the oxidation of alcohol. The use of hemodialysis should be considered in comatose patients with extremely high blood alcohol concentrations (>500 mg/dL), particularly if accompanied by acidosis, and in those who have concurrently ingested methanol or ethylene glycol or some other dialyzable drug.

**Methyl, Amyl, and Isopropyl Alcohols and Ethylene Glycol** Poisoning with alcohols other than ethyl alcohol is a relatively rare occurrence. Amyl alcohol (fusel oil) and isopropyl alcohol are used as industrial solvents and in the manufacture of varnishes, lacquers, and pharmaceuticals; in addition, isopropyl alcohol is readily
Methyl alcohol (methanol, wood alcohol) is a component of antifreeze and many combustibles and is used in the manufacture of formaldehyde, as an industrial solvent, and as an adulterant of alcoholic beverages, the latter being the most common source of alcohol intoxication. The oxidation of methyl alcohol to formaldehyde and formic acid proceeds relatively slowly; thus, signs of intoxication do not appear for several hours or may be delayed for a day or longer. Many of the toxic effects are like those of ethyl alcohol, but in addition severe methyl alcohol poisoning may produce serious degrees of acidosis (with an anion gap), damage to renal ganglion cells—giving rise to scotomata and varying degrees of blindness, dilated unreactive pupils, and retinal edema—and bilateral degeneration of the putamens, readily visible on computed tomography (CT) scans. Survivors may be left blind and parkinsonian (McLean et al). The most important aspect of treatment is the intravenous administration of large amounts of sodium bicarbonate. Hemodialysis may be a useful adjunct because of the slow rate of oxidation of methanol.

Fig. 42-1: Relation of acute neurologic disturbances to cessation of drinking. The shaded drinking period is greatly forestshortened and not intended to be quantitative. The period preceding in the baseline represents the tremulousness, nausea, and so on that occur following a night's sleep. The time relations of the various groups of symptoms to withdrawal are explained in the text. (Adapted from Victor M, Adams RD: The effect of alcohol on the nervous system. Res Publ Assoc Res Nerv Ment Dis 32:526, 1953, by permission.)

Tremulousness and Associated Symptoms

The most common single manifestation of the abstinence syndrome is tremulousness, often referred to as "the shakes" or "the jitters," combined with general irritability and gastrointestinal symptoms, particularly nausea and vomiting. These symptoms first appear after several days of drinking, usually in the morning after a night's abstinence. The patient "quiets his nerves" with a few drinks and is then able to drink for the rest of the day without undue distress. The symptoms return on successive mornings with increasing severity. The duration of drinking of this type varies greatly. It is terminated most often because of increasing severity of the recurrent tremor and vomiting, but for other reasons as well, such as profound general weakness, self-disgust, injury, concurrent illness, a lack of funds, and so forth. The symptoms then become greatly augmented, reaching their peak intensity 24 to 36 h after the complete cessation of drinking.

At this stage, the patient presents a distinctive clinical picture. The face is deeply flushed, the conjunctivae are injected, and there is usually tachycardia, anorexia, nausea, and vomiting. The patient is fully awake, startles easily, and complains of insomnia. He is inattentive, and disinclined to answer questions, and may respond in a rude or perfunctory manner. The patient may be mildly disoriented in time and have a poor memory for events of the last few days of the drinking spree, but he shows no serious confusion, being generally aware of his immediate surroundings and the nature of his illness.

Generalized tremor is the most obvious feature of this illness. It is of fast frequency (6 to 8 Hz), slightly irregular, and variable in severity, tending to diminish when the patient is in quiet surroundings and to increase with motor activity or emotional stress. The tremor may be so violent that the patient cannot stand without help, speak clearly, or eat without assistance. Sometimes there is little objective evidence of tremor, and the patient complains only of being "shaky inside."

Within a few days, the flushed facies, anorexia, tachycardia, and tremor subside to a large extent, but the overalertness, tendency to startle easily, and jerkiness of movement may persist for a week or longer, and the feeling of uneasiness may not leave the patient completely for 10 to 14 days. These features are suggestive of adrenergic hyperactivity, and indeed the concentrations of norepinephrine and its metabolites are elevated in both the blood and CSF (Porjesz and Begleiter, certain electrophysiologic abnormalities (diminished amplitudes of sensory evoked potentials and prolonged latencies and conduction velocities of auditory brainstem potentials) remain altered long after the clinical abnormalities have subsided.

Hallucinosis

Symptoms of disordered perception occur in about one-quarter of hospitalized tremulous patients. The patient may complain of "bad dreams"—nightmarish episodes associated with disturbed sleep—which he finds difficult to separate from real experience. Sounds and shadows may be misinterpreted, or familiar objects may be distorted and assume unreal forms (illusions). Although these are not hallucinations in the strict sense of the term, they represent the most common forms of disordered sense perception in the alcoholic.

Hallucinations may be purely visual in type, mixed visual and auditory, tactile, or olfactory, in this order of frequency. There is little evidence to support the popular belief that certain visual hallucinations (bugs, pink elephants) are specific to alcoholism. Actually, the hallucinations comprise the full range of visual experience. They are more often animate than inanimate; persons or animals may appear singly or in panoramas, shrunken or enlarged, natural and pleasant, or distorted, hideous, and frightening. The hallucinations may be an isolated phenomenon lasting for a few hours and it may later be attended by other withdrawal signs.

Acute and Chronic Auditory Hallucinosis

A special type of alcoholic psychosis, consisting of a more or less pure auditory hallucinosis, has been recognized for many years. Kraepelin referred to it as the "hallucinatory insanity of drunkards," or "alcoholic mania." A report of 75 such cases was made by Victor and Hope. The central feature of the illness, in the beginning, is the occurrence of auditory hallucinations despite an otherwise clear sensorium; i.e., the patients are not disoriented or obtunded, and they have an intact memory. The hallucinations may take the form of unstructured sounds such as buzzing, ringing, gunshots, or clicking (the...
elementary hallucinations of Bleuler), or they may have a musical quality, like a low-pitched hum or chant. The most common hallucinations, however, are human voices. When the voices can be identified, they are often attributed to the patient's family, friends, or neighbors—rarely to God, radio, or radar. The voices may be addressed directly to the patient, but more frequently they discuss him in the third person. In the majority of cases the voices are maligning, reproachful, or threatening in nature and are disturbing to the patient; a significant proportion, however, are not unpleasant and leave the patient undisturbed. To the patient, the voices are clear and may be heard intensely real and they tend to be exteriorized; i.e., they come from behind a radiator or door, from the corridor, or through a wall, window, or floor. Another feature of auditory hallucinosis (and of visual hallucinosis as well) is that the patient's response is more or less understandable in light of the hallucinatory content. The patient may call on the police for protection or erect a barricade against invaders; he may even attempt suicide to avoid what the voices threaten. The hallucinations are most frequent during the night, and their duration varies greatly: they may be momentary, or they may recur intermittently for days on end, or, in exceptional instances, for weeks or months.

While hallucinating, most patients have no appreciation of the unreality of their hallucinations. With improvement, the patient begins to question the reality of his hallucinations and may be reluctant to talk about his own sanity. Full recovery is characterized by the realization that the voices were imaginary and by the ability to recall, sometimes with remarkable clarity, some of the abnormal thought content of the psychotic episode.

A unique feature of this psychoses is its evolution, in a small proportion of the patients, to a state of chronic auditory hallucinosis. The chronic disorder begins like the acute one; but after a short period, perhaps a week or two, the symptomatology begins to change. The patient becomes quiet and resigned, even though the hallucinations remain threatening and derogatory. Ideas of reference and influence and other poorly systematized paranoid delusions become prominent. At this stage the illness may be mistaken for paranoid schizophrenia and indeed was so identified by Bleuler. There are, however, important differences between the two disorders: the thought process is no longer fixed in close relation to a drinking bout and the past history rarely reveals schizoIdeas of reference and influence and other poorly systematized paranoid delusions become prominent. At this stage the illness may be mistaken for paranoid schizophrenia and indeed was so identified by Bleuler. There are, however, important differences between the two disorders: the thought process is no longer fixed in close relation to a drinking bout and the past history rarely reveals schizoid personality traits. Moreover, alcoholic patients with hallucinosis are not distinguished by a high incidence of schizophrenia within their families (Schudack and Winokur, Scott), and a large number of such patients, whom we evaluated long after their acute attacks, did not show an increased incidence of schizophrenia. There is some evidence that repeated attacks of acute auditory hallucinosis render the patient more susceptible to the chronic state.

Withdrawal Seizures ("Rum Fits") In the setting of alcohol withdrawal (i.e., where relative or absolute abstinence follows a period of chronic inebriation), convulsive seizures are a common occurrence. More than 90 percent of withdrawal seizures occur during the 7- to 48-h period following the cessation of drinking, with a peak incidence between 13 and 24 h. During the period of seizure activity, the electroencephalogram (EEG) is usually abnormal, but it reverts to normal in a matter of days, even though the patient may go on to develop delirium tremens. Also during the period of seizure activity, the patient is unusually sensitive to stroboscopic stimulation; almost half the patients respond with generalized myoclonus or a convulsive seizure (photomyogenic or photoparoxysmal response). By contrast, this type of response to photic stimulation is observed only rarely in nonalcoholic epileptics, and then usually in those with tonic-clonic seizures on awakening.

Seizures occurring in the abstinence period have a number of other distinctive features. There may be only a single seizure, but in the majority of cases the seizures occur in bursts of two to six, occasionally even more; 2 percent of our patients developed status epilepticus. The seizures are grand mal in type, i.e., generalized, tonic-clonic convulsions with loss of consciousness. Focal seizures should always suggest the presence of a focal lesion (most often traumatic) in addition to the effects of alcohol. Twenty-eight percent of our patients with generalized withdrawal seizures went on to develop delirium tremens (the percentage has been less in other series); invariably the seizures preceded the delirium. The postictal confusional state may blend imperceptibly with the onset of the delirium, or the postictal state may clear over several hours or even a day or longer before the delirium sets in. Seizures of this type typically occur in patients whose drinking history has extended over a period of many years and must be distinguished from other forms of seizures that have their onset in adult life. It is suggested that the term rum fits, or whiskey fits—i.e., the names sometimes used by alcoholics—be reserved for seizures with the attributes described above. This serves to distinguish the form of seizure activity that occurs only in the immediate abstinence period from seizures that occur in the interdrinking period, long after withdrawal has been accomplished.

It is important to note that the common idiopathic or posttraumatic forms of epilepsy are also influenced by alcohol. In these types of epilepsy, a seizure or seizures may be precipitated by a short period of drinking (e.g., a weekend, or even one evening of heavy drinking); interestingly, in these circumstances, the seizures occur not when the patient is intoxicated but usually the morning after, in the "sobering-up" period.

The EEG findings in alcoholic subjects with abstinence seizures do not support the notion that the seizures merely represent latent epilepsy made manifest by alcohol. Instead, the EEG reflects a sequence of changes induced by alcohol itself: a decrease in the frequency of brain waves during the period of chronic intoxication; a rapid return of the EEG toward normal immediately after cessation of drinking; a brief period of dysrhythmia (sharp waves and paroxysmal discharges) that coincides with the flurry of convulsive activity; and again, a rapid return of the EEG to normal. Except for the transient dysrhythmia in the withdrawal period, the incidence of EEG abnormalities in patients who have had rum fits is no greater than in normal persons, in sharp contrast to the EEGs of nonalcoholic patients with recurrent seizures.

Treatment of Withdrawal Seizures Many cases do not require the use of anticonvulsant drugs, since the entire episode of seizure activity—whether a single seizure or a brief flurry of seizures—may have terminated before the patient is brought to medical attention. The parenteral administration of diazepam or sodium phenobarbital is the withdrawal period of patients with a previous history of idiopathic or posttraumatic epilepsy, a seizure or seizures may be expected to develop seizures on withdrawal of alcohol, but this prophylactic plan has never been documented satisfactorily. Recently however, D'Onofrio and colleagues have presented data that support the effectiveness of intravenous lorazepam (2 mg in 2 mL of normal saline) in preventing recurrent seizures in the withdrawal period. The long course of anticonvulsants (i.e., the names sometimes used by alcoholics—be reserved for seizures with the attributes described above. This serves to distinguish the form of seizure activity that occurs only in the immediate abstinence period from seizures that occur in the interdrinking period, long after withdrawal has been accomplished.

It is important to note that the common idiopathic or posttraumatic forms of epilepsy are also influenced by alcohol. In these types of epilepsy, a seizure or seizures may be precipitated by a short period of drinking (e.g., a weekend, or even one evening of heavy drinking); interestingly, in these circumstances, the seizures occur not when the patient is intoxicated but usually the morning after, in the "sobering-up" period.

The EEG findings in alcoholic subjects with abstinence seizures do not support the notion that the seizures merely represent latent epilepsy made manifest by alcohol. Instead, the EEG reflects a sequence of changes induced by alcohol itself: a decrease in the frequency of brain waves during the period of chronic intoxication; a rapid return of the EEG toward normal immediately after cessation of drinking; a brief period of dysrhythmia (sharp waves and paroxysmal discharges) that coincides with the flurry of convulsive activity; and again, a rapid return of the EEG to normal. Except for the transient dysrhythmia in the withdrawal period, the incidence of EEG abnormalities in patients who have had rum fits is no greater than in normal persons, in sharp contrast to the EEGs of nonalcoholic patients with recurrent seizures.

Delirium Tremens ("DTs") This is the most dramatic and grave of all the alcoholic illnesses. It is characterized by profound confusion, delusions, vivid hallucinations, tremor, agitation, and sleeplessness as well as by the signs of increased autonomic nervous system overactivity—i.e., dilated pupils, fever, tachycardia, and profuse perspiration. The clinical features of delirium are presented in detail in Chap. 45.

Delirium tremens develops in one of several settings. The patient, an excessive and steady drinker for many years, may have been admitted to the hospital for an unrelated illness, accident, or operation and, after 2 to 4 days, occasionally even later, becomes delirious. Or, following a prolonged drinking binge, the patient may have no specific precipitating factors and, after several days of tremulousness and hallucinosis or one more seizures and may even be recovering from these symptoms when delirium tremens develops, rather abruptly as a rule.

As to the frequency of delirium tremens, Fox and Kay reported an incidence of 0.65 percent of all patients admitted for other reasons to a large general hospital. Among 200 consecutive alcoholics admitted to a city hospital, Ferguson et al reported that 24 percent developed delirium tremens; of these, 8 percent died—figures that are considerably higher than those recorded in our hospitals. Of course, the reported incidence of delirium tremens will vary greatly, depending on the population served by a particular hospital, the admission policy of the hospital, and the strictness with which delirium tremens is defined and distinguished from lesser forms of alcohol withdrawal.

In the majority of cases delirium tremens is benign and short-lived, ending as abruptly as it begins. Consumed by relentless activity and wakefulness for several days, the patient falls into a deep sleep and then awakens lucid, quiet, and exhausted, with virtually no memory of the events of the delirious period. Somewhat less commonly, the delirious state subsides gradually with intermittent episodes of recurrence. In either event, when delirium tremens occurs as a single episode, the duration is 72 h or less in over 80 percent of cases. Frequently still, there may be one or more relapses, several episodes of delirium of varying severity being separated by intervals of relative lucidity—the entire process lasting for several days or occasionally for as long as 4 to 5 weeks.

In the past, approximately 15 percent of cases of delirium tremens ended fatally, but the figure now is closer to 5 percent. In many of the fatal cases there is an associated infectious illness or injury, but in others no complicating illness is discernible. Many of the patients die in a state of hyperthermia; in some, death comes so suddenly that the nature of the terminal events cannot be determined. Reports of a negligible mortality in delirium tremens can usually be traced to a failure to distinguish between delirium tremens and the minor forms of the withdrawal syndrome, which are far more common and practically never fatal.

Atypical Delirious-Hallucinatory or Confusional States These are alcohol withdrawal states, closely related to delirium tremens and about as frequent, in which
one facet of the delirium tremens complex assumes prominence, to the virtual exclusion of the other symptoms. The patient may simply exhibit a transient state of quiet confusion, agitation, or peculiar behavior lasting several days or weeks. There may be a vivid hallucinatory-delusional state and abnormal behavior consistent with the patient’s false beliefs. Unlike typical delirium tremens, the atypical states usually present as a single circumscribed episode without recurrences, are only rarely preceded by seizures, and do not end fatally. This may be another way of saying that they are a partial or less severe form of the disease.

Pathology Pathologic examination is singularly unrevealing in patients with delirium tremens. Edema and brain swelling have been absent in the authors’ pathologic material except when shock or hypoxia had occurred temporarily. There have been no significant light-microscopic changes in the brain, which is what one would expect in a disease that is essentially reversible. Abnormalities of the CSF occur unpredictably, as do changes on CT scanning or MRI; they may indicate the presence of other medical or surgical complications.

Enlargement of the third and lateral ventricles is a common finding (see below). The EEG findings have been discussed in relation to withdrawal seizures.

Other Laboratory Findings Rarely, blood glucose is seriously depressed in the alcohol withdrawal states, for the reasons given earlier, under “Absorption, Distribution, and Metabolism of Alcohol.” Ketaocidosis with normal blood glucose is another infrequent finding. Disturbances of electrolytes are of varying frequency and significance. Serum sodium levels are altered infrequently and are more often increased than decreased. The same is true for chlorides and phosphate. Serum calcium and potassium were found to be lowered in about one-quarter of our patients. Most patients show some degree of hyponagamaglobulinaemia, low PCO₂, and high arterial pH—abnormalities that are probably important in the pathogenesis of withdrawal symptoms (see below).

Pathogenesis of the Tremulous-Hallucinatory-Delirious Disorders For many years prior to 1950, it was the common belief that these symptoms represented the most severe forms of alcohol intoxication—an idea that fails to satisfy the simplest clinical logic. The symptoms of toxicity—consisting of slurred speech, unihibited behavior, staggering gait, stupor, and coma—are in themselves distinctive and, in a sense, the opposite of the symptoms of the tremor, fits, and delirium. The former symptoms are associated with an elevated blood alcohol level, whereas the latter become evident only when the blood alcohol has been reduced. Finally, the symptoms of intoxication increase in severity as more alcohol is consumed, whereas tremor and hallucinosis and even full-blown delirium tremens are diminished or nullified by the administration of alcohol. Also, although much discussed in the past, there is no convincing evidence that an endocrine abnormality (other than the central release of norepinephrine) or nutritional deficiency plays a role in the genesis of delirium tremens and related symptoms.

It is evident, from observations in both humans and experimental animals, that the most important and the one indispensable factor in the genesis of delirium tremens and associated states is the withdrawal of alcohol. Withdrawal symptoms in the alcohol addict are a biological impossibility, moreover, for the simple reason that the normal drinking habit is a continuous one and, therefore, the end of drinking is a chronic event, not a sudden and complete one.

A wide variety of drugs are effective in controlling withdrawal symptoms. The more popular ones in recent years have been chlordiazepoxide (Librium), diazepam (Valium), mebrobamate, hydroxyzine (Vistaril) and the ancillary medications, clonidine and beta-adrenergic blockers, and newer anticonvulsant drugs such as gabapentin, which may reduce the requirement for sedative drugs. There is little to choose among these drugs in respect to their therapeutic efficacy. More importantly, however, there are few data to indicate that any one of them can prevent hallucinosis or delirium tremens or shorten the duration or alter the mortality rate of the latter disorder (Kaim et al). In general, phenothiazine drugs should be avoided because they reduce the threshold to seizures.

Currently, chlordiazepoxide and diazepam are the most frequently used drugs for treatment of withdrawal symptoms. If parenteral medication is necessary, we prefer 10 mg of diazepam or chloralhydrate given intravenously and repeated once or twice at 20- to 30-min intervals until the patient is calm but awake. Virtually equivalent alternatives are lorazepam parenteral, in doses of 120 mg or haloperidol (10 mg) repeated at 3- to 4-h intervals intramuscularly (provided there is no serious liver disease). Beta-blocking agents, such as propranolol and atenolol, are helpful in reducing heart rate, blood pressure, and the tremor to some extent. Lofexidine, an alpha agonist that blocks autonomic outflow centrally, and clonidine are similarly effective. Corticosteroids have no place in the treatment of the withdrawal syndrome.

Nutritional Diseases of the Nervous System Alcoholism provides the ideal setting for the development of nutritional diseases of the nervous system. Although only a small proportion of alcoholics develop nutritional diseases, the overall number of cases is substantial because of the frequency of alcoholism. The importance of the alcohol-induced deficiency diseases relates to the fact that they are preventable and, if neglected, may lead to permanent disability. These illnesses are discussed fully in the preceding chapter, “Diseases of the Nervous System Due to Nutritional Deficiency.”

Disorders of Uncertain Pathogenesis Associated with Alcoholism
Also discussed in Chap. 41 are so-called alcoholic cerebellar degeneration and Marchiafava-Bignami disease. The former is almost certainly of nutritional origin; in the latter a nutritional-metabolic etiology seems likely but has not been established. Central pontine myelinolysis, though frequently observed in alcoholics, is more appropriately considered with the acquired metabolic disorders (Chap. 40). Certain disorders of skeletal and cardiac muscle associated with alcoholism (alcoholic myopathy and cardiomyopathy) are described in Chap. 51, with the myopathies due to drugs and toxins. There remain to be discussed several diverse disorders that have been attributed to alcoholism but whose causal relationship to alcohol abuse, nutritional deficiency, or some other factor is not clear.

Alcoholic Dementia and Cerebral Atrophy

The term alcoholic dementia is used widely and often indiscriminately to designate a presumably distinct form of dementia that is attributable to the chronic, direct effects of alcohol on the brain. An immediate problem with this category of alcoholic disease is its definition. A syndrome subsumed under the title of alcoholic dementia and its many synonyms (alcoholic deteriorated state, chronic alcoholic psychosis, chronic or organic brain syndrome due to alcohol) has never been delineated satisfactorily, either clinically or pathologically. In the Comprehensive Textbook of Psychiatry, it has been defined as "a gradual disintegration of personality structure, with emotional lability, loss of control, and dementia" (Sadock and Sadock). To other psychiatrists (Strecker et al), the alcoholic deteriorated state denotes "that characteristically reacts to them alcohol's or do not of some accident or intermittent episode." Purported examples of this state show a remarkably diverse group of symptoms, including jealousy and suspiciousness; coarsening of moral fiber and other personality and behavioral disorders; deterioration of work performance, personal care, and living habits; and dissociation, impaired judgment, and defects of intellectual function, particularly of memory. Some early authors were apparently impressed with similarities between the alcoholic deteriorated state and general paresis, hence the term alcoholic pseudoparesis. Mercifully this term no longer appears in medical writings.

In recent years, there have been attempts to redefine alcoholic dementia. Cutting and also Lishman have expressed the view that the term Korsakoff psychosis should be limited to patients with a fairly pure disorder of memory of acute onset and that patients with more global symptoms of intellectual deterioration, of gradual evolution, be considered to have alcoholic dementia. These are rather weak diagnostic criteria. As pointed out in Chap. 41, Korsakoff psychosis may have an insidious onset and gradual progression, and patients with this disorder, in addition to an amnesic defect, characteristically show disturbances of cognitive functions that depend little or not at all on memory. More importantly, in none of the patients designated by these authors as having alcoholic dementia was there a neuropathologic examination, without which the clinical assessment must remain arbitrary and imprecise.

The pathologic changes that purportedly underlie primary alcoholic dementia are even less precisely defined than the clinical syndrome. Courville, whose writings have been quoted most frequently in this respect, described a series of cerebral cortical changes that he attributed to the toxic effects of alcohol. Some of these changes turn out on close inspection to be quite nonspecific. Many of the cellular changes noted by Courville may have reflected a state of hepatic failure or terminal anoxia, and others reflect nothing more than the effects of aging or the insignificant artifacts of tissue fixation and staining.

More recently, Harper and colleagues have reported that the mean brain weight is decreased in alcoholics and the pericerebral space is increased—findings that do not necessarily confirm the brain shrinkage that is demonstrable by CT scans in many alcoholics and is reversible with sustained abstinence (see below). Also, using an automated cell-counting method, they reported a reduction in the number of neurons in the superior frontal cortex. Other investigators, using more accurate (stereologic) counting methods, have not duplicated these findings (Hansen et al; Jensen and Pakkenberg), nor have experimental studies in animals settled the problem.

In our experience, the majority of cases that come to autopsy with the label of alcoholic dementia or deteriorated state prove to have the lesions of the Wernicke-Korsakoff Syndrome. Traumatic brain damage is commonly added. Other contributions are the lesions of alcoholic encephalopathy, communicating hydrocephalus, Alzheimer disease, ischemic necrosis, or some other disease quite unrelated to alcoholism. Practically always, in our material, the clinical state can be accounted for by one or a combination of these disease processes, and there has been no need to invoke a hypothetical toxic effect of alcohol on the brain. This has also been the experience of Tonvik and associates; with a few exceptions, such as coincidental Alzheimer disease, all their cases that had been diagnosed as having alcoholic dementia turned out, on neuropathologic examination, to have the chronic lesions of Wernicke-Korsakoff disease.

In brief, the most serious flaw in the concept of a primary alcoholic dementia is that it lacks a distinctive, well-defined pathology. Until such time as the morphologic basis is established, it is at best an illusory concept. A more detailed discussion of this subject and of so-called alcoholic cerebral atrophy (see below) can be found in the review by one of the present authors (M.V.), listed in the References.

Cerebral Atrophy in Chronic Alcoholism

This disorder, like the "alcoholic deteriorated state," does not constitute a well-defined entity. The concept of alcoholic cerebral atrophy was the product originally of pneumoencephalographic studies. Relatively young alcoholics, some with and some without symptoms of cerebral disease, were often found to have enlarged cerebral ventricles and widened sulci, mainly of the frontal lobes (see, for example, reports of Brewer and Perrett and of Haug). Similar findings have been reported in chronic alcoholics examined by CT scanning and MRI (see review by Carlen et al).

The clinical correlates of these radiologic findings are quite unclear. In some patients, so-called cerebral atrophy is associated with an overt complication of alcoholism—e.g., the Wernicke-Korsakoff syndrome (about one-quarter of our autopsied cases). In other patients, there is a history of recurrent seizures or evidence of liver disease, cerebral trauma, or some other event that might have resulted in ventricular enlargement. More often, however, the finding of large ventricles occurs as an isolated finding with no signs of neurologic or the usual mental status abnormalities. In this connection, the findings of Wilkinson are of particular importance. He demonstrated that in clinically normal alcoholics, the radiologic measures of "brain atrophy" were age-related; once the age factor was removed, the CT findings in these subjects did not differ significantly from those in nonalcoholic controls.

In the term alcoholic cerebral atrophy implies that chronic exposure of the brain to alcohol causes an irreversible loss of cerebral tissue. However, this idea is open to criticism, for dilated ventricles have in fact been reversible to a considerable extent when abstinence is maintained (Carlen et al, Lishman, Zipursky et al, Schroth et al). Moreover, a similar ventricular enlargement, or brain shrinkage, also reversible, has been observed in patients with the Cushing syndrome, anorexia nervosa, and Lennox-Gastaut syndrome (treated with ACTH and corticosteroids). This reversibility would suggest that a shift of fluids had occurred in the brain (over many months), rather than loss of tissue. A rapid increase of the alcohol-inhibited antidiuretic hormone or a rise in protein synthesis after alcohol withdrawal are other possible explanations. Until this matter has been studied further, it would be preferable to refer to this condition as an asymptomatic ventricular enlargement and sulcal widening in alcoholics, rather than as cerebral atrophy.

Alcoholic Paranoia and Jealousy

These are outmoded terms that were used in the past to designate what was thought to be a special type of paranoid reaction in chronic alcoholics, in which the patient, usually a male, developed ideas of infidelity on the part of his wife. The delusions of jealousy that might occur acutely in the course of alcoholic intoxication or withdrawal, or chronically as part of the "alcoholic deteriorated state," were generally not included under this rubric. The notion that paranoia and jealousy are a special reaction to alcohol is not warranted, since the delusional jealousy that develops in alcoholics differs in no essential way from that in nonalcoholics. Nevertheless, among individuals with the syndrome of morbid jealousy, chronic alcoholism may be an important associated factor (11 of 66 cases reported by Langfeld). Among the alcoholic patients, the delusions of jealousy may at first be evident only in relation to episodes of acute intoxication, but later they evolve, through a stage of constant suspicion and efforts to detect infidelity, into a fixed morbid reaction that persists during periods of sobriety as well.

Fetal Alcohol Syndrome

That parental alcoholism may have an adverse effect on the offspring has been a recurrent theme in medical lore. Probably the first documented occurrence of such a relationship was that of Sullivan (1899), who reported that the mortality among the children of drunken mothers was more than twice greater than that among children of nondrinking women of "simlar stock." This increased mortality was attributed by Sullivan and later by Haggard and Jeffink to postrnatai influences such as poor parental care and a home environment adverse to the health and well-being of the infant. The idea that maternal alcoholism could damage the fetus was generally rejected and relegated to the category of superstitions about alcoholism or the claims of temperance ideologues.

In the late 1960s, the effects of alcohol on the fetus were rediscovered, so to speak, by Lemoine and associates in France and then Ulleland and Jones and Smith in the United States described a distinctive pattern of abnormalities in infants born of severely alcoholic mothers. The affected infants are small in length in comparison to weight, and most of them fall below the third percentile for head circumference. They are also distinguished by the presence of short palpebral fissures (stenolined distance between inner and outer canthi) and epicanthal folds; maxillary hypoplasia, micrognathia, indistinct philtrum, and thin upper lip; and longitudinally oriented creases on the dorsum of the fingers, and a limited range of motion of other joints. Cardiac anomalies (usually spontaneously closing septal defects), anomalous external genitalia, and cleft lip and palate are much more frequent than in the general population. The newborn infants suck and sleep poorly,
and many of them are irritable, restless, hyperactive, and tremulous; these last symptoms resemble those of alcohol withdrawal except that they persist.

The first long-term study of children with what has come to be called fetal alcohol syndrome (FAS) was reported by Jones and coworkers. Among 23 infants born to alcoholic mothers, there was a neonatal mortality of 17 percent; among the infants who survived the neonatal period, almost half failed to achieve normal weight, length, and head circumference or remained backwardly retarded to a varying degree, even under optimal environmental conditions. Several large groups of FAS children have now been observed for 20 years or longer (see Steinschneider). Distractibility, inattentiveness, hyperactivity, and impairment of fine motor coordination are prominent features in early childhood. Most such children are given the diagnosis of attention-deficit hyperactivity disorder. Slow growth of head circumference is a consistent finding throughout infancy and childhood. The physical stigmata of the syndrome become less distinct after puberty, but practically all adolescents are left with some degree of mental retardation and behavioral abnormalities.

The pathologic changes that underlie the FAS have been studied in a small number of cases. Clarrren and colleagues found extensive leptomeningeval neuroglial heterotopias and an obstructive hydrocephalus. Neuronal ectopias in the cerebral white matter and agenesis of the corpus callosum were also present. Peiffer and colleagues described a broader spectrum of malformations, including cerebellar heterotopias similar to those of the Dandy-Walker syndrome, schizencephaly, agenesis of the corpus callosum, and signs of arhinencephaly.

Although the relationship of this syndrome to severe maternal alcoholism seems undoubted, the mechanism by which alcohol produces its effects is not fully understood. It is noteworthy that infants born to nonalcoholic mothers who had been subjected to severe dietary deprivation during pregnancy (during World War II) were small and often premature, but these infants did not show the pattern of malformations that characterizes FAS. Alcohol readily crosses the placenta in humans and animals; in the mouse, rat, chick, miniature swine, and beagle dog, alcohol has been shown to have both embryotoxic and teratogenic effects. Thus, the evidence for the harmful effects of alcohol, although the possible toxic effect of acetaldehyde and the effect of alcohol, although the contribution of nutritional deficiency have not been totally excluded. As to the specific mechanisms by which alcohol impairs the growth and development of the fetus, a compromised blood flow to the placenta and an ethanol-induced increase in prostaglandins have been suggested but are as yet unproved hypotheses (Schenker et al).

Unequivocal cases of FAS observed to date have occurred only in infants born to severely alcoholic mothers (many of them with delirium tremens and liver disease) who continued to drink heavily throughout pregnancy. Far less secure is a relationship to lesser degrees of alcohol intake. Data derived from the collaborative study sponsored by the National Institutes of Health indicate that about one-third of the offspring of women who are heavy drinkers have the FAS. Abel and Sokol have estimated that the worldwide incidence of the FAS is 1.9 per 1000 live births and have pronounced it to be the leading known cause of mental retardation in the western world. The degree of maternal alcoholism that is necessary to produce the syndrome and the critical stage in gestation during which it occurs are still vague. The various teratogenic effects described above are estimated to occur in the embryonic period, i.e., in the first 2 months of fetal life. Other nonteratogenic effects appear to be related to periods during gestation when the fetus is exposed to particularly high alcohol levels.

Diagnostic difficulties arise when only some components of the syndrome occur in association with heavy maternal drinking, in the absence of the fully developed syndrome; these have been termed fetal alcohol effects, and their incidence is more difficult to determine. A comprehensive account of alcohol-related birth defects and other relevant issues surrounding this subject is contained in a special issue of Alcohol Health and Research World, published by the National Institutes of Health (Vol. 18, 1994).

Neurologic Complications of Alcoholic Cirrhosis and Portal-Systemic Shunts

This category of alcoholic disease is discussed in Chap. 40, in connection with the acquired metabolic disorders of the nervous system.

Treatment of Alcohol Addiction

Following recovery from the acute and neurologic complications of alcoholism, the underlying problem of alcohol dependence remains. To treat only the medical complications and leave the management of the drinking problem to the patient alone is shortsighted. Almost always, drinking is resumed, with a predictable recurrence of medical illness. For this reason the physician must be prepared to deal with the addiction or at least to initiate treatment.

The problem of excessive drinking is formidable but not nearly as hopeless as it is generally made out to be (see review of O'Connor and Schottenfeld). A common misconception among physicians is that specialized training in psychiatry and an inordinately large amount of time are required to deal with the alcoholic drinker. Actually, a successful program of treatment can be initiated by any interested physician, using the standard techniques of history taking, establishing rapport with the patient, and setting up a schedule of frequent visits, though not necessarily for prolonged periods. Our position on this matter was reinforced by a controlled study of problem drinkers in whom treatment was equally successful whether carried out by general practitioners or by specialists (Drummond et al). Useful points at which to undertake treatment are during convalescence from a serious medical or neurologic complication of alcoholism or in relation to loss of employment, arrest, or threatened divorce. Such a crisis may help to convince the patient, more than any argument presented by family or physician, that the drinking problem has reached serious proportions.

The requisite for successful treatment is total abstinence from alcohol; for all practical purposes, this represents the only permanent solution. It is generally agreed that the alcoholic has a drinking habit that will fail if the patient continues to drink. There are said to be alcohol addicts who have been able to reduce their intake of alcohol and eventually to drink in moderation, but they must represent only a small proportion of the addict population. Also, it is frequently stated that alcoholics must recognize that they are alcoholics—i.e., that their drinking is beyond their control—and must express willingness to be helped. Undoubtedly there is truth in both these statements, but they should not be interpreted to mean that alcoholic patients must gain this recognition and willingness entirely on their own initiative and that they will be helped only after they have done so. The physician can do a great deal to help such patients understand the nature of their problem and thus to motivate them to accept treatment. The help of family, employer, courts, and clergy should be enlisted in an attempt to convince these patients that abstinence is preferable to chronic inebriety. Alcoholics must be made fully aware of the medical and social consequences of continued drinking and must also be made to understand that the patient who has been given the treatment (in any of the diagnostic and treatment settings) who is in no way to blame for their illness; there appears to be an advantage in making them feel that they are responsible for doing something about their drinking.

The prevalent belief that an alcoholic will not stop drinking under duress also requires qualification. In fact, one of the few careful studies of this matter disclosed that relatively few patients would have sought help unless pressure had been exerted by family or employer; furthermore, those who came to the clinic under duress of this sort did just as well as those who came voluntarily.

A number of methods have proved valuable in the short- and long-term management of patients. The more important of these are admission to a detoxification or special hospital unit, rehabilitation therapy, aseptic treatment, the use of disulfiram (Antabuse), and the participation in self-help organizations for recovery from alcoholism. Detoxification clinics and special hospital units for the treatment of alcoholism are now widely available. The physician should be fully aware of all the community resources available for the management of this problem and should be prepared to take advantage of them in appropriate cases. Most inpatient programs include individual and group counseling, didactics about the illness and recovery, and family intervention. Outpatient treatment (of individuals or groups) is widely available, either from specialized facilities or from specialized therapists in general mental health facilities; family counseling is usually offered as well and is often beneficial. Most professional alcoholism treatment in the United States includes an introduction to the methods and utilization of Alcoholics Anonymous (AA, see below).

Aversion treatment consists of the simultaneous administration of a drink of alcohol and injection of an emetic. The violent nausea and vomiting that ensue are beneficial. Most professional alcoholism treatment in the United States includes an introduction to the methods and utilization of Alcoholics Anonymous (AA, see below).

Disulfiram interferes with the metabolism of alcohol, so that a patient who takes both alcohol and disulfiram accumulates an inordinate amount of acetaldehyde in the tissues, resulting in nausea, vomiting, and hypotension, sometimes pronounced in degree. It is no longer considered necessary to demonstrate these effects to patients; it is sufficient to warn them of the severe reactions that may result if they drink while they have the drug in their bodies. Treatment with disulfiram is initiated only after the patient has been sober for several days, preferably longer. It should never be given to patients with cardiac or advanced liver disease. The drug is taken each morning or at another suitable time daily in a dosage of 250 mg, preferably under supervision. This form of treatment may be of value in the spree or periodic
drinker, in whom relapse from abstinence usually represents an impulsive rather than a carefully planned or premeditated act. The patient taking disulfiram, aware of the dangers of mixing liquor and the drug, is "protected" against the impulse to drink, and this protection may be renewed every 24 h by the simple expedient of taking a pill. The willingness with which the patient accepts this form of treatment also serves as a rough test of his willingness to stop drinking. Should the patient drink while taking disulfiram, the ensuing reaction is usually severe enough to require medical attention, and a protracted spree can thus be prevented. Disulfiram may cause a polyneuropathy if continued over a period of months or years, but this is a rare complication.

Several other drugs may be helpful in maintaining abstinence. The opioid antagonist naloxone (50 mg/day) has been used for this purpose, with mixed results. In Europe, a modicum of success has been achieved with acamprosate (2000 mg daily), but this drug is not yet available in the United States.

Alcoholics Anonymous (AA), an informal fellowship of recovering alcoholics, has proved to be the single most effective form in the rehabilitation of alcoholic patients. The philosophy of this organization is embodied in its "12 steps," a series of principles for sober living that guide the patient to recovery. These steps have been adopted by analogous fellowships for recovery from other addictive states, such as compulsive overeating, gambling, and dependence on narcotics. The AA philosophy stresses in particular the practice of making restitution, the necessity to help other alcoholics, trust in a higher power, the group confessional, and the belief that the alcoholic alone is powerless over alcohol. The AA philosophy also embodies the 24-h plan, in which the alcoholic strives to be abstinent for just a day at a time (a concept inspired by the Sermon on the Mount) as a means of facilitating the maintenance of sobriety. Although accurate statistics are lacking, it is said that about one-third of the members who express more than a passing interest in the program attain a state of long-sustained or permanent sobriety. Although the methods used by AA are not preferred by every patient, most who persist can benefit; in particular, the physician should not accept a patient's initial negative reaction as reason to abandon AA as a mode of treatment.

Finally, it should be noted that alcoholism is frequently associated with psychiatric diseases of other type, particularly sociopathy and affective illness. In the latter case, the prevailing mood is far more often one of depression than of mania and is more often encountered in women, who are more apt to drink under these conditions than are men. In these circumstances, expert psychiatric help should be sought, preferably from someone who is also familiar with addictive diseases.

CHAPTER REFERENCES

Subsumed under this title is a diverse group of disorders of the nervous system that result from introduction into the body of drugs and other injurious or poisonous substances. A drug can be broadly defined as any chemical agent that affects living processes, but for purposes of this chapter, the discussion is limited to such drugs as are useful in the prevention and treatment of diseases of the nervous system. In addition, the neurologist must be concerned with the myriad of chemical agents that have no therapeutic utility but may adversely affect the nervous system; they abound in the environment as household products, insecticides, industrial solvents, and other poisons, the toxic effects of which must be recognized and treated. Also included among neurotoxins are those generated by bacteria and other infectious agents as well as several found in nature, such as marine toxins and agents elaborated by living animals. These are designated as endogenous if they arise within the body and exogenous if introduced from outside. Such a division cannot always be sharply drawn, as in the case of toxins produced by certain bacteria after being introduced from the outside (e.g., tetanus).

It would hardly be possible within the confines of this chapter to discuss with any degree of completeness the innumerable drugs and toxins that affect the nervous system. The interested reader is referred to a number of comprehensive monographs and references listed at the end of this chapter. In addition, an up-to-date handbook of pharmacology and toxicology should be part of the library of every physician.

The presentation of this subject is introduced by some general remarks on the action of drugs on the nervous system and then focuses on the more common categories of drugs and chemical agents that affect the nervous system selectively or predominantly. The references at the end of the chapter are listed in relation to each of these categories:

1. Action of drugs on the nervous system: general principles
2. The addicting drugs: opiates and synthetic analgesics
3. Sedative-hypnotic drugs

Such a division cannot always be sharply drawn, as in the case of toxins produced by certain bacteria after being introduced from the outside (e.g., tetanus).

The scope of this chapter is also limited because the therapeutic and adverse effects of many drugs are considered elsewhere in this volume, in relation to particular symptoms and diseases. Thus, the toxic effects of ethyl, methyl, amy, and isopropyl alcohol, as well as ethylene glycol, are discussed in Chap. 42, on alcohol. The adverse effects of antibiotics on cochlear and vestibular function and on neuromuscular transmission are discussed in Chap. 15 and Chap. 53, respectively. Many of the undesirable side effects of the common drugs used in the treatment of extrapyramidal motor symptoms, pain, headache, convulsive seizures, sleep disorders, psychiatric illnesses, and so forth are considered in the chapters dealing with each of these disorders. Cyanide and carbon monoxide poisoning are discussed in relation to anoxic encephalopathy (Chap. 40). A number of therapeutic agents that damage the peripheral nerves (e.g., cisplatin, disulfiram, vincristine, dapsone, etc.) are mentioned in this chapter but are discussed further in Chap. 46, and those affecting muscle, in Chap. 51.

The presentation of this subject is introduced by some general remarks on the action of drugs on the nervous system and then focuses on the more common categories of drugs and chemical agents that affect the nervous system selectively or predominantly. The references at the end of the chapter are listed in relation to each of these categories:

1. Action of drugs on the nervous system: general principles

5. Antidepressant drugs
6. Stimulants
7. Psychoactive drugs
8. Systemic toxins
9. Plant poisons, venoms, bites, and stings
10. Heavy metals
11. Nervous system poisons
12. Antineoplastic and immunosuppressive agents
13. Thalidomide
14. Aminoglycoside antibiotics (ototoxicity) and penicillin derivatives (seizures)
15. Cardiovascular agents (beta blockers, digitalis derivatives, amioidone)

NEUROPHARMACOLOGY: GENERAL PRINCIPLES

Of primary importance is the manner in which a therapeutic agent, specifically its chemical structure, affects the biochemistry and physiology of neurons and their supporting elements (pharmacodynamics). The rational use of any drug also requires a knowledge of the best route of administration, the drug's absorption characteristics, its distribution in the nervous system and other organs, and its biotransformations and excretion (pharmacokinetics). Since every drug, if given in excess, has some adverse effects, toxicology and toxicology are inseparable.

Drug–Nervous System Interactions

In no other field of neurology is it more apparent that all systems of neurons are not identical. Each has its own vulnerabilities to particular drugs and toxic agents. This principle, originally enunciated by O. and C. Vogt in their theory termed pathoclisis, has been elegantly confirmed by tracing chemical molecules to specific aggregates of neurons. Thus, pathoclisis explains the preferential effects of anesthetics on the neurons of the upper brainstem reticular formation, which, with its diffuse cortical connections, undergoes consciousness. There are examples not only of certain groups of nerve cells being destroyed by a particular agent but also of their function and presynaptically particular parts of their structure being altered. Drugs may be targeted to the terminal axons, dendrites, neurofilaments, or receptors on pre- and postsynaptic surfaces of neurons or to certain of their metabolic activities, whereby they synthesize and release neurotransmitters or maintain their cellular integrity by the synthesis of RNA, DNA, and other proteins. Parkinson disease and the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) are excellent examples of pathoclisis, in which a disease process and a synthetic toxin effect a progressive loss of melanin-bearing nigral neurons and a depletion of their neurotransmitter, dopamine. Evidence is also accumulating about the mechanisms by which drugs and toxins can alter particular steps in the formation, storage in presynaptic vesicles, release, uptake, catabolism, and resynthesis of neurotransmitters such as dopamine, serotonin, norepinephrine, acetylcholine, and other catecholamines. Johnston and Silverstein have summarized current views of how these transmitters and modulating agents, by attaching to receptors at neuronal synapses, are able to increase or decrease the permeability of ion channels and stimulate or inhibit second cytoplasmic messengers. Drugs such as L-dopa, tryptophan, and choline are believed to act by enhancing the synthesis of dopamine, serotonin, and acetylcholine, respectively. Baclen is thought to modulate the release of gamma-aminobutyric acid (GABA), the main inhibitory transmitter in the central nervous system (CNS). Clonidine prevents the release of norepinephrine; butulinus has a similar effect on acetylcholine, and tetanus toxin on GABA in Renshaw cells of the spinal cord. Amantadine, an antiviral agent, is thought to promote the release of dopamine, and glutethimide, of acetylcholine. Benzodiazepines, bromocriptine, and methylphenidate are viewed as receptor agonists; the phenoxythiazines and antihistamines act as receptor antagonists. Certain drugs enhance the activity of neurotransmitters by inhibiting their reuptake, as, for example, the antidepressant class of drugs, which has a relatively selective influence on the reuptake of serotonin. One must not assume that these are the exclusive modes of action of each of these drugs, but these new data are instructive and indicate the future direction of neuropharmacology.

Lacking still is information about the precise mechanisms of even the most common anesthetics. It is assumed that by their lipid solubility they alter the physicochemical properties of the cell membrane and thus impair the activities of the membrane receptor systems that regulate ion channels, particularly the chloride and sodium channels. Antiviral agents such as acyclovir possibly block viral replication in neuron and glial cells once the inactive form of the drug is activated by thymidine kinase in these cells. A similar mode of action is postulated for azidothymidine (AZT), used in the treatment of acquired immunoodeficiency syndrome (AIDS).

Bioavailability

A majority of drugs that act on the nervous system are ingested; factors that govern their intestinal absorption must, therefore, be taken into account. Small molecules usually enter the plasma by diffusion, larger ones by pinocytosis. The substances with which the drugs are mixed (excipients); the presence of food, other drugs, or intestinal diseases; and the age of the patient all influence the rate of absorption and blood concentrations. Different calculations are necessary for intramuscular, subcutaneous, or intrathecal routes of administration. To some extent, the solubility of drugs (in lipids or water) determine the routes by which they can be given; some drugs, such as morphine, can be administered by manifold routes. Carried in the blood, the drug (or toxin) reaches many tissues, including the nervous system; protein binding in the plasma has an important influence on distribution. Many drugs and toxic substances bind to serum albumin and other serum proteins, limiting the availability of the ionized form. The common drug and toxin transformations involve hydroxylation, deamination, oxidation, and dealkylation, which enhance their solubility and elimination by the kidney. Most of these catalytic processes occur in liver cells and utilize multiple enzymes.

To enter the extracellular compartment of the nervous system, the drug or toxic agent in question must transgress the tight capillary endothelial barrier (blood-brain barrier) and the barrier between the blood and cerebrospinal fluid (CSF). Intrathecal injection circumvents these barriers, but then the agent tends to concentrate in the immediate subpial and subependymal regions. The process of movement from plasma to brain is by diffusion through capillaries or by facilitated transport. The solubility characteristics of the drug determine its rate of diffusion.

In the following exposition on neurotoxins, the reader will be repeatedly exposed to a number of novel phenomena: tolerance (lessening effect of increasing dose), dependence and addiction (insatiable need), habituation, drug-seeking behaviors, and abstinence and associated withdrawal effects. These were described in Chap. 42 on alcoholism and are further elaborated below. Particularly difficult in reference to drugs such as nicotine is the separation of habituation from addiction, i.e., of psychologic dependence from physical dependence (see further on).

To make intelligent use of any of the pharmacologic agents described below, the neurologist must know about their pharmacodynamic and pharmacokinetic properties. The few examples given above are intended to provide a glimpse of the complex interactions between chemical agents and the cells of the nervous system. For more specific information, the reader is referred to: The Biochemical Basis of Neuropharmacology by Cooper, Bloom, and Roth, an excellent text that we have consulted through its seven editions. The continued elucidation of the modes of action of the several hundred drugs and toxins that act on the nervous system promises to yield important information about the biochemical physiology of neurons and opens for study an inviting field of experimental neuropharmacology.

OPIATES AND SYNTHETIC ANALGESIC DRUGS

The opiates, strictly speaking, include all the naturally occurring alkaloids in opium, which is prepared from the seed capsules of the poppy Papaver somniferum. For clinical purposes, the term opiate refers only to the alkaloids that have a high degree of analgesic activity, i.e., morphine and codeine. The terms opioid and narcotic are used to designate drugs with actions similar to those of morphine. Compounds that are chemical modifications of morphine include diactymorphine, or heroin (still the most commonly abused opioid), hydromorphone (Dilaudid), codeine, hydrocodone (Hydrocot), oxymorphone (Normorph), and oxycodone (Percodan). A second class of opioids comprises the purely synthetic analogues: meperidine (Demerol) and its congeners, notably fentanyl (Sublimaze), methadone (Dolophine), levorphanol (Levo-Dromoran), propoxyphene (Darvon), pentazocine (Talwin), diphenoxylate (the main component of Lomotil), and phenozone (Pripranol). The synthetic analogues are similar to the opiates, in both their pharmacologic effects and patterns of abuse, the differences being mainly quantitative.

The clinical effects of the opiates are considered from two points of view: (1) acute poisoning and (2) addiction.

Opioid Overdose

Because of the common and particularly the illicit use of opioids, poisoning is a frequent occurrence. This happens as a result of ingestion or injection with suicidal intent, errors in the calculation of dosage, the use of a substitute or contaminated street product, or unusual sensitivity. Children exhibit an increased susceptibility to opioids, so that relatively small doses may prove toxic. This is true also of adults with myxedema, Addison disease, chronic liver disease, or pneumonia. Acute
poisoning may also occur in addicts who are unaware that available opioids vary greatly in potency and that tolerance for opioids declines quickly after the withdrawal of the drug, upon resumption of the habit, a formerly well-tolerated dose can be fatal.

Varying degrees of unresponsiveness, shallow respirations, slow respiratory rate (e.g., 2 to 4 per minute) or periodic breathing, pinpoint pupils, bradycardia, and hypothermia are the well-recognized clinical manifestations of acute opioid poisoning. In the most advanced stage, the pupils dilate, the skin and mucous membranes become cyanotic, and the circulation fails. The immediate cause of death is usually respiratory depression, with consequent asphyxia. Patients who suffer a cardiopulmonary arrest are sometimes left with all the known residual of anoxic encephalopathy. Others who recover from coma may occasionally reveal a hemiplegia, presumably due to vascular occlusion. Mild degrees of intoxication are betrayed by anoxia, nausea, vomiting, constipation, and loss of sexual interest.

**Treatment**

This consists of the administration of naloxone (Narcan), a specific antidote to the opiates and also to the synthetic analgesics. The dose of naloxone is 0.7 mg/kg body weight intravenously, repeated if necessary once or twice at 5-min intervals. In cases of opioid poisoning, the improvements in circulation and respiration and reversal of miosis are usually dramatic. In fact, failure of naloxone to produce such a response should cast doubt on the diagnosis of opioid intoxication. If an adequate respiratory and pupillary response to naloxone is obtained, the patient should be observed carefully for 24 h and further doses of naloxone (50 percent higher than the ones previously found effective) should be given intramuscularly as often as necessary. Naloxone has little direct effect on consciousness, however, and the patient may remain drowsy for many hours. This is not harmful provided that respiration is well maintained. Gastric lavage is a useful measure if the drug was taken orally. This procedure may be efficacious many hours after ingestion, since one of the toxic effects of opioids is severe pylorospasm and ileus, which causes much of the drug to be retained in the stomach.

The patient regains consciousness, complaints such as pruritus, sneezing, tearing, pilocerection, diffuse body pains, yawning, and diaphoresis may appear. These are the recognizable symptoms of the opioid abstinence, or withdrawal, syndrome, described below. An antidote therefore must be used with great caution in an addict who has taken an overdose of opioid, because in this circumstance it may precipitate withdrawal phenomena. Nausea and severe abdominal pain, due presumably to pancreatitis (from spasm of the sphincter of Oddi), are other troublesome symptoms of opiate use or withdrawal. Seizures are rare.

**Opioid Addiction**

Just 30 to 35 years ago there was an estimated 60,000 persons addicted to narcotic drugs in the United States, exclusive of those who were receiving drugs because of their physician’s prescription. This represents a relatively small fraction of the population. Opioid addiction was of serious proportions in only a few cities—New York, Chicago, Los Angeles, Washington, and Detroit. Since the late 1960s, a remarkable increase in opioid (mainly heroin) addiction has taken place. The precise number of opioid addicts is not known but is currently estimated by the Drug Enforcement Administration to be more than 500,000 (a disproportionate number in New York and a few other large cities). The prevalence and patterns of opioid abuse have been reviewed by Brust.

**Etiology and Pathogenesis**

A number of factors—socioeconomic, psychologic, and pharmacologic—contribute to the genesis of opioid addiction. In our culture, the most susceptible addicts are young men or delinquents living in depressed areas of large cities, but significant numbers are now found in the suburbs and in small cities as well. The onset of opioid use is usually in adolescence, with a peak at 17 to 18 years; fully two-thirds of addicts start using the drugs before the age of 21. Almost 90 percent of addicts engage in criminal activity, often to obtain their daily ration of drugs, but most of them have a history of arrests or convictions antedating their addiction. Also, many of them have psychiatric disturbances, conduct disorder and sociopathy being the most common. Monroe and colleagues (1970) have reported that 49 percent of their patients had shown evidence of antisocial personality disorder, evaluated by the Antisocial Personality Test. Forty-two percent of the addicts had a history of drug addiction, and 42 percent, emotional disturbance in 29 percent, and thinking disorder in 22 percent; only 7 percent were free of such disorders. Obviously, vulnerability to addiction is not confined to one personality type.

Association with addicts is the apparent explanation for beginning addiction. One addict recruits another person into addiction, and the new recruit does likewise. In this sense opioid addiction is contagious, and as a result of this pattern, heroin addiction has attained epidemic proportions. A small, almost insignificant proportion of addicts are introduced to drugs by physicians in the course of an illness. One seldom hesitates, therefore, to prescribe opiates to patients with chronic pain (e.g., cancer pain) because of the risk of addiction.

Opioid addiction consists of three recognizable phases: (1) episodic intoxication, or “euphoria,” (2) pharmacogenic dependence or drug-seeking behavior (addiction), and (3) the propensity to relapse after a period of abstinence.

Some of the symptoms of opioid intoxication have already been considered. In patients with severe pain or pain-anticipatory anxiety, the administration of opioids produces a sense of unusual well-being, a state that has traditionally been referred to as morphine euphoria. It should be emphasized that only a negligible proportion of such persons continue to use opioids habitually after their pain has subsided. The vast majority of potential addicts are not suffering from painful illnesses at the time they initially use opioids, and the term addiction is used to signify a drug dependence that is not incapacitated by the alleviation of the primary cause. These persons, as indicated above, are teenagers or young adults who, usually with the acquiescence of the self-administering addicts under the tutelage of their peers. They learn, after several repetitions, to recognize a “high,” despite the subsequent recurrence of unpleasant, or dysphoric, symptoms (nursing, vomiting, faintness, as the drug wears off). The repeated self-administration of the drug (“reinforcement” in the language of operant psychology) is the important factor in the genesis of addiction. Regardless of how one characterizes the state of mind that is produced by episodic injection of the drug, the individual quickly discovers the need to increase the dose in order to obtain the original effects. Although the initial effects may not be fully recapitulated, the progressively increasing dose of the drug does relieve the discomfort that arises as the effects of each injection wear off. In this way a new pharmacogenically induced need is developed, and the use of opioids becomes self-perpetuating. At the same time a marked degree of tolerance is produced, so that enormous amounts of drugs, e.g., 5000 mg of morphine daily, have eventually been administered without the development of toxic symptoms.

The pharmacologic criteria of addiction, as indicated in the chapter on alcoholism, are tolerance and physical dependence. The latter refers to the symptoms and signs that become manifest when the drug is withdrawn following a period of continued use. These symptoms and signs constitute a specific clinical state, termed the abstinence or withdrawal syndrome (see below). The mechanisms that underlie the development of tolerance and physical dependence are not fully understood. However, it is known that opioids activate the brain’s opioid antinociceptive system (enkephalins, dynorphins, endorphins) and specific opioid receptors, which are located at different levels of the nervous system (these are described in Chap. 6, on pain; see also the review of Fields).

**The Opioid Abstinence Syndrome**

The intensity of the abstinence or withdrawal syndrome depends on the dose of the drug and the duration of addiction. The onset of abstinence symptoms in relation to the last exposure to the drug, however, is related to the pharmacologic half-life of the agent. With morphine, the majority of individuals receiving 240 mg daily for 30 days or more will moderately severe abstinence symptoms following withdrawal. Mild signs of opiate abstinence can be precipitated by narcotic antagonists in persons who have taken as little as 15 mg of morphine or an equivalent dose of methadone or heroin three times daily for 3 days.

The abstinence syndrome that may be precipitated by the morphine addict may be taken as the prototype of the opioid group. The first 8 to 16 h of abstinence usually pass symptomatically. At the end of this period, yawning, rhinorrhea, sweating, pilocerection, and lacrimation become manifest. Mild at first, these symptoms increase in severity over a period of several hours and then remain constant for several days. The patient may be able to sleep during the early abstinence period but is restless, and thereafter abstinence remains a prominent feature. Dilatation of the pupils, recurring waves of gooseflesh, and legs and of “hot and cold flashes”; he frequently asks for blankets. At about 36 h the restlessness becomes more severe, and nausea, vomiting, and diarrhea usually develop. Temperature, respiratory rate, and blood pressure are slightly elevated. All these symptoms reach their maximum extent at about 72 h, after which time there is a gradual return to the pre-drug state.

Habitation, also designated as emotional or psychologic dependence, refers to the substitution of drug-seeking activities for all other aims and objectives in life and is the essence of addiction. It is this feature (craving or “purposive” abstinence changes) that fosters relapse to the use of the drug long after the physiologic (“nonpurposive”) abstinence changes seem to have disappeared. The cause for relapse is not fully understood. Theoretically, fragments of the abstinence syndrome may remain as a conditioned response, and these abstinence signs may be evoked by the appropriate environmental stimuli. Thus, when a “cured” addict is in a situation where narcotic drugs are readily available or in a setting that was associated with the initial use of drugs, the incompletely extinguished drug-seeking behavior may reappear itself.

The characteristics of addiction and of abstinence are qualitatively similar with all drugs of the opiate group as well as the related synthetic analgesics. The
Medical and Neurologic Complications of Opioid Use

In addition to the toxic effects of the opioid itself, the addiction can vary a number of neurologic and infectious complications resulting from the injection of contaminated adulterants (quininne, talc, lactose, powdered milk, and fruit sugars) and of various infectious agents (injections administered under unsterile methods). The most important of these is HIV infection, but septicaemia and endocarditis and viral hepatitis may also occur. Particulate matter that is injected with heroin or a vasodilator that is commonly used by heroin abusers may cause occlusion of cerebral arteries, with hemiplegia or other focal neurologic signs. Amyloidosis due probably to the toxic effects of quinia in the heroin mixtures, has been reported, as well as transverse myelopathy and several types of peripheral neuropathy. The spinal cord disorder expresses itself clinically by the abrupt onset of paraplegia with a level on the trunk below which motor function and sensation are lost or impaired and by urinary retention. Pathologically, there is an acute necrotizing lesion involving both gray and white matter subsequent to a cerebrovascular accident. In chronic cases a myelopathy has formed. The first intravenous injection of heroin after a prolonged period of abstinence. We have seen several cases of cervical myelopathy from heroin-induced stupor that had a prolonged period of immobility with the neck hyperextended over the back of a chair or sofa. We have also observed several instances of a progressive cerebral leukoencephalopathy attributed to heroin use, similar to those that occurred in Amsterdam in the 1980s, of the result of inhalation of heroin pyrolysis or an adrenergic to the thoracic and occasionally the cervical cord. The myelopathy has formed. The first intravenous injection of heroin after a prolonged period of abstinence. We have seen several cases of cervical myelopathy from heroin-induced stupor that had a prolonged period of immobility with the neck hyperextended over the back of a chair or sofa. We have also observed several instances of a progressive cerebral leukoencephalopathy attributed to heroin use, similar to those that occurred in Amsterdam in the 1980s, of the result of inhalation of heroin pyrolysis or an adrenergic to the thoracic and occasionally the cervical cord. In our patients the white matter changes were concentrated in the posterior portions of the hemispheres and in the internal capsules. A similar leukoencephalopathy has also been observed in cocaine users, in some of whom a hypertensive encephalopathy or an adrenergic-induced vasculopathy may have played a role. Damage to single individual nerves, particularly the radial nerve, and painful affection of the brachial plexus, apparently unrelated to compression and remote from the sites of the spinal cord disorder expresses itself clinically by the abrupt onset of paraplegia with a level on the trunk below which motor function and sensation are lost or impaired and by urinary retention. SEDATIVE-HYPNOTIC DRUGS

This class of drugs, also referred to as depressants, consists of two main groups. The first includes the barbiturates and chloral hydrate. These drugs are now little used, largely replaced by synthetic compounds, especially of benzodiazepine and other glyceral derivatives, the benzodiazepines, the most important of which are chlordiazepoxide (Lorazepam), lorazepam (Alvian), alprazolam (Xanax), and diazepam (Valium). Closely related are the non-benzodiazepine hypnotics, typified by zolpidem (Ambien). The advantages of the benzodiazepine drugs are their relative low toxicity and addictive potential and their minimal interactions with other drugs.

Barbiturates

Despite the marked reduction in the medical use of barbiturates during the past three decades, the improper use of these drugs—particularly their nonmedical and illicit use—still leads to suicide, accidental death, and addiction. In the past, about fifty barbiturates were marketed for clinical use, but only the following are now encountered with any regularity: pentobarbital (Nembutal), secobarbital (Seconal), amobarbital (Amytal), thiopental (Pentothal), barbital (Veronal), and phenobarbital (Luminal). The first three are the ones most commonly abused.

Mechanism of Action

All the common barbiturates are derived from barbituric acid; the differences between them depend on variations in the side chains of the parent molecule. The potency of each drug is a function of the ionization constant and lipid solubility. The higher its lipid solubility, the greater the drug's potency and the quicker and briefer its action. The lowering of plasma pH increases the rate of entry of the ionized form into the brain. The action of barbiturates is to suppress neuronal transmission, presumably by enhancing GABA inhibition at pre- and postsynaptic receptor sites, and to reduce excitatory postsynaptic potentials. The major points of action in the CNS are similar to those of alcohol and other coma-producing drugs; impaired consciousness or coma relates to inactivation of neurons in the reticular formation of the upper brainstem. The liver is the main locus of drug metabolism, and the kidney is the locus of elimination. All the barbiturates are similar pharmacologically and differ only in the speed of onset and duration of their action. The clinical problems posed by the barbiturates are different, however, depending on whether the intoxication is acute or chronic.

Acute Barbiturate Intoxication

This results from the ingestion of large amounts of the drug, either accidentally or with suicidal intent. The latter is most frequently the effect of an acutely depressed person. The hysteric or sociopath may take an overdose as a suicidal gesture and become seriously intoxicated because of miscalculation or ignorance of the toxic dosage. Often the drug is taken while the individual is inebriated—a dangerous situation, since alcohol and barbiturate have an additive effect.

Diagnosis of Barbiturate Intoxication

The symptoms and signs vary with the type and amount of drug as well as with the length of time that has elapsed since it was ingested. Pentobarbital and secobarbital produce their effects quickly, and recovery is relatively rapid. Phenobarbital induces coma more slowly, and its effects tend to be prolonged. The duration of action of these drugs can be judged by the hypnotic effect of an aversive oral dose. In the case of long-acting barbiturates, such as phenobarbital and barbital, the effect lasts 6 h or more; with the intermediate-acting drugs, amobarbital and apropobarbital, 3 to 6 h; and with the short-acting drugs, secobarbital and pentobarbital, less than 3 h. Most fatalities follow the ingestion of secobarbital, amobarbital, or pentobarbital. The ingestion by adults of more than 3.0 g of these drugs at one time will prove fatal unless intensive and skilled treatment is applied promptly. The potentially fatal dose of phenobarbital is 6 to 10 g. The lowest plasma concentration associated with lethal overdosage of phenobarbital or barbital is 80 mg/mL and that of amobarbital and pentobarbital is 10 mg/mL.

In regard to prognosis and treatment, it is useful to recognize three grades of severity of acute barbiturate intoxication. Mild intoxication follows the ingestion of approximately 0.3 g pentobarbital (Nembutal); the hypnotic dose in an unhabituated patient is 100 mg or less. The patient is drowsy or asleep, although readily roused if called or shaken. The symptoms resemble those of alcohol intoxication. The patient thinks slowly, and there may be mild disorientation, liability of mood, impairment of judgment, slurred speech, drunken gait, and nystagmus. Moderate intoxication follows the ingestion of 5 to 10 times the oral hypnotic dose. The patient is stuporous, tendon reflexes are usually depressed or absent, and respirations are slow but not shallow. Corneal and pupillary reflexes are retained, with occasional exceptions. Usually the patient can be roused by vigorous manual stimulation; when awakened, he is confused and dysarthric and, after a few moments, drifts back into stupor. Severe intoxication occurs with the ingestion of 10 to 20 times the oral hypnotic dose. The patient cannot be roused by any means. Respiration is slow and shallow or irregular, and pulmonary edema and cyanosis may be present. The tendon reflexes are usually but not invariably absent. Most patients show no response to plantar stimulation, but in those who do, the responses are extensor. With deep coma, the corneal and gag reflexes may also be abolished. Ordinarily the pupillary light reflex is retained in severe intoxication and is lost only if the patient is asphyxiated; but in advanced cases, the pupils become miotic and poorly reactive, simulating opiate intoxication. At this point respiration is greatly depressed and oculocephalic and oculovestibular reflex responses are usually abolished. In the early hours of coma, there may be a phase of flexor or extensor posturing or rigidity of the limbs, hyperactive reflexes, ankle clonus, and extensor plantar signs; persistence of these signs indicates that anoxic damage has been added. The temperature may be subnormal, the pulse is thready and rapid, and the blood pressure is at shock levels.

There are few conditions other than barbiturate intoxication that cause a flaccid coma with small reactive pupils, hypothermia, and hypotension. A pontine hemorrhage may do so, but a hysterical trance or catatonic stupor supposes the main problem in differential diagnosis. The use of gas and high-pressure liquid chromatography provides a reliable means of identifying the type and amount of barbiturate in the blood. A patient who has also ingested alcohol may be comatose with relatively low blood barbiturate concentrations. Contrariwise, the addicted (tolerant) patient may show only mild signs of intoxication with very high blood barbiturate concentrations.

The electroencephalogram (EEG) may also be useful in diagnosis. In mild intoxication, the normal activity is replaced by fast (beta) activity, in the range of 20 to 30 cycles per second, and is most prominent in the frontal regions. In more severe intoxication, the fast waves become less regular and interspersed with 3- to 4-per-second slow activity; in still more advanced cases, there are short periods of suppression of all activity, separated by bursts of slow (delta) waves of variable frequency. In coma, the 4-per-second slow activity becomes more prominent, all electrical activity ceases. This is one instance in which a "flat" EEG cannot be equated with brain death, and the effects are fully reversible unless anoxic damage has been sustained.

Management

In mild or moderate intoxication, recovery is the rule and vigorous treatment is not required. If the patient is unresponsive, special measures must be taken to maintain respiration and prevent infection. An endotracheal tube should be inserted, with suctioning as necessary. Any risk of respiratory depression or underventilation requires the use of a positive-pressure respirator.

Hemodialysis or hemofiltration with charcoal may be used in profoundly comatose patients who fail to respond to the measures outlined above. They are particularly useful in cases of coma due to long-acting barbiturates and are mandatory if anuria or uraemia has developed. Treatment with analeptic drugs (e.g., picrotoxin, pentyleneetetrazol), which enjoyed a brief period of popularity, has been generally abandoned, since these drugs do not affect the rate of metabolism or the excretion of barbiturates.

Occasionally, in the case of a barbiturate addict who has taken an overdose of the drug, recovery from coma is followed by the development of abstinence symptoms, as described below.

Barbiturate Addiction (Chronic Barbiturate Intoxication)

Chronic barbiturate intoxication, like other drug addictions, tends to develop on a background of some psychiatric disorder, most commonly a depressive illness with symptoms of anxiety and insomnia. Addiction to alcohol or to opiates may predispose to barbiturate addiction. Alcoholics find that barbiturates effectively relieve their nervousness and tremor. They may then continue to take both alcohol and barbiturate, or the barbiturate may replace the alcohol. As with other drug addictions, the incidence of barbiturism is particularly high in individuals with ready access to drugs, such as physicians, pharmacists, and nurses.

The manifestations of barbiturism are much the same as those of alcohol intoxication. The barbiturate addict thinks slowly, exhibits increased emotional lability, and becomes irritable and aggressive. The characteristic neurologic signs are hyperesthesia, agranular dysmetria, nystagmus, and cerebellar incoordination. If the dosage is elevated rapidly, the signs of moderate or severe intoxication, as described above, become manifest.

A characteristic feature of chronic barbiturate intoxication is the development of tolerance, sometimes striking in degree. The average addict ingests about 1.5 g a day and does not manifest signs of severe intoxication unless this amount is exceeded. Tolerance to barbiturates does not develop as rapidly as to opiates. Most persons can ingest 0.4 g daily for as long as 3 months without developing major withdrawal symptoms (seizures or delirium). With a dosage of 0.8 g daily for a period of 2 weeks to 2 months, abrupt withdrawal will result in serious symptoms in the majority of patients (see below).

Barbiturate Abstinence, or Withdrawal, Syndrome

Immediately following withdrawal, the patient seemingly improves over a period of 8 to 12 h, as the symptoms of...
intoxication diminish. Then a new group of symptoms develops, consisting of nervousness, tremor, insomnia, postural hypotension, and weakness. With chronic phenoxybarbital or barbitral intoxication, withdrawal symptoms may not become apparent until 48 to 72 h after the final dose. Generalized seizures with loss of consciousness, usually occurring between the second and fourth days of abstinence but occasionally as long as 6 or 7 days after withdrawal. There may be a single seizure, several seizures, or, rarely, status epilepticus. Characteristically, in the withdrawal period, there is a greatly heightened sensitivity to photic stimulation, to which the patient responds with myoclonus or a seizure accompanied by paroxysmal changes in the EEG. The convulsive phase may be followed directly by a delusional-hallucinatory state or a full-blown delirium indistinguishable from delirium tremens, or a varying degree of improvement may follow the seizures before the delirium becomes manifest. Death has been reported under these circumstances. The abstinence syndrome may occur in varying degrees of completeness; some patients have seizures and recover without developing delirium, and others have a delirium without preceding seizures. The abrupt onset of seizures or an acute psychosis in adult life should always raise the suspicion of addiction to barbiturates or other sedative-hypnotic drugs.

**Treatment of Chronic Barbiturate Intoxication** This should always be carried out in the hospital. If the diagnosis of addiction is made before signs of abstinence have become manifest, “withdrawal dosage” should first be determined. This is the amount of short-acting barbiturate required to produce mild symptoms of intoxication (nystagmus, slight ataxia, and dysarthria). Usually 0.2 g of pentobarbital given orally every 6 h is sufficient for this purpose. Then a gradual withdrawal of the drug is undertaken, 0.1 g daily, the reduction being stopped for several days if abstinence symptoms appear. In this way, a severely addicted person can be withdrawn in 14 to 21 days. The patient who presents with severe withdrawal symptoms, such as seizures, is given 0.3 to 0.5 g of phenobarbital intramuscularly and then enough to maintain a state of mild intoxication. Most other anticonvulsant medicines are ineffective against barbiturate withdrawal convulsions. Withdrawal should then be carried out as indicated above. If the abstinence symptoms are not severe, it is not necessary to reintoxicate the patient, but treatment can proceed along the lines laid down for other forms of delirium and confusion. After recovery has taken place, whether from acute or chronic intoxication, the psychiatric problem requires evaluation and an appropriate plan of therapy.

**Chloral Hydrate**

This is the oldest and one of the safest, most effective, and most inexpensive of the sedative-hypnotic drugs. After oral administration, chloral hydrate is reduced rapidly to trichloroethanol, which is responsible for the depressant effects on the CNS. A significant portion of the trichloroethanol is excreted in the urine as the glucuronide, which may give a false-positive test for glucose.

Tolerance and addiction to chloral hydrate develop only rarely; for this reason it is an appropriate medication for the management of insomnia, particularly the type that is associated with depression. Poisoning with chloral hydrate is a rare occurrence and resembles acute barbiturate intoxication except for the finding of miosis, which is said to characterize the former. Treatment follows along the same lines as for barbiturate poisoning. Death from poisoning is due to respiratory depression and hypotension; patients who survive may show signs of liver and kidney disease.

Paraadylene, another member of this group of sedative drugs, is no longer being manufactured in the United States, and chloral hydrate is now available mainly as an elixir for pediatric use.

**Benzodiazepines**

With the introduction of chlordiazepoxide in 1960 and the benzodiazepine drugs that followed (particularly diazepam), the older sedative drugs (barbiturates, paraldehyde, chloral hydrate) have become virtually obsolete. Indeed, the benzodiazepines are the most commonly prescribed drugs in the world today. According to Hollister, 15 percent of all adults in the United States use a benzodiazepine at least once yearly and about half this number use the drug for a month or longer. As mentioned earlier, the benzodiazepines, compared with the older sedatives, have relatively minor hypnotic effects and low abuse potential and are relatively safe when taken in overdose.

The benzodiazepines have been used extensively for the treatment of anxiety and insomnia, and they are especially effective when the anxiety symptoms are severe. Also, they have been used to control overactivity and destructive behavior in children and the symptoms of alcohol withdrawal in adults. Diazepam is particularly useful in the treatment of delirious patients who require parenteral medication. The benzodiazepines possess anticonvulsant properties, and the intravenous use of diazepam, lorazepam, and midazolam is an effective means of controlling status epilepticus, as described on page 361. Diazepam in massive doses has been used with considerable success in the management of muscle spasm in tetanus and in “stiff man” syndrome (page 1569). Diazepam has been far less successful in the treatment of extrapyramidal movement disorders and dystonic spasms. Alprazolam (Xanam) has a central place in the treatment of panic attacks and other anxiety states, as an adjunct in some depressive illnesses, and in the behavioral disturbances in Alzheimer disease. It seems, however, to create more dependence than some of the others in its class.

Other important benzodiazepine drugs are flurazepam (Draline), triazolam (Halcion), chlordiazepate (Tranxene), temazepam (Restoril), and other newer varieties, all widely used in the treatment of insomnia (page 414), and clonazepam (Klonipin), which is useful in the treatment of myoclonic seizures (pages 357 and 360) and intention myoclonus (page 110). Midazolam (Versed), a short-acting parenteral agent, is used frequently to achieve the brief sedation required for procedures such as MRI or endoscopy and is useful in the treatment of status epilepticus, but it is known to cause respiratory arrest on occasion. Lorazepam (Ativan) and oxazepam (Serax) are to be preferred to other benzodiazepines in treating the elderly and those with impaired liver function. Many other benzodiazepine compounds have appeared in recent years, but a clear advantage over the original ones remains to be demonstrated (Hollister, Pidossy and Koh). Zolpidem (Ambien) differs from the benzodiazepines structurally but is pharmacologically the same.

The benzodiazepine drugs, like barbiturates, have a depressant action on the CNS by binding to specific receptors on GABA inhibitory systems. The benzodiazepines act in concert with GABA to open chloride ion channels and hyperpolarize postsynaptic neurons and reduce their firing rate. The primary sites of their action are the cerebral cortex and limbic system, which accounts for their anticonvulsant and anxiolytic effects. While quite safe in the recommended dosages, they are far from ideal. They frequently cause unsteadiness of gait and drowsiness and at times hypotension and syncope, confusion, and impairment of memory, especially in the elderly. If taken in large doses, the benzodiazepines can produce a depression of the state of consciousness, resembling that of other sedative-hypnotic drugs but with less respiratory suppression and hypotension. Flumazenil, a specific pharmacologic antagonist of the CNS effects of benzodiazepines, rapidly but briefly reverses most of the symptoms and signs of benzodiazepine overdose. It acts by binding to benzodiazepine receptors and thereby blocking the activation of inhibitory GABAergic synapses. Flumazenil may also have diagnostic utility in cases of coma due to unknown etiology and in hepatic encephalopathy (see page 1196).

Signs of physical dependence and true addiction, though relatively rare, undoubtedly occur in chronic benzodiazepine users, even in those taking therapeutic doses. The withdrawal symptoms are much the same as those that follow the chronic use of other sedative drugs (anxiety, jitteriness, insomnia, seizures) but may not appear until the third day after the cessation of the drug and may not reach their peak of severity until the fifth day (Hollister). In chronic benzodiazepine users, the gradual tapering of dosage over a period of 1 to 2 weeks minimizes the withdrawal effects.

**Carbonic Acid Derivatives**

These drugs are capable of modest depressant action and are effective in relieving mild degrees of nervousness, anxiety, and muscle tension. Meprobamate (Equanil, Miltown) is the best-known member of this group. It was the first of the new antianxiety drugs, a chemical variant of the weak and ineffective muscle relaxant mephenesin. With average doses (400 mg three or four times a day), the patient is able to function quite effectively; larger doses cause ataxia, drowsiness, stupor, coma, and vasomotor collapse.

Meprobamate has turned out to have the same disadvantages as the barbiturates, including death from overdosage. Addiction to meprobamate may occur, and if four or more of the recommended dose is administered over a period of weeks to months, withdrawal symptoms (including convulsions) may appear. Because of this tendency to produce physical dependence and other disadvantages (serious toxic reactions and a high degree of sedation), meprobamate and its congeners are now seldom used except illicily.

**Other Antianxiety Agents** A new class of antianxiety agents, exemplified by the selective SHT-2 serotoninergic agent buspirone (Buspar), is chemically and pharmacologically different from the benzodiazepines, barbiturates, or other sedatives. Because of its apparently reduced potential for abuse and tolerance, it is not a controlled pharmaceutical substance in the United States, but adverse interactions with MAO inhibitors are known; its use with other psychotropic drugs is still under investigation. It does not block the withdrawal syndrome due to other sedative-hypnotic drugs.
ANTIPSYCHOTIC DRUGS

In the mid-1950s, a large series of pharmacologic agents, originally referred to as tranquilizers (later, as psychotropic or neuroleptic drugs), came into prominent use—mainly for the control of schizophrenia, psychotic states associated with “organic brain syndromes,” and affective disorders (depression and manic-depressive disease). The introduction of these drugs was followed by a dramatic reduction in the incidence of these syndromes, by which these drugs ameliorate acute disturbances of thought and affect in psychotic states are not fully understood, but presumably they act by blocking the postsynaptic dopamine receptor (there are four subtypes, termed D₁ through D₄) on neuronal membranes. The D₂ receptors are located mainly in the frontal cortex, hippocampus, and limbic cortex, and the D₄ receptors in the striatum. There is also some adrenergic blocking effect. The blockade of dopamine receptors in the striatum is thought to be responsible for the parkinsonian side effects of this entire class of drugs, and the blockade of another dopaminergic (lateral geniculate body) system produces the so-called “hyperkinetic” side effects. A number of antipsychotic drugs, typified by clozapine (Clozaril), apparently achieve the same degree of D₂ and D₄ blockade in the temporal lobes while exhibiting substantially less antagonistic activity in the striatum—accounting for their lesser parkinsonian side effects.

Since the introduction, in the 1950s, of the phenothiazine chlorpromazine as an anesthetic agent and its application to schizophrenia as a result of serendipitously discovered antipsychotic activity, a large number of antipsychotic drugs have been marketed for clinical use. No attempt is made here to describe or even list all of them. Some have had only an evanescent popularity, and others have yet to prove their value. Chemically, these compounds form a heterogeneous group; eight of them merit particular clinical importance: (1) the phenothiazines; (2) the thioxanthenes; (3) the butyrophenones; (4) the rauwolfia alkaloids; (5) an indole derivative, loxapine (Loxitan), and a unique dithydropyridione, molindone (Moban); (6) a diphenylybutylophenidin, pimozide (Orap); (7) dibenzodiazepines, typified by clozapine (Clozaril) and olanzapine (Zyprexa); and (8) a benzoaxazolopyridone, risperidone (Risperdal). The last four of these drugs were introduced more recently than the others and also have a more limited use. Molindone and loxapine are about as effective as the phenothiazines in the management of schizophrenia, and their side effects are also similar; their main use is in patients who are not responsive to the older drugs or who suffer intolerable side effects from them. The antipsychotic agents in the class of clozapine have attracted greater interest, since—as already mentioned—they appear to be relatively free of extrapyramidal side effects. For this reason, they are particularly successful in controlling the confusion and psychosis of parkinsonian patients. The other new class of drugs, of which risperidone is the main example, has fewer extrapyramidal side effects and a more rapid onset of action than the traditional antipsychotic medications. Pimozide may be useful in the treatment of haloperidol-refractory cases of Gilles de la Tourette syndrome (page 117); its main danger is its tendency to produce cardiac arrhythmias.

Phenothiazines

This group comprises some of the most widely used tranquilizers, such as the phenothiazines chlorpromazine (Thorazine), promazine (Sparine), triflupromazine (Vesprin), prochlorperazine (Compazine), perphenazine (Trilafon), fluphenazine (Permiil, Prolixin), thioridazine (Mellaril), mesoridazine (Serentil), and trifluperazone (Stelazine). In addition to their psychotherapeutic effects, these drugs have a number of other actions, so that certain members of this group are used as antineuritics (prochlorperazine) and antihistaminics (promazine).

The phenothiazines have had their widest application in the treatment of the psychoses (schizophrenia and, to a lesser extent, manic-depressive psychosis). Under the influence of these drugs, many patients who would otherwise be hospitalized are able to live at home and even work productively. In the hospital, the use of these drugs has greatly facilitated the care of hyperactive and combative patients (see Chap. 57 and Chap. 59 for details of the clinical usage of these drugs).

Side effects of the phenothiazines are frequent and often serious. All of them may cause a cholestatic type of jaundice, agranulocytosis, convulsive seizures, orthostatic hypotension, skin sensitivity reactions, mental depression, and, most importantly, immediate or delayed extrapyramidal motor disorders. The neuroleptic malignant syndrome is the most extreme complication and is discussed separately further on. The following types of extrapyramidal symptoms, also discussed on page 1637, have been noted in association with all of the phenothiazines [as well as the butyrophenones and, to a lesser extent, metoclopramide (Reglan) and pimozide, which block dopaminergic receptors]:

1. A parkinsonian syndrome—masked facies, tremor, generalized rigidity, shuffling gait, and slowness of movement. These symptoms may appear after several days of drug therapy but more often after several weeks. Suppression of dopamine in the striatum (similar to the effect of loss of nigral cells) is presumably the basis of the parkinsonian syndrome.

2. Dyskinesia and dystonia, taking the form of involuntary movements of lower facial muscles (mainly around the mouth) and protrusion of the tongue (buccolingual or oral-masticatory syndrome), dysphagia, torticolis and retrocolic, oculogyric crises, and tonic spasms of a limb. These complications usually occur early in the course of administration of the drug, sometimes after the initial dose, in which case they can be dramatically improved by immediate discontinuation of the drug. Among the phenothiazines, the most severe is pimozide, particularly if given in a high dosage. Meprobamate is sometimes helpful in ameliorating the symptoms. Amisulpride (Solian) and ketanserin (Mebexol) are useful in the treatment of tardive dyskinesia.

3. An inner restlessness reflected by a persistent shifting of the body and feeling of being restless, sometimes diminishing in response to the drug and sometimes increasing in response. Patients often report that they are “on their feet” and are unable to sit still, which is a state that persists during the course of drug therapy. This symptom may be a feature of tardive dyskinesia. The symptoms may worsen during heavy use of alcohol or other drugs and improve with frequent drug holidays. The symptoms can persist for months or years after discontinuation of the drug. Treatment is symptomatic and includes the use of benzodiazepines such as lorazepam (Ativan), clonazepam (Klonopin), and diazepam (Valium). Amantadine (Symmetrel) may be effective in the treatment of tardive dyskinesia.

4. A group of late and persistent complications of neuroleptic therapy, which may continue after removal of the offending drug, comprises lingual-facial-buccal-cervical dyskinesias, choreathetotic and dystonic movements of the trunk and limbs, diffuse myoclonus (rare), perioral tremor (“rabbit syndrome”), and dysarthria or anarthria. These movement abnormalities constitute the important group of tardive dyskinesias. Snyder has postulated that the movement disorders may be due to hypersensitivity of dopaminergic neurons in the basal ganglia, secondary to prolonged blockade of the receptors by antipsychotic medication. Balsanen estimates that 5 to 10% of patients receiving long-term antipsychotic medication develop tardive dyskinesia of some degree. A pathology has never been ascertained.

5. The neuroleptic malignant syndrome, which is discussed separately below.

Butyrophenones

Haloperidol (Haldol) is the only member of this group approved for use as an antipsychotic in the United States. It has much the same therapeutic effects as the phenothiazines in the management of the acute psychoses. It also has the same side effects as the phenothiazines but has little or no adrenergic blocking action. Haloperidol is the drug of choice in the treatment of haloperidol-refractory cases of Gilles de la Tourette syndrome (the other being pimozide) and the movement disorder of Huntington chorea.

Treatment of Neuroleptic Side Effects

As indicated above, acute dystonic spasms usually respond to diphenhydramine (Benadryl). The purely parkinsonian syndrome usually improves as well, but the tardive dyskinesias may persist for months or years and may be permanent. Administration of antiparkinsonian drugs of the anticholinergic type (tioxyphenidip, procyclidine, and benzotropine) may hasten recovery from some of the symptoms. Oral, lingual, and laryngeal dyskinasias are affected relatively little by any antiparkinsonian drugs. Amantadine (Symmetrel) in doses of 50 to 100 mg tid has been used in some cases of postphenothiazine dyskinesia. Many other drugs have been tried in the treatment of tardive dyskinesia, with uncertain results. No treatment has been uniformly successful in the present authors’ experience. Nevertheless, we have noted a tendency for most of the obstinate forms of tardive dyskinesia to subside slowly even after several years of unsuccessful therapy. The use of low doses of antipsychotic drugs and frequent drug holidays, especially in the more susceptible older patients, may help to prevent the development of tardive dyskinesia.

Neuroleptic Malignant Syndrome

This is the most dreaded complication of neuroleptic therapy and its incidence is thought to be 0.2 percent of patients receiving neuroleptics (Caroff and Mann), and its seriousness is underscored by a mortality rate of 15 to 30 percent if not recognized and treated promptly. It may occur during, weeks, or months after neuroleptic treatment is begun. The syndrome consists of catatonic rigidity, stupor, unstable blood pressure, variable hyperthermia, diaphoresis and other signs of autonomic dysfunction, high serum creatine kinase (CK) values (up to 60,000 units), and, in fatal cases, renal failure due to myoglobinuria. The syndrome was first observed in patients being treated with haloperidol, and since then other neuroleptic drugs have been incriminated, particularly the highly potent thioxanthine derivative thiothixene and the phenothiazines—chlorpromazine, fluphenazine, and thioridazine—but also, on rare occasions, the keppidine and pimozide. The syndrome has become evident that antipsychotic drugs, and specifically clozapine, are also capable of inducing the syndrome. All of these drugs are thought to act through blockade of dopamine receptors in the basal ganglia and hypothalamus.

The neuroleptic malignant syndrome bears a close relationship to malignant hyperthermia, not only in its clinical aspects but also in its response to bromocriptine and dantrolene. Malignant hyperthermia is an inherited disorder that, in susceptible individuals, is triggered by inhalation anesthetics and skeletal muscle relaxants (page 1635). This disorder was described before the introduction of neuroleptic drugs and has recently been related to a mutation of the ryanodine receptor gene on chromosome 19q. A genetic factor is also suspected to underlie the neuroleptic malignant syndrome, possibly provoked by fatigue and dehydration.

If treatment is started early, when consciousness is first altered and the temperature is rising, bromocriptine in oral doses of 5 mg tid (up to 20 mg tid) will terminate
the condition in a few hours. Once oral medication can no longer be taken, dantrolene, 0.25 to 3.0 mg intravenously may be lifesaving. Once coma has supervened, shock and anuria may prove fatal or leave the patient in a vegetative state. The rigors during high fever may cause muscle damage and myoglobinuria, and the circulatory collapse may lead to hypoxic-ischemic brain injury.

Meningitis, heat stroke, lithium intoxication, and acute dystonic reactions figure in the differential diagnosis. Of course, neuroleptic medication must be discontinued as soon as any of the severe extrapyramidal reactions are recognized, and it is felt that the offending neuroleptic should not be used in the future; but the risk of using another class of antipsychotic agent has not been fully addressed.

It hardly needs to be pointed out that the antipsychotic drugs have been much overused. This would be suspected just from the frequency with which they are being prescribed. These powerful medications have specific indications, noted above and in Chap. 56, Chap. 57, and Chap. 58, and the physician should be certain of the diagnosis before using them. The fact that the neuroleptic drugs can produce tardive dyskinesia in nonpsychotic patients is reason enough not to use them for nervousness, apprehension, anxiety, mild depression, and the many normal psychologic reactions to trying environmental circumstances. These drugs are not curative but only suppress or partially alleviate symptoms, and they should not serve as a substitute for, or divert the physician from, the use of other measures for the relief of abnormal mental states.

**Antidepressants**

Four classes of drugs—the monoamine oxidase (MAO) inhibitors, the tricyclic compounds, the serotoninergic drugs, and lithium—are particularly useful in the treatment of depressive illnesses. The adjective antidepressant refers to their therapeutic effect and is employed here in deference to common clinical practice.

Antidepressive or antidepressant drugs would be preferable, since the term depressant still has a pharmacologic connotation that does not necessarily equate with the therapeutic effect. For example, barbiturates and chloral hydrate are depressants in the pharmacologic sense and mood elevators or antidepressants in the clinical sense.

**Monoamine Oxidase Inhibitors**

The observation that iproniazid, an inhibitor of monoamine oxidase (MAO), had a mood-elevating effect in tuberculous patients initiated a great deal of interest in compounds of this type and led quickly to their exploitation in the treatment of depression. Iproniazid proved exceedingly toxic to the liver and was soon taken off the market. Subsequently developed MAO inhibitors, but other drugs in this class, much better tolerated, are still available. These include isocarboxazid (Marplan), phenelzine (Nardil), and tranylcypromine (Parnate), the latter two being the more frequently used. Tranylcypromine, which bears a close chemical resemblance to dextroamphetamine, may produce unwanted stimulation, but the most common adverse effect of all the MAO inhibitors is postural hypotension. Also, interactions with a wide array of other drugs and ingested substances may produce severe hypertension.

Monoamine oxidase is located on the outer surface of the mitochondria in neurons and is utilized in the catabolism of catecholamines (Coyle). In the gut and liver, this enzyme normally serves to deaminate phenethylamine, tyramine, and tryptamine—the products of protein catabolism. Inhibition of MAO allows these dietary amines, which normally have a negligible action, to enter the brain in small quantities, thus releasing their sympathomimetic effect and increasing heart rate and blood pressure. Probably more relevant to their action as antidepressants, the MAO inhibitors also have in common the ability to block the intraneuronal oxidative deamination of naturally occurring amines (norepinephrine, epinephrine, and serotonin), and it has been suggested that the accumulation of these substances is responsible for the antidepressant effect. However, many enzymes other than monoamine oxidase are inhibited by MAO inhibitors, and the latter drugs have numerous actions unrelated to enzyme inhibition. Furthermore, many agents with antidepressant effects like those of the MAO inhibitors do not inhibit MAO. One cannot assume that the therapeutic effect of these drugs has a direct relation to the property of MAO inhibition in the brain.

The MAO inhibitors must be dispensed with great caution and constant awareness of their potentially serious side effects. They may at times cause excitement, restlessness, agitation, insomnia, and anxiety, occasionally with the usual dose but more often with an overdose. Mania and convulsions may occur (especially in epileptic patients). Other side effects are muscle twitching and involuntary movements, urinary retention, skin rashes, tachycardia, jaundice, visual impairment, enhancement of glaucoma, impotence, sweating, muscle spasms, paresthesias, and a serious degree of orthostatic hypotension.

Patients taking MAO inhibitors must be warned against the use of phenelzines, CNS stimulants, tricyclic and serotoninergic antidepressants (see below), and also sympathomimetic amines and tyramine; the combination of an MAO inhibitor and any of these drugs or amines may induce severe hypertension, atrial and ventricular arrhythmia, pulmonary edema, stroke, and even death. Symptomatogenic amines are contained in some commonly used cold remedies, nasal sprays, nose drops, and certain foods—aged cheese, beer, red wine, pickled herring, sardines, sausages, and preserved meat or fish. Exaggerated responses to the usual dose of meperidine (Demerol) and other narcotic drugs have also been observed; respiratory function may be depressed to a serious degree, and hyperpyrexia, agitation, and pronounced hypotension may occur as well, sometimes with fatal issue. Unpredictable side effects may also accompany the simultaneous administration of barbiturates and MAO inhibitors. The abrupt occurrence of severe occipital headache, nausea, vomiting, pupillary dilation, or visual blurring should suggest a hypertensive crisis; treatment is with intravenous phentolamine 5 mg, nitroprusside, or a calcium channel blocker administered slowly to prevent hypotension. Overdosage presents with coma, for which there is no treatment other than supportive care.

The therapeutic use of MAO inhibitors is discussed further in Chap. 56 and Chap. 57.

**Tricyclic Antidepressants**

Soon after the first successes with MAO inhibitors, a new class of tricyclic compounds appeared. The first was imipramine (Tofranil), soon followed by amitriptyline (Elavil) and then by desipramine (Norpramin) and nortriptyline (Pamelor). Another important dibenzazepine derivative is carbamazepine (Tegretol), which is widely used in the control of seizures but has also found a role in the treatment of lancinating neuropathic and myelopathic pain and possibly of depression and mood instability. Subsequently, a number of additional antidepressant drugs were introduced. Included are variants of the conventional tricyclic drugs (amoxapine, protriptyline, trimipramine, doxepin), tetracyclics (maprotiline), bicyclics (zimeldine), and others (trazodone, buproprion). A full account of these drugs, which cannot

The mode of action of these agents is not fully understood, but there is evidence that they block the reuptake of amine neurotransmitters, both norepinephrine and serotonin. Blocking this amine pump mechanism (called the presynaptic plasma transporter), which ordinarily terminates synaptic transmission, permits the persistence of neurotransmitter substances in the synaptic cleft and supports the hypothesis that endogenous depression is due to a deficiency of noradrenergic or serotoninergic transmission.

The tricyclic antidepressants and the serotoninergic drugs discussed in the next section, are presently the most effective drugs for the treatment of patients with depressive illnesses, the former being particularly useful for those with anergic depressions associated with hyposomnia, early morning awakening, and decreased appetite and libido. The side effects of the tricyclic drugs are far less frequent and serious than those of the MAO inhibitors.

The tricyclic (dibenazepine) compounds are potent anticholinergic agents, which accounts for their most prominent and serious side effects—orthostatic hypotension and urinary bladder weakness. They may also produce CNS excitement—leading to insomnia, agitation, and restlessness—but usually these effects are readily controlled by small doses of phenothiazines or benzodiazepines given concurrently or in the evenings. Occasionally they may cause ataxia and blood dyscrasias. As indicated above, the tricyclic drugs should not be given with an MAO inhibitor; serious reactions have allegedly occurred when small doses of imipramine were given to patients who had discontinued the MAO inhibitor 1 week previously. Finally, it must be repeated that both the MAO inhibitors and the tricyclic antidepressants are extremely dangerous drugs when taken in excess.

Tricyclic compounds are a frequent cause of accidental poisoning and a favorite suicidal instrument of depressed patients. It is common for the intoxicated patient to have taken several drugs, in which case chemical analyses of the blood and urine are particularly helpful in determining the drugs involved and in sorting out there interactions. Mortality from overdosage is due to cardiac disturbances, particularly tachycardia, arrhythmias and impaired conduction. Treatment consists of gastric aspiration and instillation of activated charcoal and the addition of physostigmine to reverse serious arrhythmias; its short action duration requires that frequent doses be given. Dialysis is of no value because of the low plasma concentrations of the drug.
Serotonin Reuptake Inhibitors and Related Drugs

The selective serotonin reuptake inhibitors (SSRI) constitute a newer class of antidepressants; paroxetine (Paxil), fluoxetine (Prozac), and sertraline (Zoloft) are the ones most often used, but others are being developed at a rapid pace. They act presumably by inhibiting the reuptake of serotonin and to a slightly lesser extent of norepinephrine, somewhat like the effect of a tricyclic. This result in potentiation of the actions of these neurotransmitters. Because they do not bind as avidly as tricyclic drugs to the muscarinic and adrenergic receptors in the brain, they produce fewer side effects, but some patients complain of anxiety or insomnia when they are first introduced. As with the tricyclic agents, the concomitant administration of MAO inhibitors is hazardous. There should be a period of at least 1 week between the administration of these two classes of drugs to allow for the washout of the last agent used. The two classes of a “serotonin syndrome” that results from excessive intake or from the concurrent use of MAO inhibitors include confusion, restlessness, myoclonus, shivering, and diaphoresis, as summarized by Sternbach.

The SSRI drugs are well tolerated, may be effective in a shorter time than the tricyclic agents, and are justifiably very popular at the moment, but their long-term therapeutic usefulness in comparison with their predecessors remains to be determined (see review of Richelson). Fluoxetine has also been used with benefit in a group of autistic children (pide 1100). Several related drugs such as venlafaxine (Effexor), nefazodone (Serzone), and citalopram (Celexa) have novel structures that are not analogous to those of the other categories of antidepressants. They are believed to act similarly to the SSRI class by inhibiting the reuptake of serotonin and norepinephrine. These newer drugs share most of the side effects of the SSRI drugs, including the danger of concomitant MAO inhibitor administration.

Lithium

The discovery of the therapeutic effects of lithium salts in mania has led to its widespread use in the treatment of manic-depressive disease (bipolar disorder). The drug has proved relatively safe and blood levels are easily monitored. Its value is much more certain in treatment of the manic phase of bipolar disorder and prevention of recurrences of cyclic mood shifts than it is in treatment of anxiety and depression. Guidelines for the clinical use of lithium are given in Chap. 57. Its mechanism of action is unclear, but there is experimental evidence that lithium blocks the stimulus-induced release of norepinephrine and enhances the reuptake of this amine—the opposite, in a sense, of what occurs with the other classes of antidepressants.

With blood levels of lithium in the upper therapeutic range, it is not uncommon to observe a fast-frequency action tremor or asterixis, together with nausea, loose stools, fatigue, polyuria, and polydipsia. These symptoms usually subside with time. Above a level of 1.5 to 2 meq/L, particularly in patients with impaired renal function also referred to as polythickuric diuretic-induced intoxication because of its manifest—dizziness, confusion, delirium, dizziness, ataxia, stammering, diffuse myoclonic twitching, and nephrogenic diabetes insipidus. Vertical (downbeating) nystagmus and opcosconus may also be prominent. This clinical state, associated with sharp waves in the EEG, may mimic Creutzfeldt-Jakob disease, but there should be no problem in diagnosis if the setting of the illness and the administration of lithium are known. At a blood lithium concentration of 3.5 meq/L, these symptoms are replaced by stupor and coma, sometimes with convulsions, and may prove fatal.

Discontinuing lithium in the intoxicated patient, which is the initial step in therapy, does not result in immediate disappearance of toxic symptoms. This may be delayed by a “crash” or, and the diabetics insipidus may persist even longer. Fluids, sodium chloride, the diabetes insipidus, and acetazolamide promote the excretion of lithium. Lithium coma may require hemodialysis, which has proved to be the most rapid means of reducing the blood lithium concentration.

STIMULANTS

Drugs that act primarily as CNS stimulants have a relatively limited therapeutic use but assume clinical importance for other reasons. Some members of this group, e.g., the amphetamines, are much abused, and others are not infrequent causes of poisoning.

Amphetamine (Benzedrine, Adderall) This drug and dextroamphetamine, its d-isomer, are powerful analeptics (CNS stimulants) and in addition have significant hypertensive, respiratory-stimulant, and appetite-depressant effects. They are useful in the management of narcolepsy but have been much more widely and indiscriminately used for the control of obesity, the abolition of fatigue, and the treatment of hyperacidity in children. Undoubtedly, they are able to reverse fatigue, postpone the need for sleep, and elevate mood, but these effects are not entirely predictable, and the user must pay for the period of wakefulness with even greater fatigue and often with depression. The intravenous use of a high dose of amphetamine produces an immediate feeling of ecstasy, the “flash.”

Because of the popularity of the amphetamines and the ease with which they can be procured, instances of acute and chronic intoxication are observed frequently. The toxic signs are essentially an exaggeration of the analeptic effects—restlessness, excessive speech and motor activity, tremor, and insomnia. Severe intoxication may give rise to hallucinations, delusions, and changes in affect and thought processes—a state that may be indistinguishable from paranoid schizophrenia. Amphetamine vasculitis and intracerebral and subarachnoid hemorrhage are well-recognized but rare complications of chronic intoxication (Harrington et al), and they may occur after acute use as well. Similar cerebrovascular complications occur with sympathomimetic agents contained in over-the-counter cold medications and in dieting aids; phenylpropanolamine has been implicated most often, but ephedrine and similar agents rarely have the same effects and induce a vasculopathy. The pathogenesis of the vascular lesion is unknown (both vasospasm and arteritis have been reported), and the same state occurs with cocaine, as described below.

Chronic use of amphetamines can lead to a high degree of tolerance and psychologic dependence. Withdrawal of the drug after sustained oral or intravenous use is regularly followed by a period of prolonged sleep (a disproportionate amount of which is REM sleep), from which the patient awakens with a ravenous appetite, fatigue and often with depression. The intravenous use of a high dose of amphetamine produces an immediate feeling of ecstasy, the “flash.”

Methylphenidate (Ritalin) This drug has much the same type of action as dextroamphetamine and is useful in the treatment of narcolepsy. Paradoxically, like amphetamine, it is useful in the management of attention-deficit hyperactivity disorder in children (see page 629).

HALLUCINOGENS

Included in this category is a heterogeneous group of drugs, the primary effect of which is to alter perception, mood, and thinking out of proportion to other aspects of cognitive function and consciousness. This group of drugs comprises cocaine, lysergic acid derivatives [e.g., lysergic acid diethylamide (LSD)], phenethylamine derivatives (mescaline or peyote), psilocybin, certain indolic derivatives, cannabis (marijuana), phencyclidine (PCP), and a number of less important compounds. They are sometimes referred to as psychoactive and psychotomimetic drugs and as hallucinogens and psychedelics—but none of these names is entirely suitable. The problems raised by the nontherapeutic use of these drugs, which has declined somewhat but is still of serious proportions, have been reviewed by Nicholli and by Perouka, and by Verebey and their associates.

Cocaine

The conventional use of cocaine as a local anesthetic has for many years been overshadowed by its illicit and widespread use as a stimulant and mood elevator. Originally, cocaine was sold as a white, lactose-adulterated powder that was usually administered intranasally (“snorted”) alone, less often, it was smoked or injected intravenously or intramuscularly. Since 1985 there has been an alarming escalation in the use of cocaine, mainly because of a relatively pure and inexpensive form of the free alkaloid base (“crack”) became readily available at that time. This form of cocaine is heat-stable and therefore suitable for smoking. According to the National Household Survey on Drug Abuse, there were, in 1998, an estimated 600,000 frequent cocaine users in the United States. (Frequent use was arbitrarily defined as use on 5 or more days in the preceding year.) The number of occasional users (less than 12 days in the preceding year) was 2.4 million. These figures are subject to significant underreporting.

A sense of well-being, euphoria, loquacity, and restlessness are the familiar effects. Pharmacologically, cocaine is thought to act like the tricyclic antidepressants; i.e., it blocks the presynaptic reuptake of biogenic amines, thus producing vasoconstriction, hypertension, and tachycardia and predisposing to generalized tremor, myoclonus, seizures, and psychotic behavior. These actions as well as its immediate mood-elevating and euphoric effects are much the same as those of dextroamphetamine (see above). The cocaine abuser readily develops psychologic dependence or habituation, i.e., an inability to abstain from frequent compulsive use (“craving”). The manifestations of physical dependence are more subtle and difficult to recognize. Nevertheless, abstinence from cocaine following a period of chronic abuse is regularly attended by insomnia, restlessness, anorexia, depression, hyperprolactinemia, and signs of dopaminergic hypersensitivity—a symptom
complex that constitutes an identifiable withdrawal syndrome.

With the increasingly widespread use of cocaine, a variety of new complications continues to emerge. The symptoms of severe intoxication (overdose), noted above, may lead to coma and death and require emergency treatment in an intensive care unit, along the lines indicated for the management of barbiturate coma. Seizures often occur in this setting and are treated more effectively with benzodiazepines than with standard anticonvulsant drugs. Spontaneous subarachnoid or intracerebral hemorrhage and cerebral infarction have rarely followed the intranasal use and smoking of cocaine (Levine et al). These complications are presumably the result of vasospasm induced by the sympathomimetic actions of cocaine. Cocaine and amphetamines also, on occasion, produce a state of generalized vasospasm leading to multiple cortical infarctions and posterior white matter changes that are evident on imaging studies, not unlike those seen with hypertensive encephalopathy (page 903). Several cases of acute hemorrhagic necrosis of the brain have been described, and instances of “hemorrhagic necrosis” of the brain have been observed. We have seen several instances of vasospasm but have no experience with the vasculitides; however, it would seem that two different types of vasculopathy can result from cocaine and amphetamine use. Roth and colleagues have described 39 patients who developed acute rhabdomyolysis after cocaine use; 13 of these had acute renal failure, severe liver dysfunction, and disseminated intravascular coagulation and 6 of them died. Some reports indicate that cocaine use during pregnancy may cause fetal damage, abortion, or persistent signs of toxicity in the newborn infant:

Anxiety, paranoia, and other manifestations of psychosis may develop within several hours of cocaine use. These complications are best treated with haloperidol.

Marijuana

During the past three decades the prevalence of marijuana use has declined by about half, but it is still the most commonly used illicit drug in the United States. Its effects, when taken by inhaling the smoke from cigarettes, are prompt in onset and evanescent. With low doses, the symptoms are like those of mild alcohol intoxication (drowsiness, euphoria, dulling of the senses, and perceptual distortions). With increasing amounts, the effects are similar to those of LSD, mescaline, and psilocybin (see below); they may be quite disabling for many hours. With even larger doses, severe depression and stupor may occur, but death is rare (for a full account, see Hollister, 1980). No damage to the nervous system has been found after chronic use.

Reverse tolerance to marijuana (i.e., increasing sensitization) may be observed initially, but on continued use, tolerance to the euphoriant effects develops. In one of the few experimental studies of chronic marijuana use, the subjects reported feeling “littery” during the first 24 h after abrupt cessation of smoking marijuana, although no objective withdrawal signs could be detected.

The mild antieptic and antinauseant effects of marijuana coupled with euphoria have led to its use as an agent to ameliorate the effects of cancer chemotherapies, and this purported therapeutic effect is the mainstay of the movement for its legalization.

Mescaline, LSD, and Psilocybin

These drugs produce much the same clinical effects if given in comparable amounts. The perceptual changes are the most dramatic: the user describes vivid visual hallucinations, alterations in the shape and color of objects, unusual dreams, and feelings of depersonalization. An increase in auditory acuity has been described, but auditory hallucinations are rare. Cognitive functions are difficult to assess because of inattention, drowsiness, and inability to co-operate in mental testing. The somatic symptoms consist of dizziness, nausea, paresthesias, and blurring of vision. Sympathomimetic effects—pupillary dilation, piloerection, hyperthermia, and tachycardia—are prominent, and the user may also show hyperreflexia, incoordination of the limbs, and ataxia.

Tolerance to LSD, mescaline, and psilocybin develops rapidly, even on a once-daily dosage. Furthermore, subjects tolerant to any one of these three drugs are cross-tolerant to the other two. Tolerance is lost rapidly when the drugs are discontinued abruptly, but no characteristic signs of physical dependence (abstinence syndrome) ensue. In this sense, addiction does not develop, although users may become dependent upon the drugs for emotional support (psychologic dependence or habituation).

Although LSD has no therapeutic value and the use of marijuana is governed by the federal narcotic laws, these drugs are widely used. They are taken by narcotic addicts as a temporary substitute for more potent drugs; by “drugheads” (i.e., individuals who use any agent that alters consciousness); and by many troubled, unhappy college and high school students for social conformity or for reasons that even they cannot ascertain. The use of these drugs is attended by a number of serious adverse reactions taking the form of acute panic attacks, long-lasting psychotic states resembling paranoid schizophrenia, and flashbacks (spontaneous recurrences of the original LSD experience, sometimes precipitated by smoking marijuana and accompanied by panic attacks). Serious physical injury may follow upon impairment of the user’s critical faculties. Whether prolonged usage leads to permanent damage to the nervous system is not certain; there are some data to suggest that this may happen, but there is little doubt that the mental state of some psychologically predisposed individuals is permanently altered. The reports claiming that LSD may cause chromosomal damage remain to be validated. Numerous claims have been made that LSD and related drugs are effective in the treatment of mental disease and a wide variety of social ills and that they have the capacity to increase one’s intellectual performance, creativity, and self-understanding. To date there have been no acceptable studies that validate any of these claims.

Phencyclidine (“Angel Dust” and “Ecstasy”)

During the early 1970s, the abuse of phencyclidine (PCP) and its many analogues was a significant problem. The popularity of these drugs has dropped sharply, but during the past decade, the abuse of phencyclidine and its many analogues has again increased. The effects of intoxication are like those of LSD and other hallucinogens and resemble those of an acute schizophrenic episode, which may last several days to a week or more. After the ingestion of a large amount (10 mg or more) of phencyclidine, it is present in the blood and urine for only a few hours. Its manufacture as a veterinary anaesthetic was stopped in 1979.

Toxicity from the illicit use of “ecstasy” (MDMA) during all-night dance parties (raves) has recently increased as a result of its ill-founded reputation for safety. It appears to cause a release of both serotonin and dopamine in the brain and produces an elated state similar to the effects of cocaine. Seizures, cerebral hemorrhages, and psychosis have been reportedly observed in previously healthy individuals (Vereby et al). A discussion of the legal implications of the illicit use of the aforementioned drugs and their social impact is beyond the scope of this chapter but can be found in the appended references.

DISORDERS DUE TO BACTERIAL TOXINS

The most important diseases in this category are tetanus, botulism, and diphtheria. Each is caused by an extraordinarily powerful bacterial toxin that acts primarily upon the nervous system.

Tetanus

The cause of this disease is the anaerobic, spore-forming rod Clostridium tetani. The organisms are found in the feces of some humans and many animals, particularly horses, whence they readily contaminate the soil. The spores may remain dormant for many months or years, but when they are introduced into a wound, especially if a foreign body or suppurrative bacteria are present, they are converted into their vegetative forms, which produce the exotoxin tetanospasmin. In developing countries, tetanus is still a common disease, particularly in newborns, in whom the spores are introduced via the umbilical cord (tetanus neonatorum). In the United States, the incidence rate of tetanus is about one per million per year. Injection of contaminated heroin is a significant cause. About two-thirds of all injuries leading to tetanus occur from deep scratches and puncture wounds in the home and about 20 percent in gardens and on farms.

Since 1903, when Morax and Marie proposed their theory of centripetal migration of the tetanus toxin, it has been taught that spread to the nervous system occurs via the peripheral nerves, the toxin ascending in the axis cylinders or the perineural sheaths. Modern studies, utilizing fluorescein-labeled tetanus antitoxin, have demonstrated that the toxin is also widely disseminated in the blood by the reticuloendothelial system, probably accounting for the generalized form of the disease. However, in local tetanus, the likely mode of spread to the CNS is by retrograde axonal transport.
Mode of Action of Tetanus Toxin

Like botulinum toxin, the tetanus toxin is a zinc-dependent protease. It blocks neurotransmitter release by cleaving surface proteins of the synaptic vesicles, thus preventing the normal exocytosis of neurotransmitter. The toxin interferes with the function of the reflex arc by the blockade of synaptic transmitters, mainly GABA, at presynaptic sites in the spinal cord and brainstem. Elicitation of the jaw jerk, for example, is normally followed by the abrupt suppression of reflex activity, manifested as an inability to voluntarily open the mouth (‘lockjaw’). In the patient with tetanus, there is a failure of this inhibitory mechanism, with a resulting increase in activation of the neurons that innervate the masseter muscles (trismus or lockjaw). Of all neuromuscular systems, the masseter innervation seems to be the most sensitive to the toxin. Not only do abnormally stimuli produce an exaggerated effect, but they also abolish reciprocal innervation; both agonists and antagonists contract, giving rise to the characteristic muscular spasms. In addition to its generalized effects on the motor neurons of the spinal cord and brainstem, there is evidence that the toxin acts directly on skeletal muscle at the point where the axon forms the end plate (accounting perhaps for localized tetanus) and also upon the cerebral cortex and the sympathetic nervous system, in the hypothalamus.

The incubation period varies greatly, from a day or two to a month or even longer. Long incubation periods are associated with mild and localized types of the disease.

Clinical Features

There are several clinical types of tetanus, usually designated as local, cephalic, and generalized.

Generalized Tetanus

This is the most common form. It may begin as local tetanus that becomes generalized after a few days, or it may be diffuse from the beginning. Trismus is frequently the first manifestation. In some cases this is preceded by a feeling of stiffness in the jaw or neck, slight fever, and other general symptoms of infection. The localized muscle stiffness and spasms spread quickly to other bulbar muscles as well as those of the neck, trunk, and limbs. A state of unremitting rigidity develops in all the involved muscles; the abdomen is board-like, the legs are rigidly extended, and the arms are retracted (‘tissue sardonicus’). The eyes are partially closed by contraction of the orbicularis oculi or the eyebrows are elevated by spasm of the frontalis. Superimposed on this persistent state of enhanced muscle activity are paroxysms of tonic contraction or spasms of muscles (tetanic seizures or convulsions), which occur spontaneously or in response to the slightest external stimulus. They are agonizingly painful. Consciousness is not lost during these paroxysms. The tonic contraction of groups of muscles results in opisthotonos or in forward flexion of the trunk, flexion and adduction of the arms, clenching of the fists, and extension of the legs. Spasms of the pharyngeal, laryngeal, or respiratory muscles carry the constant threat of asphyxia or suffocation. Fever and pneumonia are common complications. Large swings in blood pressure and pulse as well as profuse diaphoresis are typical, mainly in response to the intense muscular contractions but also related to the action of the toxin on the CNS. Death is usually attributable to asphyxia from laryngospasm, to heart failure, or to shock, the latter resulting from the action of the toxin on the hypothalamus and sympathetic nervous system.

Generalized spasms and rigidity of trunk and limbs developing in a neonate a few days after birth should always suggest the diagnosis of tetanus. This form of tetanus occurs when there has been inadequate sterile treatment of the umbilical cord stump in a neonate born to an unimmunized mother.

Local Tetanus

This is the most benign form. The initial symptoms are stiffness, tightness, and pain in the muscles in the neighborhood of a wound, followed by twitches and spasms of the affected muscles. Most commonly, the toxin spreads to the jaw muscles, to a wound of the hand or forearm, rarely in the abdominal or paravertebral muscles. Gradually, some degree of continuous involuntary spasm becomes evident. This is referred to as rigidity, hypertonc contractions, or tetanic spasticity, terms that denote the sustained tautness of the affected muscles and resistance of the part to passive movement. Superimposed on this background of more or less continuous motor activity is brief, intense spasms, lasting from a few seconds to minutes and occurring ‘spontaneously’ or in response to all variety of stimulation (Stryker et al.). Early in the course of the illness there may be periods when the affected muscles are palpably soft and appear to be relaxed. A useful diagnostic maneuver at this stage is to have the patient perform some repetitive voluntary movements, such as opening and closing the hand, in response to which there occurs a gradual increase in the tonic contraction and spasms of the affected muscles, followed by spread to neighboring muscle groups (recruitment spasms). The phenomenon resembles paradoxical myotonia (page 1559). Even with mild localized tetanus there may be a slight trismus, a useful diagnostic sign.

Symptoms may persist in localized form for several weeks or months. Gradually the spasms become less frequent and more difficult to evoke, and they finally disappear without residue. Complete recovery is to be expected, since there are no pathologic changes in muscles, nerves, spinal cord, or brain, even in the most severe generalized forms of tetanus.

Cephalic Tetanus

This form of tetanus follows wounds of the face and head. The incubation period is short, 1 or 2 days as a rule. The affected muscles (most often facial) are weak or paralyzed. Nevertheless, during accessions of tetanic spasm, the palsied muscles are seen to contract. Apparently the disturbance in the facial motoneurons is sufficient to prevent voluntary movement but insufficient to prevent the strong reflex impulses that elicit facial spasm. The spasms may involve the tongue and throat, with persistent dysarthria, dysphonia, and dysphagia. Ophthalmoplegia is known to occur but is difficult to verify because of severe blepharospasm. In a strict sense these cephalic forms of tetanus are examples of local tetanus that frequently becomes generalized. Many cases prove fatal.

Diagnosis

This is made from the clinical features and a history of preceding injury. The latter is sometimes disclosed only after careful questioning, the injury having been trivial and forgotten. The organisms may or may not be recovered from the wound by the time the patient receives medical attention; other laboratory tests, apart from the EMG, are of little value. Serum CK may be moderately elevated if the rigidity is generalized. The EMG recorded from muscles in spasm shows continuous discharges of normal motor units like those recorded from a forceful voluntary muscle contraction. Most characteristic of tetanus, as mentioned earlier, is a loss of the silent period that occurs 50 to 100 ms after reflex contraction. This pause, normally effected by the recurrent inhibition of Renshaw cells, is blocked by tetanus toxin. In generalized tetanus the loss of the silent period can almost always be demonstrated in the masseter, and it is found in a muscle affected by local tetanus. Interestingly, the silent period is preserved in the stiff man syndrome (page 1569). Tetany due to hypocalcemia, the spasms of strychnine poisoning or black widow spider bite, trismus due to painful conditions in and around the jaw, the dysphagia of rabies, hysterical cramps, rigidity and dystonic spasms caused by neuroleptic drugs, and the spasms of the stiff man syndrome all resemble the spasms of tetanus but should not be difficult to distinguish when all aspects of these disorders are considered.

The death rate from tetanus is about 50 percent overall; it is highest in newborns, heroin addicts, and patients with the cephalic form of the disease. The patient usually recovers if there are no severe generalized muscle spasms during the course of the illness or if the spasms remain localized.

Treatment

This must be directed along several lines. At the outset, a single dose of antitoxin (3000 to 6000 units of tetanus immune human globulin) should be given and a 10-day course of penicillin (1.2 million units of procaine penicillin daily), metronidazole (500 mg every 6 h intravenously or 400 mg rectally), or tetracycline (2 g daily) instituted. These drugs are effective against the vegetative forms of tetanus, the inoculum being given in a continuous intravenous infusion.

Failure of these measures to control the tetanic paroxysms demands that intravenous administration of neuromuscular blocking agents such as pancuronium or vecuronium be used to abolish all muscle activity, appropriate sedative medication is instituted for as long as necessary, breathing being maintained entirely by a positive-pressure respirator. Many units favor the use of neuromuscular paralytic drugs in all but the mildest cases. Further details concerning treatment in the intensive care unit can be found in the recent review by Farrar et al.

All persons should be immunized against tetanus and receive a booster dose of toxoid every 10 years—a practice that is frequently neglected in the elderly. Injuries that carry a threat of tetanus should be treated by an injection of toxoid if the patient has not received a booster injection in the preceding year, and a second dose of toxoid should be given 6 weeks later. If the injured person has not received a booster injection since the original immunization, he or she should receive an injection of both toxoid and tetanus antitoxin; the same collision applies to the injured person who has never been immunized. An attack of tetanus does not confer permanent immunity, and all persons who recover should be actively immunized.
Diphtheria

Diphtheria, an acute infectious disease caused by *Corynebacterium diphtheriae*, is now quite rare in the United States and western Europe. The faecal-pharyngeal form of the disease, which is the most common clinical type, is characterized by the formation of an inflammatory exudate of the throat and trachea; at this site, the bacteria elaborate an exotoxin, which affects the heart and nervous system in about 20 percent of cases.

The involvement of the nervous system follows a predictable pattern (Fisher and Adams). It begins locally, with palatal paralysis (nasal voice, regurgitation, and dysphagia) between the fifth and twelfth days of illness. At this time or shortly afterward, other cranial nerves (trigeminal, facial, vagus, and hypoglossal) may also be affected. Ciliary paralysis with loss of accommodation and blurring of vision appears usually in the second or third week. Very rarely the extracranial muscles are involved. The cranial nerve signs may clear without further involvement of the nervous system, or a sensorimotor polyneuropathy may develop between the fifth and eighth weeks of the disease. The latter varies in severity from a mild, predominantly distal affection of the limbs to a rapidly evolving, ascending paralysis, like that of the Guillain-Barré syndrome; CSF findings are similar as well (acellular fluid with elevated protein). The neuropathic symptoms progress for a week or two, and if the patient does not succumb to respiratory paralysis or cardiac failure (cardiomyopathy), these conditions stabilize and then improve slowly and more or less completely.

The early oropharyngeal symptoms, the unique ciliary paralysis, and the subacute evolution of a delayed symmetrical sensorimotor peripheral neuropathy distinguish diphtheritic polyneuropathy from other forms of polyneuropathy. The long latency between the initial infection and the involvement of the nervous system has no clear explanation. In experimental animals, Waksman and colleagues have shown that the toxin reaches the Schwann cells in the most vascular parts of the peripheral nervous system within 24 to 48 h of infection, but its metabolic effect on cell membranes extends over a period of weeks. As in humans, the toxin produces demyelination in the proximal parts of spinal nerves, in dorsal root ganglia, and in spinal roots. The cardiac musculature and the conducting system of the heart undergo focal necroses.

The source of diphtheritic infection may be extrafacial—a penetrating wound, skin ulcer, or umbilicus. The systemic and neurologic complications of faecal diphtheria can also be observed in the extrafacial form of the disease, after a similar latent period. It is probable, therefore, that the toxin reaches its neural site via the bloodstream; but, in addition, some action is exerted locally, as evidenced by palatal paralysis in faecal cases and by initial weakness and sensory impairment in the neighborhood of the infected wound.

There is no specific treatment for any of the neurologic complications of diphtheria. It is generally agreed that the administration of antitoxin within 48 h of the earliest symptoms of the primary diphtheric infection lessens the incidence and severity of complications.

The polyneuropathy of diphtheria is discussed further in *Chap. 46* (page 1389).

**Botulism**

Botulism is a rare form of food-borne illness caused by the exotoxin of *Clostridium botulinum*. Outbreaks of poisoning are more often due to home-preserved than to commercially canned products, and vegetables and home-cured ham are incriminated more commonly than any other food product. Very rarely, a contaminated wound is the source of infection. Although the disease is ubiquitous, five western states (California, Washington, Colorado, New Mexico, and Oregon) account for more than half of all reported outbreaks in the United States. *Neonatal and infantile forms* of the disease have been reported, due to absorption of the toxin formed by germination of ingested spores (rather than ingestion of preformed toxin), an important source of which is contaminated natural (raw) honey. A few adult cases may have a similar source.

It is now well established, on the basis of observations in both animals and humans, that the primary site of action of botulinus toxin is at the neuromuscular junction, more specifically on the presynaptic ends. The toxin interferes with the release of acetylcholine quanta by a mechanism like that of tetanus toxin (see previous discussion). The physiologic defect is similar to the one that characterizes the myasthenic syndrome of Lambert-Eaton (page 1547) but different from that of myasthenia gravis.

Symptoms usually appear within 12 to 36 h of ingestion of the tainted food. Anorexia, nausea, and vomiting occur in most patients. As a rule, blurred vision and diplopia are the initial neural symptoms; their association with ptosis, strabismus, and extracranial muscle palsies, particularly of the sixth nerve, may at first suggest a diagnosis of myasthenia gravis. In botulism, however, the pupils are often unreactive. Other symptoms of bulbar involvement—nasality of the voice and hoarseness, dysarthria, dysphagia, and an inability to phonate—follow in quick succession, and these, in turn, are followed by progressive weakness of muscles of the face, neck, trunk, and limbs by respiratory insufficiency. Despite the oropharyngeal weakness, it is not unusual for the gag reflex to be retained. Tendon reflexes are lost in cases of severe weakness. These symptoms and signs evolve rapidly, over 2 to 4 days as a rule, and may be mistaken for those of the Guillain-Barré syndrome. Sensation remains intact, however, and the spinal fluid usually shows no abnormalities. Severe constipation is characteristic of botulism, due perhaps to parasympathetic involvement of smooth muscle of the intestine. Consciousness is retained throughout the illness unless severe degrees of anoxia develop. In the past, the mortality was consistently above 60 percent, but it has declined in recent decades, with improvements in the intensive care of acute respiratory failure and the effectiveness of *C. botulinum* antitoxins.

The clinical diagnosis can be confirmed by electrophysiologic studies (reduced amplitude of evoked muscle potentials and an increase in amplitude with rapid repetitive nerve stimulation). In patients who recover, improvement begins within a few weeks, first in oculomotor movement, then in other cranial nerve function. Complete recovery of paralyzed limb and trunk musculature may take many months.

The three types of botulinus toxin, A, B, and E, cannot be distinguished by their clinical effects alone, and it is likely that the patient should receive the trivalent antiserum as soon as the clinical diagnosis is made. This antitoxin can be obtained from the Centers for Disease Control and Prevention, Atlanta. An initial dose of 10,000 units is given intravenously after intradermal testing for sensitivity to horse serum, followed by daily doses of 50,000 units intramuscularly until improvement begins.

Guaniidine hydrochloride (50 mg/kg) has reportedly been useful in reversing the weakness of limb and extraocular muscles. Antitoxin and guanidine probably change the course of the illness relatively little, and recovery, in the final analysis, depends upon the effectiveness of respiratory care, maintenance of fluid and electrolyte balance, prevention of infection, and so on.

The skilled injection of small quantities of botulinus toxin (Botox) into a muscle will weaken or paralyze it for weeks to months. Advantage is taken of this phenomenon in the treatment of the localized dystonias (page 114).

**POISONING DUE TO PLANTS, VENOMS, BITES, AND STINGS**

**Ergotism**

Ergotism is the name applied to poisoning with ergot, a drug derived from the rye fungus *Claviceps purpurea*. Ergot is used therapeutically to control postpartum hemorrhage due to uterine atony; one of its alkaloids, ergotamine, is a frequently used drug in the treatment of migraine, and a class of dopamine agonists used in the treatment of Parkinson disease has ergot activity. Chronic overdosage of the drug is the usual cause of ergotism; acute overdosage in the postpartum state or in the treatment of migraine may cause an alarming rise in blood pressure.

Two types of ergotism are recognized: gangrenous, due to a vasospastic, occlusive process in the small arteries of the extremities, and convulsive, or neurogenic ergotism. The latter is characterized by fasciculations, myoclonus, and spasms of muscles, followed by seizures. In nonfatal cases, a tabes-like neurologic syndrome may develop, with loss of knee and ankle jerks, ataxia, and impairment of deep and superficial sensation. The pathologic changes are said to consist of degeneration in the proximal parts of spinal nerves, in dorsal root ganglia, and in spinal roots. The cardiac musculature and the conducting system of the heart undergo focal necroses.

**Lathyrism**

*Lathyrism* is a neurologic syndrome characterized by the relatively acute onset of pain, paresthesias, and weakness in the lower extremities, progressing to a permanent spastic paraplegia. It is a serious medical problem in India and in some North African countries and is probably due to a toxin contained in the chickling
Mushroom Poisoning

The gathering of wild mushrooms, a popular pastime in late summer and early fall, always carries with it the danger of poisoning. As many as one hundred species of mushrooms are poisonous. Most of them can cause only transient gastrointestinal symptoms, but some elaborate toxins that can be fatal. The most important of these toxins are the cyclopeptides, which are contained in several species of _Amanita phalloides_ and _muscaria_ and account for more than 90 percent of fatal mushroom poisonings. These toxins disrupt RNA metabolism, causing hepatic and renal necrosis. Symptoms of poisoning with _Amanita_ usually appear between 10 and 14 h after ingestion and consist of nausea, vomiting, colicky pain, and diarrhea, followed by irritability, restlessness, ataxia, hallucinations, convulsions, and coma. There may be added evidence of a polymyopathy presenting as flaccid areflexic paralysis, high serum CK, diminished EMG potentials, and fiber necrosis.

Other important toxins are methylhydrazine (contained in the _cyanocephalus_ species) and muscarine (inocecy and _clitocybe_ species). The former gives rise to a clinical picture much like that caused by the cyclopeptides. The symptoms of muscarine poisoning, which appear within 30 to 60 min of ingestion, are essentially those of parasympathetic stimulation—miosis, lacrimation, salivation, nausea, vomiting, diarrhea, perspiration, Bradycardia, and hypotension. Tremor, seizures, and delirium occur in cases of severe poisoning.

The mushroom toxins have no effective antidotes. If vomiting has not occurred, it should be induced with specac, following which activated charcoal should be administered orally in order to bind what toxin remains in the gastrointestinal tract. A local poison control center may help identify the poisonous mushroom and its toxic. Even more important, the gathering and ingestion of field varieties of mushrooms should be left to those absolutely certain of their identity.

Buckthorn Poisoning

A rapidly progressive and sometimes fatal paralysis follows the ingestion of the small fruit of the buckthorn shrub that is indigenous to northern Mexico and the neighboring parts of the United States. The responsible toxin causes a predominantly motor polyneuropathy, probably of axonal type. Except for a normal spinal fluid protein concentration, the disorder closely resembles Guillain-Barré syndrome and tick paralysis, and its recognition depends upon awareness of ingestion of the fruit in endemic areas.

Neurotoxin Fish Poisoning (Ciguatera)

Ingestion of marine toxins that block neural sodium channels is a common form of poisoning throughout coastal areas and islands of the world. It results from eating fish that have fed on toxin-containing microscopic dinoflagellates. Reef fish and shellfish are subject to high concentrations of the organisms during periodic upswings in the population of the dinoflagellates, which may be so profuse as to color the surrounding water (red tide). Although the toxins differ (tetradotoxin, pufferfish, ciguatoxin, snails; saxitoxin and brevitoxin, shellfish), the neurologic and gastrointestinal symptoms that follow the ingestion of affected fish are similar. The initial symptoms are diarrhea, vomiting, or abdominal cramps coming on minutes to hours after the ingestion of the poisoned fish. These are followed by paresthesias that often begin peripherally and then involve the limbs distally. The C50 fish, hot and cold sensory stimuli (e.g., ice cream) are characteristically associated with electrical-like or burning paresthesias. Muscle aches and shooting pains are also mentioned by most patients. In pufferfish poisoning and in advanced stages poisoning from other fish, weakness occurs, and there have been a few reports of coma and of respiratory failure. The recognition of this type of fish poisoning is straightforward in endemic areas, in some of which there is a seasonal clustering of cases. In tourists returning home from endemic areas or in persons consuming imported fish, the illness may be mistaken for the Guillain-Barré syndrome. Prominent perioral paresthesias should suggest the correct diagnosis. Supportive treatment is all that is required, but treatment with intravenous mannitol appears to hasten recovery.

Venoms, Bites, and Stings

These are relatively rare but nonetheless important causes of mortality in the United States. The venoms of certain species of snakes, lizards, spiders (especially the black widow spider), and scorpions contain neurotoxins that may cause a fatal depression of respiration and curare-like failure of neuromuscular transmission. In the United States, there are about 40 species of venomous snakes. One of these, the black snake (venomous, _rattlesnakes, water moccasin snakes)_ cause tissue necrosis and circulatory collapse. The serious effects of _Hymenoptera stings_ (bees, wasps, hornets, and fire ants) are due mainly to hypersensitivity and anaphylaxis. All of these disorders are discussed in detail in _Harrison’s Principles of Internal Medicine._

Tick Paralysis

This rare condition is the result of a toxin secreted by the gravid tick. In Canada and the northwestern United States, the wood tick, _Dermacentor andersoni_ is mainly responsible; in the southeastern United States it is _Dermacentor variabilis_, a dog tick, but various other ticks may occasionally have the same effect. Most cases occur in children because their small body mass makes them susceptible to the effects of only modest amounts of the toxin. The illness arises almost exclusively in the spring, when the mature ticks are most plentiful. The illness requires that the gravid tick be attached to the skin for several days. When the tick is removed, the paralysis begins to resolve. The central nervous system is affected, and the motor and sensory components are involved to a variable degree. The paralysis is usually limited to the lower extremities and may be mistaken for the Guillain-Barré syndrome. Prominent perioral paresthesias should suggest the correct diagnosis. Supportive treatment is all that is required, but treatment with intravenous mannitol appears to hasten recovery.

Other important toxins are methylhydrazine (contained in the _vetch_ species), and _scorpions_ contain neurotoxins that may cause a fatal depression of respiration and curare-like failure of neuromuscular transmission. In the United States, there are about 40 species of venomous snakes. One of these, the black snake (venomous, _rattlesnakes, water moccasin snakes)_ cause tissue necrosis and circulatory collapse. The serious effects of _Hymenoptera stings_ (bees, wasps, hornets, and fire ants) are due mainly to hypersensitivity and anaphylaxis. All of these disorders are discussed in detail in _Harrison’s Principles of Internal Medicine._

HEAVY METALS

Lead

The causes and clinical manifestations of lead poisoning are quite different in children and adults.

**Lead Poisoning in Children** In the United States, the disease occurs most often in 1- to 3-year-old children who inhabit urban slum areas where old, deteriorated housing prevails. (Lead paint was used in most houses built before 1940 and in many built before 1960.) The chewing of lead objects, the most common sources of _lead_ in most houses built before 1940 and in many built before 1960. (Lead paint was used in most houses built before 1940 and in many built before 1960.) The chewing of leaded paint, the most common sources of _lead_ in children because their small body mass makes them susceptible to the effects of only modest amounts of the toxin. The illness arises almost exclusively in the spring, when the mature ticks are most plentiful. The illness requires that the gravid tick be attached to the skin for several days. When the tick is removed, the paralysis begins to resolve. The central nervous system is affected, and the motor and sensory components are involved to a variable degree. The paralysis is usually limited to the lower extremities and may be mistaken for the Guillain-Barré syndrome. Prominent perioral paresthesias should suggest the correct diagnosis. Supportive treatment is all that is required, but treatment with intravenous mannitol appears to hasten recovery.

**Clinical Manifestations** These develop over a period of 3 to 6 weeks. The child becomes anorectic, less playful and less alert, and more irritable. These symptoms may be misinterpreted as a behavior disorder or mental retardation. Intermittent vomiting, vague abdominal pain, clumsiness, and ataxia may be added. If these early signs of intoxication are not recognized and the child continues to ingest lead, more flagrant signs of acute encephalopathy may develop—most frequently in the summer months, for it is during this period that the symptoms are most likely to occur. The child becomes drowsy, stuporous, and drowsy, and finally seizures, papilledema, and coma supervene. This syndrome evolves in a period of a week or less and most rapidly in children under 2 years of age; in older children, it is more likely to develop in recurrent and less severe episodes. This clinical syndrome must be distinguished from tuberculous
malignancy, viral meningoencephalitis, and the various conditions causing acute increased intracranial pressure. Usually, in lead encephalopathy, the CSF is under increased pressure and may show a slight lymphocytic pleocytosis and elevated protein, but glucose values are normal. It follows that lumbar puncture should be done with caution and only if it is essential for diagnosis.

In children who die of acute lead encephalopathy, the brain is massively swollen, with herniation of the temporal lobes and cerebellum, multiple microscopic ischemic foci in the cerebral cortex and cerebellum, and endothelial damage and deposition of proteinaceous material and mononuclear inflammatory cells around many of the small blood vessels.

**Diagnosis**

Since the symptoms of plumbism are nonspecific, the diagnosis depends upon an appreciation of the causative factors, a high index of suspicion, and certain laboratory tests. The presence of lead lines at the metaphyses of long bones and basophilic stippling of red cells are too inconsistent to be relied upon, but basophilic stippling of bone marrow normoblasts is uniformly increased. Impairment of heme synthesis, which is exquisitely sensitive to the toxic effects of lead, results in the increased excretion of urinary coproporphyrin (UCP) and of d-aminolevulinic acid (ALA). These urinary indices and the lead concentrations in the serum bear an imperfect relationship to the clinical manifestations. In the test for UCP, which is readily performed in the clinic and emergency department, a few milliliters of urine are acidified with acetic acid and shaken with an equal volume of ether; if coproporphyrin is present, the ether layer will reveal a reddish fluorescence under a Wood's lamp. This test is strongly positive when the whole blood concentration of lead exceeds 80 µg/dL. The diagnosis can be confirmed by promoting lead excretion with calcium disodium edetate (CaNa₂EDTA), given in three doses (25 mg/kg) at 8-h intervals. Excretion of over 500 mg in 24 h is indicative of plumbism. The measurement of zinc protoporphyrin (ZPP) in the blood is another reliable means of determining the presence and degree of lead exposure. The binding of erythrocyte protoporphyrin to zinc occurs when lead impairs the normal binding of erythrocyte protoporphyrin to iron. Elevated ZPP can also occur when access to iron is limited by other conditions, such as iron deficiency anemia.

**Treatment**

At blood lead concentrations of 70 µg/dL or above, symptoms may be minimal, but acute encephalopathy may occur abruptly and unpredictably, for which reason the child should be hospitalized for chelation therapy. Some children with a blood lead level of 50 µg/dL may have symptoms of severe encephalopathy, whereas others may be asymptomatic. In the latter case, an attempt should be made to discover and remove the source of lead intoxication and the child should be reexamined at frequent intervals. The seriousness of lead encephalopathy is indicated by the fact that most of the children who become stuporous or comatose remain mentally retarded despite treatment. The physician's aim, therefore, is to institute treatment before the severe manifestations of encephalopathy have become manifest.

The plan of therapy includes the following:

1. Establishment of urinary flow, following which intravenous fluid therapy is restricted to basal water and electrolyte requirements.
2. In cases of acute encephalopathy, combined chelation therapy with 2,3-dimercaptopropanol (BAL, 12 to 24 mg/kg) and CaNa₂EDTA (0.5 to 1.5 g/m² body surface area) for 5 to 7 days. This is followed by a course of oral penicillamine (40 mg/kg, not exceeding 1 g per day). In acute cases the goal is to reduce the serum lead levels below 40 µg/dL. Once the absorption of lead has ceased, chelating agents remove lead only from soft tissues and not from bone, where most of the lead is stored. Any intercurrent illness may result in a mobilization of lead from bones and soft tissues and an exacerbation of symptoms of lead intoxication.
3. Repeated doses of mannitol for relief of cerebral edema.
4. Microcytic hypochromic anemia is treated with iron once the chelating agents have been discontinued.
5. Seizures are best controlled with oral diazepam or midazolam.

**Prevention**

The prevention of reintoxication (or intravascular) demands that the child be removed from the source of lead. Although this is axiomatic, it is often difficult to accomplish, despite the best efforts of local health departments and hospital and city social workers. Nevertheless, an attempt to correct the environmental factor must be made in each case. Such attempts, among other things, have resulted in a marked decrease in the incidence of acute lead encephalopathy in the past two decades. Although fluid examples of this encephalopathy are now uncommon, undue exposure to lead (blood levels > 30 µg/dL) remains inordinately prevalent and a continuing source of concern to public health authorities. As to the levels that pose a danger to the child, there is still some uncertainty. Rutter, who reviewed all of the evidence up to 1980, concluded that persistent blood levels above 40 µg/dL may cause slight cognitive impairment and, less certainly, an increased risk of behavioral difficulties. The oral lead chelator succimer is approved for outpatient treatment of asymptomatic children with blood lead levels higher than 45 µg/dL. A 3-week course of treatment is given, with weekly monitoring of blood lead levels to identify lead mobilization from bones and soft tissues.

In 1988, on the basis of epidemiologic and experimental studies in the United States, Europe, and Australia, the Agency for Toxic Substances and Disease Registry set a much lower threshold for neurobehavioral toxicity (10 to 15 µg/dL). They estimated that 3 to 4 million American children have blood levels in excess of this amount. Needham et al studied the long-term effects of low doses of lead in asymptomatic children. 132 of whom had had demonstrable levels of lead in the dentin of shed teeth (average 24 µg/dL). Eleven years later, the children were found to have behavioral abnormalities proportionate to their early lead levels. In comparison to a normal population, more had dropped out of school and more had lower vocabulary and grammatical reasoning scores, more reading difficulty, poorer hand-eye coordination performance, slower finger-tapping rates, and longer reaction times. The authors claimed to have eliminated other confounding variables such as lower social class and genetic factors. These findings have been confirmed by the long-term studies of Baghurst et al (see also Mahaffey).

**Lead Intoxication in Adults**

This is much less common than in children. The hazards to adults are exposure to dust of inorganic lead salts and to fumes resulting from the burning of lead or processes that require the use of high temperatures. Painting, printing, pottery glazing, lead smelting, and storage battery manufacturing are the industries in which these hazards are likeliest to occur. Miners and brass foundry and garage workers (during automobile radiator repair, when soldered joints are heated) are the ones most at risk.

The usual manifestations of lead poisoning in adults are colic, anaemia, and peripheral neuropathy. Encephalopathy is decidedly rare; usually it results from consumption of illicit liquor contaminated by lead solder in the pipes of stills. Lead colic, frequently precipitated by an intercurrent infection or by alcohol intoxication, is characterized by severe, poorly localized abdominal pain, often with rigidity of abdominal muscles but without fever or leukocytosis. The pain responds to the intravenous injection of calcium salts, at least temporarily, but very little to morphine. Mild anemia is common. A black line of lead sulfide may develop along the gingival margins. Peripheral neuropathy, usually a bilateral wrist drop, is a rare manifestation and is discussed on page 1393.

The diagnostic tests for plumbism in children are generally applicable to adults, with the exception of bone films, which are of no value in the latter. Also, the treatment of adults with chelating agents follows the same principles as in children.

Intoxication with tetraethyl and tetramethyl (organic) lead, used as additives in gasoline, presents a special problem. It is caused by inhalation of gasoline fumes and is characterized by severe, poorly localized abdominal pain, often with rigidity of abdominal muscles but without fever or leukocytosis. The pain responds to the intravenous injection of calcium salts, at least temporarily, but very little to morphine. Mild anemia is common. A black line of lead sulfide may develop along the gingival margins. Peripheral neuropathy, usually a bilateral wrist drop, is a rare manifestation and is discussed on page 1393.

The diagnostic tests for plumbism in children are generally applicable to adults, with the exception of bone films, which are of no value in the latter. Also, the treatment of adults with chelating agents follows the same principles as in children.

**Arsenic**

In the past, medications such as Fowler's solution (potassium arsenite) and the arsenamines, used in the treatment of syphilis, were frequent causes of intoxication, but now the most common cause is the suicidal or accidental ingestion of herbicides, insecticides, or rodenticides containing copper acetoarsenate (Paris green) or calcium arsenate. Occasional cases of poisoning are reported in industries in which these hazards are likeliest to occur. Miners and brass foundry and garage workers (during automobile radiator repair, when soldered joints are heated) are the ones most at risk.

Since the symptoms of plumbism are nonspecific, the diagnosis depends upon an appreciation of the causative factors, a high index of suspicion, and certain laboratory tests. The presence of lead lines at the metaphyses of long bones and basophilic stippling of red cells are too inconsistent to be relied upon, but basophilic stippling of bone marrow normoblasts is uniformly increased. Impairment of heme synthesis, which is exquisitely sensitive to the toxic effects of lead, results in the increased excretion of urinary coproporphyrin (UCP) and of d-aminolevulinic acid (ALA). These urinary indices and the lead concentrations in the serum bear an imperfect relationship to the clinical manifestations. In the test for UCP, which is readily performed in the clinic and emergency department, a few milliliters of urine are acidified with acetic acid and shaken with an equal volume of ether; if coproporphyrin is present, the ether layer will reveal a reddish fluorescence under a Wood's lamp. This test is strongly positive when the whole blood concentration of lead exceeds 80 µg/dL. The diagnosis can be confirmed by promoting lead excretion with calcium disodium edetate (CaNa₂EDTA), given in three doses (25 mg/kg) at 8-h intervals. Excretion of over 500 mg in 24 h is indicative of plumbism. The measurement of zinc protoporphyrin (ZPP) in the blood is another reliable means of determining the presence and degree of lead exposure. The binding of erythrocyte protoporphyrin to zinc occurs when lead impairs the normal binding of erythrocyte protoporphyrin to iron. Elevated ZPP can also occur when access to iron is limited by other conditions, such as iron deficiency anemia.

The symptoms of encephalopathy (headache, drowsiness, mental confusion, delirium, and convulsive seizures) may also occur as part of acute or chronic intoxication. In the latter case, they are accompanied by weakness and muscular aching, hemolysis, chilling and fever (in patients exposed to arsenic gas), mucosal irritation, a diffuse scaly desquamation, and transverse white lines, 1 to 2 mm in width, above the tunica of each fingernail (Mees lines). Acute poisoning by the oral
route is associated with severe gastrointestinal symptoms, circulatory collapse, and death in a large proportion of patients. The CSF is normal. Examination of the brain in such cases discloses numerous punctate hemorrhages in the white matter. Microscopically, the lesions consist of pericapillary zones of degeneration, which, in turn, are ringed by red cells (brain purpura or encephalorrhagia, incorrectly referred to as hemorrhagic encephalitis). These neuropathologic changes are not specific for arsenical poisoning but have been observed in such diverse conditions as pneumonia, gram-negative bacillary septicaemia from urinary tract infections, sulfonamide and phosgene poisoning, dysentery, disseminated intravascular coagulation, and others.

The diagnosis of arsenical poisoning depends upon the demonstration of increased levels of arsenic in the hair and urine. Arsenic is deposited in the hair within 2 weeks of exposure and may remain fixed there for years. Concentrations of more than 0.1 mg arsenic per 100 mg hair are indicative of poisoning. Arsenic also remains within bones for long periods and is slowly excreted in the urine and feces. Excretion of more than 0.1 mg arsenic per liter of urine is considered abnormal; levels greater than 1 mg/L may occur soon after acute exposure. The CSF protein level may be raised (50 to 100 mg/dL).

Acute poisoning is treated by gastric lavage, vasopressor agents, dimercaprol (BAL), maintenance of renal perfusion, and exchange transfusions if massive hemoglobinuria occurs. Once polyneuropathy has occurred, it is little affected by treatment with BAL, but other manifestations of chronic arsenical poisoning respond favorably. There has been a gradual recovery from the polyneuropathy in our cases.

Manganese

Manganese poisoning results from the chronic inhalation and ingestion of manganese particles and occurs in miners of manganese ore and in workers who separate manganese from other ore. Several clinical syndromes have been observed. The initial stages of intoxication may be marked by a prolonged confusional-hallucinatory state. Later, the symptoms are predominantly extrapyramidal. They are often described as parkinsonian in type, but in the patients seen by the authors, the resemblance was not close: an odd gait ("cock walk"), dystonia and rigidity of the trunk, postural instability, and falling backwards were features seen in two South American miners. Others, however, have reported stiffness and awkwardness of the limbs, often with tremor of the hands, "cogwheel" phenomenon, gross rhythmic movements of the trunk and head, and retropulsive and propulsive gait. Corticospinal and corticobulbar signs may be added. Progressive weakness, fatigability, and sleepiness as well as psychiatric symptoms (manganese madness) are other clinical features. Rarely, severe axial rigidity and dystonia, like those of Wilson disease, are said to have been the outstanding manifestations.

Neuronal loss and gliosis, affecting mainly the pallidum and striatum but also the frontoparietal and cerebellar cortex and hypothalamus, have been described, but the pathologic changes have not been carefully studied. The neurologic abnormalities have not responded to treatment with chelating agents. In the chronic "dystonic form" of manganese intoxication, dramatic and sustained improvement has been reported with the administration of L-dopa, patients with the more common "parkinsonian type" of manganese intoxication have shown only slight if any improvement with L-dopa.

Mercury

Mercury poisoning arises in two forms, one due to inorganic compounds (elemental or mercury salt) and the other, more dangerous, to organic mercury. Among the latter, methyl mercury compounds give rise to a wide array of serious neurologic symptoms that may be delayed for days or weeks after exposure, including tremor of the extremities, tongue, and lips; mental confusion; and a progressive cerebellar syndrome, with ataxia of gait and of the arms, intention tremor, and dysarthria. Chronic mercurialism and parkinsonian facies have also been described. Changes in mood and behavior are prominent, consisting at first of subjective weakness and fatigue and later of extreme depression and lethargy alternating with irritability. This delayed form of subacute mercury poisoning has been reported in chemical laboratory workers after exposure to methyl mercury compounds. These agents, particularly dimethyl mercury, are extremely hazardous because they are absorbed transdermally and by inhalation, allowing severe toxicity to occur with even brief contact. In a fatal case of a chemist reported by Nierenberg et al, a rapidly progressive ataxia and encephalopathy developed 154 days after exposure; the cerebellum was most severely affected, with loss of all cortical neuronal elements, and the calcaneal fissures were affected in a pattern similar to the Minamata cases described below. The pathologic changes are characterized by neuronal loss and gliosis of the calcaneal cortex and to a lesser extent of other parts of the cerebral cortex and a striking degeneration of the granular layer of the cerebellar cortex, with relative sparing of the Purkinje cells.

The chronic form of inorganic mercury poisoning occurs in persons exposed to large amounts of the metal used in the manufacture of thermometers, mirrors, incandescent lights, x-ray machines, and vacuum pumps. Since mercury volatilizes at room temperature, it readily contaminates the air and then condenses on the skin and respiratory mucous membranes. Nitrate of mercury, used in the manufacture of felt hats ("mad hatters"), and phenyl mercury, used in the paper, pulp, and electrochemical industries, are other sources of intoxication. Paresthesias, astasias, confusion, incoordination, and intention tremor are characteristic, and, with continued exposure, delirium occurs. Headache, various bodily pains, visual and hearing symptoms, and corticospinal signs may be added, but their pathologic basis is unknown. The term "erethism" was coined to describe the timidity, memory loss, and insomnia that were said to be characteristic of chronic intoxication. Unless the exposure has been of minimal amounts over a long period of time, gastrointestinal disturbances are prone to occur (anorexia, weight loss) as well as stomatitis and gingivitis with loosening of the teeth. Acute exposure to inorganic mercury in larger amounts is even more corrosive to the gastrointestinal system and produces nausea, vomiting, hematemesis, abdominal pain, and bloody diarrhea as well as renal tubular necrosis.

Isolated instances of polyneuropathy associated with exposure to mercury have also been reported (Albers et al, Agocs et al) and may be responsible for the paresthesias that accompany most cases and the acrodynic syndrome described below. The inhalation of vaporized mercury as a result of extensive dental work has been alleged to affect the peripheral nerves, but the connection is very tenuous.

The presence of mercury in industrial waste has contaminated many sources of water supply and fish, which are ingested by humans and cause mercurial poisoning. So-called Minamata disease is a case in point. Between 1953 and 1956, a large number of villagers living near Minamata Bay in Kyushu Island, Japan, were afflicted with a syndrome of chronic mercurialism, traced to the ingestion of fish that had been contaminated with industrial wastes containing methyl mercury. Concentric gliosis of the calcarine cortex and to a lesser extent of other parts of the cerebral cortex and a striking degeneration of the granular layer of the cerebellar cortex, with progressive ataxia and encephalopathy developed 154 days after exposure; the cerebellum was most severely affected, with loss of all cortical neuronal elements, and the calcaneal fissures were affected in a pattern similar to the Minamata cases described below. The pathologic changes are characterized by neuronal loss and gliosis of the calcaneal cortex and to a lesser extent of other parts of the cerebral cortex and a striking degeneration of the granular layer of the cerebellar cortex, with relative sparing of the Purkinje cells.

Phosphorus and Organophosphate Poisoning

Nervous system function may be deranged as part of acute and frequently fatal poisoning with inorganic phosphorus compounds (found in rat poisons,roach powders, and matches). More important clinically is poisoning with organophosphorus compounds, the best known of which is triortho cresyl phosphate (TOCP).

Organophosphates are widely used as insecticides. Since 1945, approximately 15,000 individual compounds have come into use. Certain ones, such as tetraethylpyrophosphate, have been the cause of major outbreaks of neurologic disorder, especially in children. These substances have an acute anticholinesterase effect but no delayed neurotoxic action. Chlorophos, which is a 1-hydroxy-2,2,2-trichloroethyphosphonate, has, in addition, a delayed action, as does TOCP.

The immediate anticholinesterase effect manifests itself by headache, vomiting, sweating, abdominal cramps, salivation, wheezing secondary to bronchial spasm, miosis, and muscular weakness and twitching. Most of these symptoms can be reversed by administration of atropine and pralidoxine. Some of the patients suffer a
delayed effect, 2 to 5 weeks following acute organophosphorus insecticide poisoning. This takes the form of a distal symmetrical sensorimotor (predominantly motor) polyneuropathy, progressing to atrophy. Recovery occurs to a variable degree, and then, in patients poisoned with TOCP, signs of corticospinal damage become detectable. The severity of paralysis and its permanence vary with the dosage of TOCP. Whether a polyneuropathy can arise without the preceding symptoms of cholinergic toxicity is debated; however, based on a review of the subject and a study of 11 patients exposed to these agents, 3 of whom later acquired sensory neuropathy, Moretto and Lotti express the view that such an occurrence must be rare.

In addition to the acute and delayed neurotoxic effects of organophosphorus, an intermediate syndrome has been described (Senanayake and Karalliedde). Symptoms come on 24 to 96 h after the acute cholinergic phase and consist of weakness or paralysis of proximal limb muscles, neck flexors, motor cranial nerves, and respiratory muscles. Respiratory paralysis may prove fatal. In patients who survive, the paralytic symptoms last for 2 to 3 weeks and then subside. The intermediate and delayed symptoms do not respond to atropine or other drugs.

Several striking outbreaks of TOCP poisoning have been reported. During the latter part of the prohibition era and to a lesser extent thereafter, outbreaks of “jaime paralysis” were traced to drinking an extract of Jamaica ginger that had been contaminated with TOCP. The authors have examined several “ginger jake” cases many years later and found only signs of corticospinal disease. Another outbreak occurred in Morocco, in 1959, when lubricating oil containing TOCP was used deliberately to dilute olive oil. Several other outbreaks have been caused by the ingestion of grain and cooking oil that had been stored in inadequately cleaned containers previously used for storing TOCP.

The effect of TOCP on the peripheral nervous system has been studied extensively in experimental animals. In cats, there occurs a dying back from the terminal ends of the largest and longest medullated motor nerve fibers, including those from the annulospiral endings of the muscle spindles (Cavanagh and Patangia). The long fiber tracts of the spinal cord show a similar dying back phenomena. Abnormal myelinated axon bundles and abnormally thickened oligodendroglia were noted by Prineas to accumulate in axoplasm before degeneration. These effects have been traced to the inhibitory action of TOCP on esterases. There is still uncertainty as to the details of these reactions, and no treatment for the prevention or control of the neurotoxic effects has been devised.

Thallium

In the late nineteenth century, thallium was used medicinally in the treatment of venereal disease, ringworm, and tuberculosis and later in rodenticides and insecticides. Poisoning was fairly common. Sporadic instances of poisoning still occur, usually as a result of accidental or suicidal ingestion of thallium-containing rodenticides and rarely from overdose of depilatory agents. Patients who survive the effects of acute poisoning develop a rapidly progressive and painful sensory polyneuropathy, optic atrophy, and occasionally ophthalmoplegia—followed, 15 to 30 days after ingestion, by diffuse aloppecia. The latter feature should always suggest the diagnosis of thallium poisoning, which can be confirmed by finding this metallic element in the urine. Two of our patients had only a severe sensory and mild motor polyneuropathy and alopecia, from which they were recovering a month later. It is not uncommon for the neuropathy to have a painful component involving acral regions. The condition can end fatally. The use of potassium chloride by mouth may hasten thallium excretion.

Other Metals

Iron, antimony, tin, aluminum, zinc, barium, bismuth, copper, silver, gold, platinum, and lithium may all produce serious degrees of intoxication. The major manifestations in these cases are gastrointestinal or renal, but certain neurologic symptoms—notably headache, irritability, confusional psychosis, stupor, coma, and convulsions—may be observed in cases of profound intoxication, often as terminal events. Gold preparations, which are still used occasionally in the treatment of anaphylaxis, may, after several months of treatment, give rise to focal or generalized myokymia and a rapidly progressive, symmetrical polyneuropathy (Katrak et al). The adverse effects of platinum are discussed below, with the antineoplastic agents. Lithium has been discussed earlier.

Attention has already been drawn to the possible causative role of aluminum intoxication in so-called dialysis dementia or encephalopathy (page 1189). Removal of aluminum from the water used in renal dialysis has practically eliminated this disorder. However, the neuropathologic changes in experimental aluminum intoxication (Senanayake et al) have been observed in dialyses in which Periels and colleagues have reported the accumulation of aluminum in tangle-bearing neurons of patients with Alzheimer disease and in the Guamanian Parkinson–dementia–amyotrophic lateral sclerosis (ALS) complex. However, analysis of neurtic plaques by nuclear microscopy, without using chemical stains, failed to demonstrate the presence of aluminum (Landsberg et al). The significance of these findings remains to be determined. Longstreth and colleagues have described a progressive neurologic disorder consisting of intention tremor, incoordination, and spastic paraparesis in three patients who had worked for more than 12 years in the same pot room of an aluminum smelting plant. Similar cases attributable to aluminum intoxication have not been reported, however.

Some of these, the heavy metals, have already been considered. In addition, a large number of synthetic organic compounds are widely used in industry and are frequent sources of toxicity, and the list is constantly being expanded. The reader is referred to the references at the end of the chapter, particularly to the most recent reviews of the subject.

Gold preparations, which are still used occasionally in the treatment of anaphylaxis, may, after several months of treatment, give rise to focal or generalized myokymia and a rapidly progressive, symmetrical polyneuropathy (Katrak et al). The adverse effects of platinum are discussed below, with the antineoplastic agents. Lithium has been discussed earlier.

Gold preparations, which are still used occasionally in the treatment of anaphylaxis, may, after several months of treatment, give rise to focal or generalized myokymia and a rapidly progressive, symmetrical polyneuropathy (Katrak et al). The adverse effects of platinum are discussed below, with the antineoplastic agents. Lithium has been discussed earlier.

Organic compounds of tin may seriously damage the nervous system. Diffuse edema of the white matter of the brain and spinal cord has been produced experimentally with triethyltin. Presumably this was the basis of the mass poisoning produced by a triethyltin-contaminated drug called Stalition. The illness was characterized by greatly elevated intracranial pressure and by a spinal cord lesion in some cases (Alajouanine et al). Trimethyltin intoxication is much rarer; seizures are the main manifestation. Experimental studies in rats have shown neuronal loss in the hippocampus, largely sparing the Sommer sector, with later involvement of neurons in the pyriform cortex and amygdala (see review by Le-Querne).

A stereotyped episodic encephalopathy has been associated with bismuth intoxication, usually arising from the ingestion of bismuth subgallate. Large outbreaks have been reported in Australia and France (Bourr et al, Bugue et al). The onset of the neurologic disturbance is usually subacute, with a mild and fluctuating confusion, somnolence, and mild ataxia. There is a tendency to develop a “fixed state,” in which the patient presents as drowsy but is otherwise alert and somewhat confused. In other persons, there occurs a rapid (24- to 48-h) worsening of the confusion and tremulousness, along with diffuse myoclonic jerks, seizures, ataxia, and inability to stand or walk. These symptoms regress over a period of a few days to weeks when the bismuth is withdrawn, but some patients have remained with chronic polyneuropathy. High concentrations of bismuth were found in the cerebral and cerebellar cortices and in the nuclear masses throughout the brain. These concentrations can be recognized as hyperdensities in the CT scan (Bugue et al).

Industrial Toxins

Some of these, the heavy metals, have already been considered. In addition, a large number of synthetic organic compounds are widely used in industry and are frequent sources of toxicity, and the list is constantly being expanded. The reader is referred to the references at the end of the chapter, particularly to the most recent reviews of the subject. Here, we can do no more than enumerate the most important ones. Chemicals such as organotins (e.g., DTT) or chlorinated polycyclic compounds (Kepone), used as insecticides; diethylene dioxide (Dioxane); carbon disulfide; the hexacarbons (e.g., hexane and methyl n-butyl ketone) may cause a polyneuropathy, which becomes evident with recovery from acute toxicity. Extrapyramidal symptoms may result from chronic exposure to carbon disulfide. A syndrome of persistent fatigue, lack of stamina, inability to concentrate, poor memory, and irritability has also been attributed to chronic exposure to solvents, but these symptoms are quite nonspecific, and evidence for such a syndrome is unsupported by convincing experimental or epidemiologic studies.

Of the aforementioned industrial toxins, the ones most likely to cause neurologic disease are toluene (methyl benzene) and the hexacarbons. The chronic inhalation of fumes containing toluene (usually in glue, contact cement, or certain brands of spray paint) may lead to severe and irreversible tremor and cerebellar ataxia, affecting movement of the eyes (opossumus, ocular dysmetria) and limbs as well as stance and gait. Cognitive impairment is usually associated; corticospinal tract signs, progressive optic atrophy, sensorineural hearing loss, and hypoaesthesia occur in some patients. Generalized cerebral atrophy and particularly cerebellar atrophy are evident in CT scans (Fornazzari et al, Hormes et al). Also, it has become apparent that acute toluene intoxication is an important cause of seizures, hallucinations, and coma in children (King et al).

The prolonged exposure to high concentrations of n-hexane or methyl n-butyl ketone may cause a sensorimotor neuropathy, so-called glue-sniffer’s neuropathy (page...
1394). These solvents are metabolized to 2,5-hexanedione, which is the agent that damages the peripheral nerves. The neuropathy may result from exposure in certain industrial settings (mainly the manufacture of vinyl products) or, more often, from the deliberate inhalation of vapors from solvents, lacquers, glue, or glue thinners containing n-hexane (see also Chap. 46). Impure trichloroethyle, through its breakdown product dichloroacetylene, has a predilection for the trigeminal nerve, which can be damaged selectively.

**ANTINEOPLASTIC AND IMMUNOSUPPRESSIVE AGENTS**

The increasing use of potent antineoplastic agents has given rise to a diverse group of neurologic complications, the most important of which are summarized below. A more detailed account of these agents—as well as the neurologic complications of corticosteroid therapy, immunosuppression, and radiation—can be found in the monograph edited by Rotenberg and in the review of Tuxen and Hansen. The neurotoxic effects of certain agents used in the treatment of brain tumors are also considered in Chap. 31.

**Vincristine**

This drug is used in the treatment of acute lymphoblastic leukemia, lymphomas, and some solid tumors. Its most important toxic side effect, and the one that limits its use as a chemotherapeutic agent, is a peripheral neuropathy. Paresthesias of the feet, hands, or both may occur within a few weeks of the beginning of treatment; with continued use of the drug, a progressive symmetrical neuropathy evolves (mainly sensory with reflex loss). Cranial nerves are affected less frequently; ptosis and lateral rectus, facial, and vocal cord palsies are the usual manifestations. Autonomic nervous system function may also be affected: constipation and impotence are frequent complications; orthostatic hypotension, atony of the bladder, and adynamic ileus are less frequent. The polynephropathy is described more fully on page 1394. Inappropriate antidiuretic hormone secretion and seizures have been reported but are relatively uncommon.

The neural complications of vinblastine are similar to those of vincristine but are usually avoided because bone marrow suppression limits the dose of the drug that can safely be employed. Vinorelbine is a more recently introduced semisynthetic vinca alkaloid. It has much the same antitumor activity as vincristine but is said to be less toxic.

**Procarbazine**

This drug, originally synthesized as an MAO inhibitor, is now an important oral agent in the treatment of Hodgkin disease and other lymphomas, bronchogenic carcinoma, and malignant gliomas. It has proved to be effective in the treatment of oligodendrogliomas. Neural complications are infrequent and usually take the form of somnolence, confusion, agitation, and depression. Diffuse aching pain in proximal muscles of the limbs and mild symptoms and signs of polyneuropathy occur in 10 to 15 percent of patients treated with relatively high doses. A reversible ataxia has also been described. Procarbazine, taken in conjunction with phenothiazines, barbiturates, narcotics, or alcohol, may produce serious degrees of oversedation. Other toxic reactions, such as orthostatic hypotension, are related to the MAO inhibitory action of procarbazine.

**L-Asparaginase**

L-Asparaginase is an enzymatic inhibitor of protein synthesis and is used in the treatment of acute lymphoblastic leukemia. Drowsiness, confusion, delirium, stupor, coma, and diffuse EEG slowing are the common neurologic effects and are dose-related and cumulative. They may occur within a day of onset of treatment and clear quickly when the drug is withdrawn, or they may be delayed in onset, in which case they may persist for several weeks. These abnormalities are at least in part attributable to the systemic metabolic derangements induced by L-asparaginase, including liver dysfunction.

In recent years, increasing attention has been drawn to cerebrovascular complications of L-asparaginase therapy, including ischemic and hemorrhagic infarction and cerebral venous and dural sinus thrombosis. Fineberg and Swenson have analyzed the clinical features of 38 such cases. These cerebrovascular complications are attributable to transient deficiencies in plasma proteins that are important in coagulation and fibrinolysis.

**5-Fluorouracil**

This is a pyrimidine analogue, used mainly in the treatment of cancer of the breast, ovary, and gastrointestinal tract. A small proportion of patients receiving this drug develop dizziness, cerebellar ataxia of the trunk and the extremities, dysarthria, and nystagmus—symptoms that are much the same as those produced by cytarabine (Ara-C; see page 1285). These abnormalities must be distinguished from metastatic involvement of the cerebellum and paraneoplastic cerebellar degeneration. The drug effects are usually mild and subside within 1 to 6 weeks after discontinuation of therapy. The anatomic basis of this cerebellar syndrome is not known.

**Methotrexate**

Administered in conventional oral or intravenous doses, methotrexate (MTX) is not neurotoxic. However, given intrathecally to treat meningeal leukemia or carcinomatosis, MTX commonly causes aseptic meningitis, with headache, nausea and vomiting, stiff neck, fever, and cells in the spinal fluid. Very rarely, probably as an idiosyncratic response to the drug, intrathecal administration results in an acute paraplegia that may be permanent. The pathology of this condition has not been studied. The most serious of the neurologic problems associated with chemotherapy is a necrotizing leukoencephalopathy or leukomyelopathy caused by MTX when given in combination with cranial or neuraxis radiation therapy (page 729). This develops several months after repeated intrathecal or high systemic doses of MTX. The full-blown syndrome consists of the insidious evolution of dementia, pseudobulbar palsy, ataxia, focal cerebral cortical deficits, or paraplegia. The brain shows disseminated foci of coagulation necrosis of white matter, usually periventricular, which can be detected with CT and MRI. Yet unsettled is the role of MTX in the development of asymptomatic CT scan abnormalities or of mild neurologic abnormalities in children with acute lymphoblastic leukemia given intrathecal MTX and cranial irradiation as prophylaxis; the same uncertainty pertains to the relation of this white matter change to that seen with the use of cyclosporin, as discussed further on. Mineralizing microangiopathy (fibrosis and calcification of small vessels, mainly in the basal ganglia) is yet another complication of MTX therapy. It may occur with MTX treatment or with cranial irradiation and is particularly common when both forms of treatment are combined. To the present authors these lesions have the features of the coagulative necrosis of radiation encephalopathy.

**Cisplatin**

Cisplatin, a heavy metal that inhibits DNA synthesis, is effective in the treatment of gonadal and head and neck tumors as well as carcinoma of the bladder, prostate, and breast. The dose-limiting factors in its use are nephrotoxicity and vomiting and a peripheral neuropathy (see also page 1394). The latter manifests itself by numbness and tingling in fingers and toes, sometimes painful—symptoms that are being observed with increasing frequency. This toxic manifestation appears to be related to the total amount administered, and it usually improves slowly after the drug has been discontinued. Biopsies of peripheral nerve have shown a primary axonal degeneration. Approximately one-third of patients receiving this drug also experience tinnitus or high-frequency hearing loss (4000 to 8000 Hz) or both. This toxicity is also dose-related, cumulative, and only occasionally reversible. Some preventative effect for cisplatin neuropathy has been claimed for the melanocortin compound ACTH (4-9), but the benefits in a trial by Gerritzen and colleagues were quite small and probably do not justify its administration on a routine basis. Retrograde axonal degeneration occurs rarely. Seizures associated with drug-induced hypotension and hypomagnesemia have been reported.

**Paclitaxel and Docetaxel**

Taxol (paclitaxel) and Taxotere (docetaxel) are new anticancer drugs derived from the bark of the western yew. Both are particularly useful in the treatment of ovarian carcinoma and breast cancer, although they have a wide range of antineoplastic activities. A purely or predominantly sensory neuropathy is a common complication. These drugs are thought to cause neuropathy by their action as inhibitors of the polymerization of tubulin, thereby promoting excessive microtubule assembly within the axon. The neuropathy is dose-dependent, occurring with doses greater than 200 mg/m² of paclitaxel and at a wide range of dose levels for docetaxel (generally over 600 mg/m²). Symptoms may begin 1 to 3 days following the first dose and affect the feet and hands simultaneously. Autonomic neuropathy (orthostatic hypotension) may occur as well. The neuropathy is axonal in type, with secondary demyelination, and is at least partially reversible after discontinuation of the drug.

**The Nitrosoureas**

Carmustine (BCNU) and lomustine (CCNU) are nitrosoureas used to treat malignant cerebral gliomas. They are not neurotoxic when given in conventional...
intravenous doses, but intracerebral injection of the drugs may cause orbital, eye, and neck pain, focal seizures, confusion, and possibly focal neurologic deficits. Postmortem examinations of patients who had been treated with BCNU have disclosed diffuse foci of swollen axis cylinders and myelin vacuolization and a diffuse vasculopathy characterized by fibrinoid necrosis and microthrombi (Burger et al, Kleinstein-de Masters).

**Cytarabine (Ara-C)**

This drug, long used in the treatment of acute nonlymphocytic leukemia, is not neurotoxic when given in systemic daily doses of 100 to 200 mg/m². The administration of very high doses of Ara-C (up to 30 times the usual dose) has been shown to induce remissions in patients refractory to conventional treatment, but it also produces a severe degree of cerebellar degeneration in a considerable proportion of cases (4 of 24 patients reported by Winkelman and Hines). Ataxia of gait and limbs, dysarthria, and nystagmus develop as early as 5 to 7 days after the beginning of high-dose treatment and worsen rapidly. Postmortem examination has disclosed a diffuse degeneration of Purkinje cells, most marked in the depths of the folia, as well as a patchy necrosis of the cerebellar cortex affecting all the cellular elements. Other patients receiving high-dose Ara-C develop a mild, reversible cerebellar syndrome with the same clinical features as the irreversible one. Patients more than 50 years of age are said to be six times more likely to develop cerebellar degeneration than those younger than 50; therefore the former should be treated with a lower dosage than the latter (Herzig et al).

**Cyclosporine and Tacrolimus (FK-506)**

These immunosuppressive drugs are used to prevent transplant rejection and to treat aplastic anemia and certain intrinsic immune diseases. Tremor is perhaps the most frequent side effect, particularly of tacrolimus, and myoclonus may be added. Sometimes these impart a staggering character to speech. Headache and insomnia are common. Seizures may be a manifestation of toxicity, but the cause may lie with the other complications of organ transplantation and immunosuppression. The neurologic effects of these drugs have been reviewed by Wijdicks. A syndrome resembling hypertensive encephalopathy—headache, vomiting, confusion, seizures, and visual loss (cortical blindness)—may follow the use of either drug (see page 903). The appearance on CT scans and MRI of symmetrical signal and density changes mainly in the posterior white matter likewise conforms to the pattern that is seen in hypertensive encephalopathy. Lesions may also appear subcortically in the frontal and parietal lobes. Hinchee and colleagues describe several such cases and suggest that cyclosporin alters the blood-brain barrier and that the fluid overload and hypertension that may accompany the use of cyclosporin may cause the syndrome and the radiologic changes. A variety of psychotic syndromes with delusions, paranoia, and visual hallucinations has also been ascribed to the use of these drugs (see Wijdicks).

**Thalidomide**

Despite the catastrophic effects of thalidomide on the developing fetus (following its introduction as a soporific in 1957), this drug has now found several specific uses in the treatment of immunologic and infectious diseases. It is highly effective in the treatment of leprosy, erythema nodosum, and the oral ulcerations of AIDS and Behçet disease. Experimental uses include suppression of graft-versus-host reactions and inhibition of blood vessel proliferation in vascular tumors. A dose-dependent sensory neuropathy is the limiting factor in its use, and serial electrophysiologic testing is recommended if the medication is to be prescribed for protracted periods. Of course, it must never be given to a woman who is or might be pregnant.

**Antibiotics and Other Drugs**

Numerous antibiotics, cardioactive medications, and other drugs may have adverse effects on the central or peripheral nervous system. Some of the latter are addressed on page 1395. Here we mention only that penicillin and its derivatives such as imipenem and cephalosporins are capable of causing seizures when high serum concentrations are attained. This occurs most often in patients with renal failure.

Other important examples are optic neuropathy due to ethambutol toxicity; ototoxicity and neuromuscular blockade from aminoglycoside antibiotics (page 1549); neuropathy, encephalopathy, and an Antabuse-like reaction to alcohol in patients taking metronidazole; INH neuropathy and optic neuropathy and possibly peripheral neuropathy due to chloramphenicol.

The most notorious of this group of drugs was clioquinol, which was sold as Entero-vioform and used in many parts of the world to prevent traveler's diarrhea and as a treatment for chronic gastroenteritis. In 1971, clinical observations began to appear in medical journals of a subacute myelo-optic neuropathy (SMON). During the 1960s, more than 10,000 cases of this neurotoxic disease were collected in Japan by Tsubaki et al. Usually the disease began with a gastrointestinal disturbance, followed by ascending numbness and weakness of the legs, paralysis of sphincters, and autonomic disorder. Later, vision was affected.

The onset was acute in about two-thirds of the cases and subacute in the remainder. The occurrence of these neurologic complications was related to the prolonged use of clioquinol. In Japan the drug was withdrawn from the market, and the incidence of SMON immediately fell, supporting the theory that it was caused by clioquinol.

Recovery is usually incomplete. Two patients seen by the authors several years after onset of the disease had been left with optic atrophy and a spastic-ataxic paraparesis.

Barbiturates, Benzodiazepines, Antidepressants, and Neuroleptic Drugs

Stimulants (Including Cocaine and Amphetamine) and Psychomimetic Drugs

Tetanus

Diseases of the nervous system may be confined to the spinal cord, where they produce a number of distinctive syndromes. The latter relate to special physiologic and anatomic features of the cord, such as its prominent function in sensorimotor conduction and relatively primitive reflex activity; its long, cylindrical shape; its small cross-sectional size; its tight envelopment by meninges; the peripheral location of myelinated fibers, next to the pia; the special arrangement of its blood vessels; and its particular relationships to the vertebral column.

Woolsey and Young estimate that there are about thirty diseases known to affect the spinal cord, of which half are seen with regularity. These diseases express themselves by a number of readily recognized syndromes and, as will be evident, certain ones preferentially evoke one syndrome and not others. The syndromic grouping of the spinal cord disorders, which is in keeping with the general plan of this book, facilitates clinical diagnosis and reduces the number of ancillary examinations needed for confirmation.

The main syndromes to be considered in this chapter are (1) a transverse sensorimotor myelopathy that may be complete or involve most of the ascending and descending tracts; (2) a combined painful radicular and transverse cord syndrome; (3) the hemiscord (Brown–Séquard) syndrome and its variants; (4) a ventral cord syndrome, sparing posterior column function; (5) a high cervical–foramen magnum syndrome; (6) a central cord or syringomyelic syndrome; (7) a syndrome of the conus medullaris; and (8) a syndrome of the cauda equina (see also pages 1332 to 1334). It is also useful to distinguish between lesions within the cord (intramedullary) and those that compress the cord from without (extramedullary). Certain processes have a proclivity to cause one or another of these syndromes, and each of them will be considered in the course of exposition of the major categories of spinal cord disease.

Some of the anatomic and physiologic considerations pertinent to an understanding of disorders of the cord (and of the spine) can be found in Chapter References.

### THE SYNDROME OF ACUTE PARAPLEGIA OR QUADRIPLEGIA DUE TO COMPLETE TRANSVERSE LESIONS OF THE SPINAL CORD

This syndrome is best considered in relation to trauma, its most frequent cause, but it occurs also as a result of infarction or hemorrhage and with rapidly advancing compressive, necrotizing, demyelinating, or inflammatory lesions (myelitis). Each of these categories of acute spinal cord disease is discussed in the following pages. For convenience of exposition we have included radiation myelopathy, which evolves subacutely.

### Trauma to the Spine and Spinal Cord

Throughout recorded medical history, signal advances in the understanding of spinal cord disease have coincided with periods of warfare. The first thoroughly documented study of the effects of sudden total cord transaction was that of Theodor Kocher in 1896, based on his observations of 15 patients. During World War I, Riddoch—and later Head and Riddoch—gave the classic descriptions of spinal transaction in humans; Lhermitte and Guillaud; and Barré made additional observations. Little could be done for these patients, however. Fully 80 percent died in the first few weeks (from infections), and survival was possible only if the spinal cord lesion was a partial one. World War II marked a turning point in the understanding and management of spinal cord injuries. The advent of antibiotics and the ability to control skin, bladder, and pulmonary infections permitted the survival of unprecedented numbers of soldiers with spinal cord injuries and provided the opportunity for long-term observation. In special centers, such as the Long Beach, Hills, and West Roxbury Veterans Administration Hospitals in the United States and the Stoke Mandeville National Spinal Injuries Centre in England, the care and rehabilitation of the paraplegic were perfected. Studies conducted in these centers have greatly enhanced our knowledge of the functional capacity of the chronically isolated spinal cord.
In the case of severe forward flexion injury, the head is bent sharply forward when the force is applied. The adjacent vertebrae are forced together at the level of maximum stress. The anterolateral edge of the upper vertebral body is driven into the one below, sometimes splitting it in two. The posterior part of the fractured body is displaced downward and forward, compressing the spinal cord. In severe instances the spinal cord damage, which can be nonetheless profound and permanent, is caused by a sudden inward bulge of the ligamentum flavum or a transient vertebral dislocation and then realignment. This type of spinal cord damage, without radiologic evidence of fracture or dislocation, is particularly common in children.

CT, MRI, and plain lateral spine films are all satisfactory means of demonstrating the vertebral injury, but the tearing and bulging of ligaments from vertebral dislocation is dependably demonstrated only by MRI (or by contrast myelography) and can only be inferred from the spinal displacement. Radiologic studies during cautious flexion or extension of the neck are the only way one can demonstrate instability from ligamentous injury alone.

Another mechanism of cord and root injury, involving extremes of extension and flexion of the neck, is so-called whiplash or recall injury. This type of injury is most often the result of an automobile accident. When a vehicle is struck sharply from behind, the head of the occupant is flung back uncontrollably; or, if a fast-moving vehicle stops abruptly, there is sudden forward flexion of the neck, followed by retroflexion. Under these conditions occipitocervical and sternocleidomastoid muscles and ligaments of the neck and head are affected much more than the spinal cord or roots. Nevertheless, in rare instances, quadratic, temporary or permanent, results from a violent whiplash injury. The exact mechanism of neural injury in these circumstances is not clear; perhaps there is a transient posterior dislocation of a vertebral body, a momentary buckling of the ligamentum flavum, or retroprolapse of the intervertebral disc into the spinal canal. Again, the presence of a congenitally narrow cervical spinal canal or of spinal diseases such as cervical spondylosis, rheumatoid arthritis, or ankylosing spondylitis greatly adds to the hazard of damage to the cord or roots. Presensitizing spondylolytic symptoms may be aggravated and become the source of chronic pain. Also, there are examples of spinal cord compression that result from the persistent hyperextension of the cervical spine during a protracted period of coma. Arterial hypotension may be an added factor in particular instances. This combination accounts for some of the cases of quadriplegia in opiate or other drug addicts following a period of sustained unresponsiveness (Ell et al).

A special type of spinal cord injury, occurring most often in wartime, is one in which a high-velocity missile penetrates the vertebral canal and damages the spinal cord directly. In some cases the missile strikes the vertebral column without entering the spinal canal but virtually shatters the contents of the dural tube or produces lesser degrees of impairment of spinal cord function. Rarely, the transmitted shock wave will cause a paralyzation of spinal cord function that is completely reversible in a day or two (spinal cord concussion, described further on).

Acute traumatic paralysis may also be the consequence of a vascular mechanism. Fibrocartilaginous emboli from an intervertebral disc that has ruptured into radicular arteries or veins of the spinal cord may cause infarction. Or, a traumatic dissecting aneurysm of the aorta may occlude the segmental arteries of the spinal cord, as in the cases reported by Weilman and Adams and by Knesley.

An analysis of 2000 cases of spinal injury collected from the medical literature by Jefferson showed that most vertebral injuries occurred at the levels of the first and second cervical, fourth to sixth cervical, and eleventh thoracic to second lumbar vertebrae. Industrial accidents most often involved the thoracolumbar vertebrae. Impact to the head with the neck flexed or sharply retroflexed, as mentioned above, was the main cause of injuries to the cervical region. These are not the most mobile portions of the vertebral column but also the regions in which the cervical and lumbar enlargements of the cord greatly reduce the space between neural and bony structures. The thoracic cord is relatively small and its spinal canal is capacious; additional protection is provided by the high arthritic facets (making dislocation difficult) and limitations in anterior movement imposed by the thoracic cage.

In the authors' experience, the usual circumstances of spinal cord injury have been motor vehicle accidents, falls (mainly during a state of alcoholic intoxication), gunshot or stab wounds, diving accidents, motor vehicle crashes, and lever injuries, in that order of frequency. The majority of the fatal cases were associated with fracture-dislocations or dislocations of the cervical spine. Respiration is paralyzed by lesions of the C1, C2, and C3 segments. Among nonfatal cases, fracture-dislocation of the lower cervical spine is the most frequent established mechanism of spinal cord injury in civilian life. In the United States, the annual incidence ranges from 1000 to 2000 cases per 100,000 population. About 3000 persons die in close relation to their injury, and another 5000 are left with complete or nearly complete loss of spinal cord function.

Pathology of Spinal Cord Injury As a result of squeezing or shearing of the spinal cord, there is destruction of gray and white matter and a variable amount of hemorrhage, chiefly in the more vascular central parts. These changes, best designated as traumatic necrosis of the spinal cord, are maximal at the level of injury and one or two segments above and below it. Rarely is the cord cut in two, and seldom is the pia-arachnoid lacerated. Separation of concomitant pathologic entities—such as hematomyelia, concussion, contusion, and hemorrathchos (bleeding into the spinal canal)—is of little value either clinically or pathologically. As a lesion heals, it leaves a glistening focus or cavitation with variable amounts of hemosiderin and iron pigment. Progressive meningeal fibrosis and cavitation (traumatic syringomyelia) will sometimes develop after an interval of months or years and lead to a delayed central or transverse cord syndrome (see further on).

In most traumatic lesions, the central part of the spinal cord, with its vascular gray matter, suffers greater injury than the peripheral parts. In some instances, the lesion is virtually restricted to the anterior and posterior gray matter, giving rise to segmental weakness and sensory loss in the arms with few long tract signs. This has been called the central cervical cord syndrome (or Schneider syndrome, see further on). Fragments of the syndrome are not uncommon as transient phenomena that reverse over several days.

As with most lesions, the total clinical effect is compounded of an irreversible structural component and a reversible disorder of function, each of which may vary in degree. The extent and permanence of the clinical manifestations are determined by the relative proportions of these two elements.

Experimental Spinal Cord Injury Investigation of the pathophysiology of acute spinal cord injury dates from the experimental studies of Allen, in the early 1950s. His method consisted of dropping graded weights onto the dura-covered thoracic cord of surgically prepared animals. The technique was refined over the years by precise measurements of the velocity, force, and direction of the dropped weights.

This type of impact on the cord, of sufficient severity to render the animal immediately paraplegic and abolish sensory evoked responses from structures below the lesion, indicates that action potentials can no longer be conducted across the injured spinal cord segment. No histologic changes, by either light or electron microscopy, can be detected for several minutes after impact. The earliest tissue alterations consist of hyperemia and small hemorrhages in the central gray matter. By 1 h, the microscopic hemorrhages coalesce and become macroscopically visible and tissue oxygen saturation is diminished in the region. Within 4 h, the central part of the cord is swollen and a spreading edema pervades the surrounding white matter; however, irrevocable white matter necrosis may not be evident for up to 8 h, an observation that has led to numerous strategies designed to spare long tracts. Surgical intervention to minimize white matter edema—such as laminectomy and myelotomy—spinal cord cooling, hyperbaric exposure, and the administration of pharmacologic measures have been tried but appear to have no effects on the evolving lesion. The early administration of high-dose corticosteroids has been a widely used mode of treatment, but the clinical benefits are questionable. Certain mechanical factors are currently under investigation to prevent the death of neural cells that are commonly invaded in spinal cord injury. These include glutamate release and exposure of neurons to calcium and agents that release free radicals. The latter mechanism may explain the salutary effect of high doses of corticosteroids rather than the osmotic effect of these drugs on edema. There are controversies concerning the putative role of accumulated vasoactive amines and opioids on the development of neuroblastoma and oedema. It is the release of norepinephrine from injured neurons in the central gray matter and that the subsequent vasoconstriction is responsible for both the central hemorhagic and lateral white matter lesions. Later experimental work failed to substantiate these suggestions. Also, the contention that opioid release at the moment of trauma plays an important role in tissue damage has not been confirmed flexion or extension is added.
Clinical Effects of Spinal Cord Injury
When the spinal cord is suddenly and completely or almost completely severed, three disorders of function are at once evident: (1) all voluntary movement in parts of the body below the lesion is immediately and permanently lost; (2) all sensation from the lower (aboral) part of the body is lost; (3) all autonomic function is lost. The last effect, called autonomic dysreflexia, is a dangerous condition which results in a high blood pressure, sweating, and headache when the bladder is emptied. There is thus an increased cardiovascular risk in patients with spinal cord injury, and this is further enhanced if autonomic dysreflexia is present.

Stage of Spinal Shock or Areflexia
The loss of motor function at the time of injury—quadriplegia (better termed tetraplegia) with lesions of the fourth to fifth cervical segments, paraplegia with lesions of the thoracic cord—is accompanied by atomic paralysis of bladder and bowel, gastric atony, loss of sensation below a level correspondingly caudal to the lesion, and absence of all spinal segmental reflex activity below the lesion. The neural elements below the lesion fail to perform their normal function because of their sudden separation from those of higher levels. Impaired also in the segments below the lesion is the control of autonomic function. Vasomotor tone, sweating, and piloerection in the lower parts of the body are temporarily abolished. Systemic hypotension, sometimes severe and contributing to the spinal cord damage, results from the loss of arterial pressure at the heart base, which is carried by the heart beat and the ventricular pressure (cutaneous and skeletal muscle vasodilation). The skin is dry and pale, and ulcerations may develop over bony prominences. The spindlers of the bladder and the rectum remain contracted to some degree due to the loss of inhibitory influence of higher central nervous system (CNS) centers, but the detrusor of the bladder and smooth muscle of the rectum are atonic. Urine accumulates until the intravesicular pressure is sufficient to overcome the sphincters; then dribbles escape (overflow incontinence). There is also passive distention of the bowel, retention of feces, and absence of peristalsis (paralytic ileus). Genital reflexes (penile erection, bulbocavernosus reflex, contraction of dartos muscle) are abolished or profoundly depressed.

The duration of the stage of complete areflexia varies considerably. In a small number of cases (5 of Kuhn's 29 patients, for example) it is permanent, or only fragmentary reflex activity is regained many months or years after the injury. In such cases the spinal segments below the level of transection may have themselves been injured—perhaps by a vascular mechanism, although this explanation is unproven. More likely (5 of patients, minimal genital and flexor reflex activity can be detected within a few days of the injury. In the majority of patients, this minimal reflex activity exists within a period of 1 to 6 weeks. Usually the bulbocavernosus reflex is the first to return. Nociceptive stimulation of the plantar surfaces evokes a tremulous twitching and brief flexion or extension movements of the great toes. Contraction of the anal sphincter can be elicited by plantar or perianal stimulation, and other genital reflexes reappear at about the same time.

The explanation of spinal shock, which is brief in submammalian forms and more lasting in higher mammals, especially in primates, is believed to be the sudden interruption of supraspinal descending fiber systems that normally keep the spinal motor neurons in a continuous state of subliminal depolarization (ready to respond). In the cat and monkey, Fulton found the facilitatory tracts in question to be the reticulospinal and vestibulospinal. Subsequent studies showed that in monkeys, spinal shock can result from a single factor, the loss of segmental inhibitory influences of supraspinal centers. In humans, because spinal shock may be very mild or inexcitable as a result of acute cerebral and brainstem lesions that interrupt the corticospinal tracts. F waves, which reflect the functioning of the motor neurons of a segment of the cord, are suppressed until spasticity supervenes, at which time they become excessively easy to elicit. Incision in recent years has focused on a possible role for neurotransmitters (catecholamines, endorphins, substance P, and 5-hydroxytryptamine). As already indicated, the claim that naltroxone and the endogenous opioid antagonist thorpyrolone releasing factor might reduce the extent of an acute spinal cord lesion has not been corroborated. Clonidine, a noradrenergic receptor activator, is reported to reduce flexor spasms and spasticity and to restore the balance between excitatory and inhibitory activity, allowing the spinal reflex generator for locomotion to function (Woolsey and Young).

Stage of Heightened Reflex Activity
This is the very familiar neurologic state that emerges within several weeks or months after the spinal injury. Usually, after a few weeks, the flexor responses to stimulation, which are initially minimal and unsustained, become stronger and more easily elicitable and come to include additional and more proximally located muscles. Gradually the typical exaggerated pattern of heightened reflexes emerges: dorsiflexion of the big toe (Babinski sign); fanning of the fingers in the toes; and plantar or perianal withdrawal with plantar or perianal movements of the foot, leg, and thigh with contraction of the tensor fasciae latae (triple flexion). Tactile stimulation of the foot may suffice as a stimulus, but a painful stimulus is more effective. The Achilles reflexes and then the patellar reflexes return. Retention of urine becomes less complete, and interjacent intervals of urinary incontinence are evoked by active contractions of the detrusor muscle. Reflex defecation also begins. After several months the withdrawal reflexes become greatly exaggerated. The point of flexion of the limb is not fixed, and reflex contraction of the muscles of the thigh and trunk is inhibited. Expansion is increased (occasionally the rectal reflex). This is the “mass reflex,” which is evoked by stimulation of the skin of the legs or by some interoceptive stimulus, such as a full bladder. Varying degrees of heightened flexor reflex activity may last for years. If the bladder is satisfactorily drained, the reflex is reduced (Kneidley). Presumably, in such cases the lateral horn cells in much of the thoracic cord are still viable and disinhibited. Above the level of the lesion, thermoregulatory sweating is exaggerated and is accompanied by cutaneous flushing, pounding headache, hypertension, and reflex bradycardia. This syndrome (“autonomic dysreflexia”) is episodic and occurs in response to a particular stimulus, such as a distended bladder or rectum. It has been ascribed to the reflex release of adrenalin from the adrenal medulla and of norepinephrine from the disinhibited sympathetic terminals caudal to the lesion.

Extensor reflexes eventually develop in most cases (18 of 22 of Kuhn's patients who survived more than 2 years), but their appearance does not lead to the abolition of the flexor reflexes. The overactivity of extensor muscles may appear as early as 6 months after the injury, but this only happens, as a rule, after the flexor responses are fully developed. Extensor responses are at first manifest in certain muscles of the hip and thigh and later of the leg. In a few patients extensor reflexes are even present before the withdrawal reflexes are fully developed. Extensive extensor movements of the foot, leg, and thigh with contraction of the tensor fasciae latae (triple flexion). Tactile stimulation of the foot may suffice as a stimulus, but a painful stimulus is more effective. The Achilles reflexes and then the patellar reflexes return. Retention of urine becomes less complete, and interjacent intervals of urinary incontinence are evoked by active contractions of the detrusor muscle. Reflex defecation also begins. After several months the withdrawal reflexes become greatly exaggerated. The point of flexion of the limb is not fixed, and reflex contraction of the muscles of the thigh and trunk is inhibited. Expansion is increased (occasionally the rectal reflex). This is the “mass reflex,” which is evoked by stimulation of the skin of the legs or by some interoceptive stimulus, such as a full bladder. Varying degrees of heightened flexor reflex activity may last for years. If the bladder is satisfactorily drained, the reflex is reduced (Kneidley). Presumably, in such cases the lateral horn cells in much of the thoracic cord are still viable and disinhibited. Above the level of the lesion, thermoregulatory sweating is exaggerated and is accompanied by cutaneous flushing, pounding headache, hypertension, and reflex bradycardia. This syndrome (“autonomic dysreflexia”) is episodic and occurs in response to a particular stimulus, such as a distended bladder or rectum. It has been ascribed to the reflex release of adrenalin from the adrenal medulla and of norepinephrine from the disinhibited sympathetic terminals caudal to the lesion.

From these observations one would suspect that the ultimate posture of the legs—flexion or extension—does not depend solely on the completeness or incompletion of the spinal cord lesion, as originally postulated by Riddoch. The development of paraplegia in flexion relates also to the level of the lesion, being seen most often with cervical lesions and progressively less often with more caudal ones. Repeated flexor spasms, which are more frequent with higher lesions, and the ensuing contractions ultimately determine a fixed flexor posture. Conversely, reduction of flexor spasms by elimination of nociceptive stimuli (infected bladder, decubitus, etc.) favors an extensor posture of the legs (paraplegia in extension). According to Guttman, the positioning of the limbs during the early stages of paraplegia greatly influences their ultimate posture. Thus, prolonged fixation of the paralyzed limbs in adduction and semiflexion favors subsequent paraplegia in flexion. Placing the patient prone or placing the limbs in abduction and extension facilitates the development of predominantly extensor postures. Nevertheless, strong and persistent extensor postures are observed only with partial lesions of the spinal cord.

Of some interest is the fact that many patients report sensory symptoms in segments of the body below the level of the lesion. Thus, a tactile stimulus above the level of the lesion may be felt below the transection (synesthesia). Patients describe a variety of parasthesias, the most common being a dull, burning pain in the skin, which may last for several minutes. Segmental damage in the low cervical or lumbar gray matter, destroying inhibitory Renshaw neurons, may release activity of remaining anterior horn cells, leading to spinal segmental plasticity. Any residual symptoms persisting after 6 months are likely to be permanent, although in a small proportion...
of patients some return of function (particularly sensation) is possible after this time. Loss of motor and sensory function above the lesion, coming on years after the trauma, occurs occasionally and is due to an enlarging cavity in the proximal segment of the cord (see further on, under “Syringomyelia”).

**Transient Cord Injury (Spinal Cord Conussion)** These terms refer to a transient loss of motor and/or sensory function of the spinal cord that recovers within minutes or hours but sometimes persists for a day or several days. In most instances the symptoms are already diminishing and no neurologic abnormalities are found at the time of the first examination. There are a number of such transient syndromes: bibralachial weakness; quadriaparesis (occasionally hemiparesis); paresthesias and dyesthesias in a similar distribution to the weakness; or sensory symptoms alone (“burning hands syndrome”). In the first and last of these the central gray matter of the cervical cord is implicated. It is assumed that the cord undergoes some form of elastic deformation when the head is struck at the vertex or frontally and that the cervical spine is compressed or hyperextended; however, the same effects can be produced by direct blows to the spine or forceful falls flat on the back and occasionally by a sharp fall on the tip of the coccyx. Little is known of the pathologic changes or the mechanisms that underlie these transient and reversible syndromes.

Spinal cord concussion is observed most frequently in athletes engaged in contact sports (football, rugby, and hockey). A congenitally narrow cervical canal is thought to predispose to spinal cord concussion and to increase the risk of recurrence. As with cerebral concussion, particularly if there have been previous concussions, a difficult decision arises—whether to allow resumption of competitive sports. There are no reliable data on which to base this decision—only guidelines that favor continued participation if the deficit has been brief. Certainly, it is advisable in most cases to be certain that spinal instability has not been induced by the injury. This can be ascertained by obtaining flexion and extension radiographs of the affected spinal region. The subject is reviewed by Zwinger and Bernstein.

**Central Cord Syndrome (Schneider Syndrome and “Cruciate Paralysis”)** In the acute central cord lesion, the loss of motor function is characteristically more severe in the upper limbs than in the lower ones and particularly severe in the hands. Bladder dysfunction with urinary retention occurs in some of the cases, and sensory loss is often slight (hyperpathia over the shoulders and arms may be the only sensory abnormality). Damage of the centrally situated gray matter (motor and sensory neurons) may leave an atrophic, areflexic paralysis and a segmental loss of pain and thermal sensation from interruption of crossing pain and thermal fibers. Retroflexion injuries of the head and neck are the ones most often associated with the central cord syndrome, but hernatomyelia, necrotizing myelitis, fibrocortilagenous embolism, and possibly infarction due to compression of the vertebral artery in the medullary-cervical region are other causes (Morse).

According to Dikman and colleagues, approximately 4 percent of patients who survive high cervical cord injuries demonstrate what these authors refer to as “cruciate paralysis.” The latter state is similar to the central cord syndrome except that the weakness is even more selective, being practically limited to the arms, a feature that is attributable to the segregation of corticospinal fibers to the arms (rostral) and to the legs (caudal) within the decussation. The patients described in the literature have had injuries, basically contusions, of the C1–C2 region. The arm weakness may be asymmetrical or even unilateral; sensory loss is inconsistent.

**Examination of the Spine-Injured Patient** The level of the spinal cord and vertebral lesions can be determined from the clinical findings. A complete paralysis of the arms and legs usually indicates a fracture or dislocation at the fourth to fifth cervical vertebrae. If the legs are paralyzed and the arms can still be abduced and flexed, the lesion is likely to be at the fifth to sixth cervical vertebrae. The level of the legs and only the hands indicates a lesion at the sixth to seventh cervical level. Below the cervical region, the spinal cord segments and roots are not opposite their similarly numbered vertebrae (Fig. 44-1). The spinal cord ends opposite the first lumbar vertebra, usually at its rostral border. Vertebral lesions below this point give rise predominantly to cauda equina syndromes; these carry a better prognosis than injuries to the lower thoracic vertebrae, which involve both cord and multiple roots. The level of sensory loss on the trunk, determined by perception of pinprick, is also an accurate guide to the level of the lesion, with a few qualifications. With lesions of the lower cervical cord, even if complete, sensation may be preserved down to the nipple line because of the contribution of the C3 and C4 cutaneous branches of the cervical plexus, which innervate skin below the clavicle. Rarely, a lesion will involve only the uppermost fibers of the spinohalamic pathways, sparing the innermost ones, in which case the sensory loss (to pain and temperature) will be below the level of the lesion. In all cases of spinal cord and cauda equina injury, the prognosis for recovery is more favorable if any movement or sensation is elicitable during the first 48 to 72 h.

If the spine can be examined safely, it should be inspected for angulations or irregularities and gentlypercussed to elicit signs of bony injury. Collateral injury of the thorax, abdomen, and long bones must always be sought.

**Management of Spinal Injury** In all cases of suspected spinal injury, the immediate concern is that there be no movement (especially flexion) of the cervical spine from the moment of the accident. The patient should be placed supine on a firm, flat surface (with one person assigned to keeping the head and neck immobile) and should be transported by a vehicle that can accept the litter. Preferably, the patient should be transported by an ambulance equipped with spine boards, to which the head is rigidly fixed by straps. This provides a more effective means of immobilization than sandbags or similar objects placed on each side of the head and neck. On arrival at the hospital, it is useful to have the patient remain on the backboard until a lateral film or a CT or MRI of the cervical spine have been obtained.

A careful neurologic examination with detailed recording of motor, sensory, and sphincter function is necessary to follow the clinical progress of spinal cord injury. A common practice is to define the injury according to the standards of the American Spinal Injury Association and to assign the injury to a point on the Frankel Scale.

1. Complete: motor and sensory loss below the lesion
2. Incomplete: some sensory preservation below the zone of injury
3. Incomplete: motor and sensory sparing, but the patient is nonfunctional
4. Incomplete: motor and sensory sparing and the patient is functional (stands and walks)
5. Complete functional recovery: reflexes may be abnormal

Obviously, groups 2, 3, and 4 have a more favorable prognosis for recovery of ambulation than does group 1.

Once the degrees of injury to spine and cord have been assessed, the usual practice during the past decade has been to administer methylprednisolone in high dosage (bolus of 30 mg/kg followed by 5.4 mg/kg every hour), beginning within 8 h of the injury and continued for 23 h. This measure, according to the multicenter National Acute Spinal Cord Study (Bracken et al) resulted in a slight but significant improvement in both motor and sensory function. Despite its widespread use, the therapeutic value of this measure has not been established beyond doubt, and its value has been questioned after careful re-analysis of the data (Nesafutur, Hurlbert). Also, in a later series of patients, the administration of ganglioside (100 mg intravenously each day from the time of the accident) was found to enhance ultimate recovery to a modest degree (Geiser et al), but again, this finding must be corroborated.

Next, radiologic examinations are undertaken to determine the alignment of vertebral bodies and pedicles, compression of the spinal cord or cauda equina due to malalignment or bone debris in the spinal canal, and the presence of tissue damage within the cord. The MRI is ideally suited to display these processes; but if it is not available and there is uncertainty regarding cord compression, myelography with CT scanning is a useful alternative. Instability of the spinal elements can often
be inferred from dislocations or from certain fractures of the pedicles, pars articularis, or transverse processes, but gentle flexion and extension of the injured areas must sometimes be undertaken and plain films obtained in each position.

If a cervical spinal cord injury is associated with vertebral dislocation, traction on the neck is necessary to secure proper alignment and maintain immobilization. This is best accomplished by use of a halo brace, which, of all the appliances used for this purpose, provides the most rigid external fixation of the cervical spine. This type of fixation is usually continued for 4 to 6 weeks, after which a rigid collar may be substituted.

In general, concerning the early surgical management of spinal cord injury, there have been two schools of thought. One, represented by Gutmann and others, advocates reduction and alignment of the dislocated vertebrae by traction and immobilization until skeletal fixation is obtained, and then rehabilitation. The other school, represented by Munro and later by Collins and Chehrazi, proposes early surgical decompression, correction of bony displacements, and removal of hemiated disc tissue and intra- and extramedullary hemorrhage; often the spine is fixed at the same time by a bone graft or other form of stabilization. The issue of acute decompressive surgery remains contentious to the present day. Most American neurosurgeons take the less aggressive stance, delaying operation or operating only on patients with compound wounds or those with progression or worsening of the neurologic deficit despite adequate reduction and stabilization. With complete spinal cord lesions, most surgeons do not favor surgery.

The results of the conservative and aggressive surgical plans of management have been difficult to compare and have not been evaluated with modern neurologic techniques. Collins, a participant in the National Institutes of Health (NIH) study of acute management of spinal cord injury, concluded that the survival rate was increased as a result of early surgical stabilization of fractures and fixation of the spine (in addition to the usual measures for the prevention of respiratory, urinary, and cutaneous complications and the early institution of rehabilitation measures). Other neurosurgeons, however, have not been able to document a reduction in neurologic disability as a result of early operation, and they have increasingly inclined toward nonoperative management of both complete and partial spinal cord lesions (Clark; Munro et al.). In any given case, the approach must be guided by the particular features of the patient's injuries. A detailed description of the orthopedic and neurosurgical treatment of spinal fracture-dislocations is beyond the scope of a textbook of neurology but can be found in the account by Ogilvy and Heron and in the book edited by Wooley and Young, listed in the References.

The greatest risk to the patient with spinal cord injury is in the first week or 10 days, when gastric dilatation, ileus, shock, and infection are the main threats to life. According to Messard and colleagues, the mortality rate falls rapidly after the first 3 months; beyond this time, 86 percent of paraplegics and 80 percent of quadriplegics will survive for 10 years or longer. In children, the survival rate is even higher (DeVivo et al.). The latter authors found that the cumulative 7-year survival rate in spinal cord–injured patients (who had survived at least 24 h after injury) was 87 percent. Advanced age at the time of injury and being rendered completely quadriplegic were the worst prognostic factors.

The aftercare of patients with paraplegia is concerned with management of bladder and bowel disturbances, care of the skin, prevention of pulmonary embolism, and maintenance of nutrition. Decubitus ulcers can be prevented by frequent turning to avoid pressure necrosis, use of special mattresses, and meticulous skin care. Deep lesions require debridement and full-thickness grafting. At first continual catheterization is necessary; then, after several weeks, the bladder can be managed by intermittent catheterization once or twice daily, using a scrupulous aseptic technique. Close watch is kept for bladder infection, which is treated promptly should it occur. Bacteriuria is common and does not require treatment with antibiotics unless there is associated pyuria. Morning suppositories and periodically spaced enemas are the most effective means of controlling fecal incontinence. Chronic pain (present in 30 to 50 percent of cases) requires the use of nonsteroidal anti-inflammatory medication, injections of local anesthetics, and transcutaneous nerve stimulation. A combination of carbamazepine and either clonazepam or tricyclic antidepressants may be helpful in cases of burning leg and trunk pain. Recalcitrant pain may require more aggressive therapy, such as epidural injections of analgesics or corticosteroids, but often even these measures are ineffective. Spasticity and flexor spasms may be troublesome; oral baclofen, diazepam, or tizanidine may provide some relief. In permanent spastic paraplegia with severe stiffness and adductor and flexor spasms of the legs, intrathecal baclofen, delivered by an automated pump in doses of 12 to 400 mg/day, has reportedly been helpful. The drug is believed to act at the synapses of spinal reflexes (Penn and Konin). One must always be alert to the threat of pulmonary embolism from deep-vein thrombi, although the incidence is surprisingly low after the first several months. Physiotherapy, muscle re-education, and the proper use of braces are all important in the rehabilitation of the patient. All this is best carried out in special centers for rehabilitation of spinal cord injuries.

Posttraumatic syringomyelia is described further on (see Fig. 44-12).

Radiation Injury of the Spinal Cord

Delayed necrosis of the spinal cord and brain is a well-recognized sequel of radiation therapy for tumors in these regions and in the thorax and neck. The peripheral nerves are more resistant to this adverse effect, although we have observed, as have others, an early reversible and a late progressive and permanent sensorimotor neuropathy coming on several months or years after irradiation. Finally, a lower motor neuron lesion, presumably due to injury to the gray matter of the spinal cord, may also follow radiation therapy.

Transient Myelopathy The “early” type of radiation myelopathy (appearing 3 to 6 months after radiotherapy) is characterized mainly by paresthesias in the extremities. The paresthesias may be evoked or exacerbated by neck flexion (Lhermitte phenomenon). In one of our patients there was impairment of vibratory and position sense in the legs but no weakness. The sensory abnormalities disappear after a few months and, according to Jones, are not followed by the delayed radiation progressive myelopathy (see below). The pathology has not been fully elucidated, but there is said to be a spongy appearance of the white matter with demyelination and depletion of oligodendrocytes.

Delayed Progressive Radiation Myelopathy This, the most dreaded complication of radiation therapy, is a progressive myelopathy that follows, after a characteristic latent period, the irradiation of malignant tissues in the vicinity of the spinal cord. The incidence of this complication is difficult to determine because many patients die of their malignant disease before the cord lesion matures, but it is estimated to be between 2 and 3 percent (Palmer). According to Douglas et al., patients who have undergone hyperthermia as a treatment for cancer are particularly vulnerable to radiation myelopathy.

Clinical Features The neurologic disorder first appears many months after the course of radiation therapy, practically always after 6 months and usually between 12 and 15 months (latent periods as long as 60 months or even longer have been reported). The onset is insidious, usually with sensory symptoms—paresthesias and dyesthesias of the feet or a Lhermitte phenomenon, and similar symptoms in the hands in cases of cervical cord damage. Weakness of one or both legs usually follows the sensory loss. Initially, local pain is notably absent, in distinction to the effects of spinal metastases. In some cases, the sensory abnormalities are transitory; more often, additional signs make their appearance and progress, at first rapidly and then more slowly and irregularly, over a period of several weeks or months, involving all levels of the spinal cord and spinal segments. Originally, the neurologic disturbance may take the form of a Brown-Séguard syndrome, but with progression it takes the form of a transverse myelopathy, with a spastic paraplegia, sensory loss below a level on the trunk, and sphincteric disturbance.
Reagan and coworkers, who have had a large experience with radiation myelopathy at the Mayo Clinic (1 percent of all cases of myelopathy were of this type), describe yet another myelopathic radiation syndrome—namely, a slowly evolving amyotrophy, with weakness and atrophy of muscles and areflexia in parts of the body supplied by anterior horn cells of the irradiated spinal segments. Most patients with this form of the disease die within a year of onset. Knowledge of the pathology is incomplete.

The CSF in delayed progressive radiation myelopathy is normal except for a slight elevation of protein content in some cases. MRI demonstrates an abnormal signal intensity, decreased in T1-weighted and increased in T2-weighted images. Early in the course of the myelopathy the cord may be swollen and there is often enhancement with gadolinium infusion. The cord lesion corresponds to the irradiated portal, which can be identified precisely by the radiation effect on the marrow of the vertebral bodies. The spinal cord lesion tends to be more extensive than the usual vascular or demyelinating lesion. These are important points to establish, because a mistaken diagnosis of intraspinal tumor may lead to another operation or further irradiation of an already damaged cord.

Pathologic Findings

In the spinal cord, corresponding with the level of the irradiated area and extending over several segments, there is an irregular zone of coagulation necrosis involving both white and gray matter, the former to a greater extent than the latter. Varying degrees of secondary degeneration are seen in the ascending and descending tracts. Vascular changes—necrosis of arteries or hyaline thickening of their walls, with thrombotic occlusion of their lumens—are prominent in the most severely damaged portions of the cord. Most neuropathologists have attributed the parenchymal lesion to the blood vessel changes; others believe that the degree of vascular change is insufficient to explain the parenchymal change (Malamud et al; Burns et al). Certainly the most severe parenchymal changes in the cord are typical of infarction; but the insidious onset and slow, steady progression of the clinical disorder and the coagulative nature of the necrosis would then have to be explained by a steady succession of vascular occlusions. Exceptional instances, in which a transverse myelopathy has developed within a few hours (as described by Reagan et al), are more readily explained by thrombotic occlusion of a larger spinal artery.

Treatment and Prevention

It must be kept in mind that radiation myelopathy is an iatrogenic disease and is therefore largely preventable. The tolerance of the adult human spinal cord to radiation—taking into account the volume of tissue irradiated, the duration of the irradiation, and the total dose—has been determined by Kragan and colleagues. These authors reviewed all of the cases in the literature up to 1980 and concluded that radiation injury could be avoided if the total dose was kept below 6000 cGy and was given over a period of 30 to 70 days, provided that each daily fraction did not exceed 200 cGy and the weekly dose was not in excess of 900 cGy. It is noteworthy that in the cases reported by Sanyal and associates, the amount of radiation surpassed these limits. Forewarned with this knowledge, physicians now have the impression that the incidence of this complication is decreasing.

A number of case reports remark on temporary improvement in neurologic function after the administration of steroids. This therapy should be tried, because in some patients the disease process appears, after a time, to be arrested short of complete destruction of all sensory and motor tracts. Claims have also been made of regression of early symptoms in response to the administration of heparin split products.

Neurologists attached to tumor treatment centers are sometimes confronted with the late development (up to 10 to 15 years after irradiation) of a slowly progressive segmental muscular atrophy (motor weakness with preserved sensibility). The condition raises questions of recurrent tumor or the development of a local sarcoma, but the absence of a mass lesion and of pain and the signs on neurologic examination are most consistent with a regional interstitial fibrosing neuropathy. Examples that we have seen are multiple cranial neuropathies after radiation of nasopharyngeal tumors, cervical and especially brachial neuropathies after laryngeal and breast cancers, and lumbosacral plexopathies with pelvic tumors. These are discussed further in Chap. 46.

Spinal Cord Injury due to Electric Currents and Lightning

Among acute physical injuries to the spinal cord, those due to electric currents and lightning should be mentioned. They can also injure the brain and peripheral nerves. These effects are noted briefly, since they are infrequent. It is the spinal cord, however, that is most severely damaged.

Electrical Injuries

In the United States, inadvertent contact with an electric current causes about 1000 deaths annually and many more nonfatal but serious injuries. About one-third of the fatal accidents result from contact with household currents, indicating the vulnerability of most of the population to this type of injury.

The factor that governs the damage to the nervous system is the amount, or amperage, of the current with which the victim has contact, not simply the voltage, as is generally believed. In any particular case, the duration of contact with the current and the resistance offered by the skin (this is greatly reduced if the skin is moist or a body part is immersed in water) are of critical importance. The physics of electrical injuries is much more complex than these brief remarks indicate (for a full discussion, see reviews by Panse and by Winkelman).

Any part of the peripheral or central nervous system may be injured by electric currents and lightning. The effects may be immediate, which is understandable, but of greater interest are the instances of neurologic damage that occur after a delay of 1 day to 6 weeks (1 week on the average). The immediate effects are apparently the result of direct heating of the nervous tissue, but the pathogenesis of the delayed effects is not understood. They have been attributed to vascular occlusive changes induced by the electric current, a mechanism that seems to underlie the delayed effects of radiation therapy (see above). However, the latent period of radiation myelopathy is measured in many months rather than in days and the course is more often progressive than self-limited. Moreover, the few postmortem studies of myelopathy due to electric injury have disclosed a widespread demyelination of long tracts, to the point of tissue necrosis in some segments, and relative sparing of the gray matter, but no abnormalities of the blood vessels.

A rare syndrome of focal muscular atrophy, occurring after an electric shock, has been described by Panse under the title of spinal atrophic paralysis. It occurs when the path of the current, usually of low voltage, is from arm to arm (across the cervical cord) or arm to leg. Pain and paresthesias occur immediately in the involved limb, but these symptoms are transient. Weakness, also unilateral, is immediate as well, followed in several weeks or months by muscle wasting, most often taking the form of segmental muscular atrophy; occasionally the syndrome simulates that of amyotrophic lateral sclerosis or transverse myelopathy (most patients have some degree of weakness and spasticity of the legs). In contrast to injuries due to high-tension current, which affects mainly the spinal white matter (see above), it is mainly the gray matter that is injured in cases of spinal atrophic paralysis, at least as judged from experimental studies.

When the head is one of the contact points, the patient may become unconscious or suffer tinnitus, deafness, or headache for a short period following the injury. In a small number of surviving patients, after an asymptomatic interval of days to months, there has been an apoplectic onset of hemiplegia with or without aphasia or a striatal or brainstem syndrome, presumably due to thrombotic occlusion of cerebral vessels with infarction of tissue.

Lightning Injuries

The factors involved in injuries from lightning are less well defined than those from electric currents, but the effects are much the same. The risk of being struck by lightning is about thirty times greater in rural areas than in cities. Direct striking is often fatal; nearby strikes produce the neurologic damage described below. Prominences such as trees, hills, and towers are struck preferentially, so these should be avoided; a person caught in the open should curl up on the ground, lying on one side with legs close together.

Arborescent red lines or burns on the skin indicate the point of contact of lightning, but the path through the body can be deduced only approximately from the clinical sequelae. Death is due to ventricular fibrillation or to the effects of intense desiccating heat on vital regions of the brain. Lightning that strikes the head is particularly dangerous, proving fatal in 30 percent of cases. Persons struck by lightning are initially unconscious, irrespective of where they are struck. In those who survive, consciousness is usually regained rapidly and completely. Rarely, unconsciousness or an agitated-confusional state may persist for a week or two. There is usually a disturbance of sensorimotor function of a limb or all limbs, which may be pale and cold or cyanotic. As a rule, these signs are also evanescent, but in some instances they persist, or an atrophic paralysis of a limb or part of a limb makes its appearance after a symptom-free interval of several months. Persistent seizures are surprisingly rare.

MYELITIS

In the nineteenth century, almost every disease of the spinal cord was labeled myelitis. Morton Prince, writing in Dercum's Textbook of Nervous Diseases in 1895, referred to traumatic myelitis, compressive myelitis, and so on, obviously giving a rather imprecise meaning to the term. Gradually, however, as knowledge of neuropathology advanced, one disease after another was removed from this category until only the truly inflammatory ones remained.

Today the spinal cord is known to be the locus of a limited number of infective and noninfective inflammatory processes, some causing selective destruction of neurons, others affecting primarily white matter (tracts), and yet another group involving the meninges and white matter or leading to a necrosis of both gray and white
matter. The currently accepted term for all these inflammatory conditions is myelitis. Other special terms are used to indicate more precisely the distribution of the process: if it is confined to gray matter, the proper expression is poliomyelitis; if to white matter, leukomyelitis. If the whole cross-sectional area of the cord is involved, the process is said to be a transverse myelitis; if the lesions are multiple and widespread over a long vertical extent, the modifying adjectives diffuse or disseminated are used. The term meningomyelitis refers to combined inflammation of meninges and spinal cord, and meningoradiculitis, to combined meningeal and root involvement. An inflammatory process limited to the spinal dura is called pachymeningitis; and if infected material collects in the epidural or subdural space, it is called epidural spinal abscess or granuloma, as the case may be. The adjectives acute, subacute, and chronic denote the tempo of evolution of myelitic symptoms—more or less within days, 2 to 6 weeks, or more than 6 weeks, respectively.

### Classification of Inflammatory Diseases of the Spinal Cord

#### I. Viral myelitis (Chap. 33)
- A. Enteroviruses (groups A and B Coxsackie virus, poliomyelitis, others)
- B. Herpes zoster
- C. Myelitis of AIDS
- D. Epstein-Barr virus (EBV), cytomegalovirus (CMV), herpes simplex
- E. Rabies
- F. Japanese B virus
- G. HTLV-I (tropical spastic paraparesis)

#### II. Myelitis secondary to bacterial, fungal, parasitic, and primary granulomatous diseases of the meninges and spinal cord
- A. Mycoplasma pneumoniae (Chap. 32)
- B. Lyme disease
- C. Pyogenic myelitis
  1. Acute epidural abscess and granuloma
  2. Abscess of spinal cord
- D. Tuberculous myelitis (Chap. 32)
- E. Post-polio disease with spinal cord compression
- F. Tuberculous meningomyelitis
- G. Tuberculoma of spinal cord
- H. Paralytic and fungal infections producing epidural granuloma, localized meningitis, or meningomyelitis and abscesses (Chap. 32)
- I. Syphilitic myelitis (Chap. 32)
- J. Chronic meningoradiculitis (tabes dorsalis)
- K. Chronic meningomyelitis
- L. Myelitis of AIDS and other AIDS-related disorders
- M. Granulomatous myelitis
- N. Gummatus meningitis including chronic spinal pachymeningitis
- O. Sarcoid myelitis (Chap. 32)

#### III. Myelitis (myelopathy) of noninfectious inflammatory type
- A. Postinfectious and postvaccinal myelitis (Chap. 36)
- B. Acute and chronic relapsing or progressive multiple sclerosis (Chap. 36)
- C. Subacute necrotizing myelitis (Chap. 36)
- D. Myelopathy with lupus or other forms of angitis
- E. Paraneoplastic myelopathy and poliomyelitis (Chap. 31)

From this outline it is evident that many different and totally unrelated diseases are under consideration, and that a general description cannot possibly encompass such a diversity of pathologic processes. Many of the myelitides are considered elsewhere in this volume in relation to the diseases of which they are a part. Here it is only necessary to comment on the three principal categories and to describe a few of the common subtypes.

**Myelitis due to Viruses**

The enteroviruses, of which Coxsackie and poliomyelitis are examples, herpes zoster, and AIDS are the important members of this category. The enteroviruses have an affinity for neurons of the anterior horns of the spinal cord and motor nuclei of the brainstem (i.e., they are poliomyelitides), and herpes zoster virus for the dorsal root ganglia; hence the disturbances of function are in terms of motor and sensory neurons, respectively, not of spinal tracts. The onset of these conditions is acute and features a febrile meningomyelitis (see Chap. 33). Although there are systemic symptoms and sometimes cutaneous ones (in the case of zoster), it is the nervous system disorder that is most significant. The patient suffers the immediate effects of nerve cell destruction, and improvement nearly always follows as altered nerve cells recover. Later in life, as the neuronal loss of aging occurs in the anterior horns and dorsal root ganglia, there may be an increased loss of strength in muscles originally weakened by poliomyelitis (“postpolio syndrome”).

The rapid expansion of knowledge of herpesvirus infections has added a new chapter to the viral myelitides. Rarely reported examples of myelitis due to herpes simplex virus (HSV types 1 and 2), varicella-zoster virus (VZV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), and SV40 virus (epidemic conjunctivitis) have been reported, some in patients with immunosuppression, particularly HIV infections. The situation is more complex clinically, since most of these agents may also produce a postinfectious variety of myelitis, described further on in this chapter and in Chap. 33 and Chap. 36. In HSV type 2 infections, there may also be an acute lumbosacral radiculitis with urinary retention; and in VZV infections, a sensory ganglionitis, vasculitis, or encephalitis. There is, in a few cases, evidence of an extensive inflammatory necrosis of the spinal cord with involvement of sensory and motor tracts. In other words, these conditions may at times simulate acute paraplegic and quadriplegic transverse or pannemylitic syndromes of nonviral type. However, pleocytosis and isolation of portions of the viral DNA by the polymerase chain reaction or direct culture from the cerebrospinal fluid (CSF) confirm the diagnosis of a primary viral infection, as discussed in Chap. 33 (see Dawson and Potts).

Affection of the white matter, with sensory and motor paralysis below the level of a lesion, has been reported in so-called dumb rabbies (in contrast to the usual form of “mad” or “furious” rabies encephalitis), zoster and simplex myelitis, EBV myelitis, and an infection transmitted by the bite of a monkey, called the B virus. Each of these is decidedly rare. Far more common is the myelopathy of AIDS; much rarer is the myelopathy of spinal spastic paraparesis (HTLV-1). With these exceptions, one may say that any myelitis that expresses itself by dysfunction of motor and sensory tracts will usually prove not to be viral in origin but due rather to one of the disease processes in category II or III of the preceding classification. The unique vacuolar myelopathy of AIDS and the myelopathy of human HTLV infections are described below and also in Chap. 33.

There are other rare forms of poliomyelitic reactions of unknown, presumably viral etiology. One such condition presents as an acute febrile meningoencephalitis and leaves all the limbs paralyzed and flaccid, sparing the brainstem and affecting the diaphragm to a variable extent. Several such patients have harbored a carcinoma or Hodgkin disease, and the pathology proved to be like that of a poliomyelitic viral infection rather than the usual paraneoplastic syndromes. We have cared for several others who have had destruction of anterior horn cells due apparently to an enterovirus other than poliomyelitis virus (see further on and page 809 and Fiala, 33, 4).**

**Vascular Myelopathy with AIDS** As the neurology of AIDS has been elucidated, this new clinical and pathologic entity has emerged. Its frequency is impressive—20 of 89 successive cases of AIDS on whom a postmortem examination was performed (Petito et al.). Often the clinical symptoms and signs of spinal cord disease are obscured by a neuropathy or one more of the cerebral disorders that complicate AIDS—dueto either to HIV or to an opportunistic infection (CMV disease, toxoplasmosis, etc.). In five cases of severe vascular myelopathy in Petito’s series, there was leg weakness or leg and arm weakness, often asymmetrical and developing over a period of weeks, to which the signs of sensory tract involvement and sphincteric disorder were added. A sensory ataxia has been a common early feature in our experience. The CSF shows a small number of lymphocytes, a slight elevation of protein, and, occasionally, bizarre giant cells. The white matter of the spinal cord is vacuolated, most severely in thoracic segments. Posterior and lateral funiculi are affected diffusely without confinement to discrete sensory or motor systems. Axons are involved to a lesser degree than myelin sheaths, and lipid-laden macrophages are present in abundance. Similar vascular lesions may be seen in the brain in some cases. Although the lesions in the spinal cord resemble those of subacute combined degeneration, levels of vitamin B12 and folic acid have been normal. A similar lesion was seen in one of our cases of chronic lupus erythematosus. Often there are coexistent features of AIDS dementia or one of the several neuropsychiatric illnesses that occur in the intermediate and advanced stages of the disease (Chap. 33). The antiretroviral drugs that slow the progress of AIDS seem to have little effect on the myelopathy, and one can only resort to the symptomatic treatment of spasticity.

**Tropical Spastic Paraparesis due to Human T-Cell Lymphotropic Virus Type I (HTLV-I)** The tropical myeloneuropathies were drawn to the attention of neurologists 45 years ago through the observations and writings of Cruickshank. However, it is only recently that a chronic infective-inflammatory disease of

---

Note: The text is a detailed medical description of various myelitides and myelopathies, including viral, bacterial, fungal, parasitic, and granulomatous causes, as well as non-infectious inflammatory conditions. It also covers the clinical presentation, diagnosis, and management of these conditions.
the spinal cord due to the retrovirus HTLV-I has been discovered. The clinical implications of this discovery are broad and extend even to the demyelinating and possibly the degenerative diseases.

Spinal cord disease of this type has been reported from the Caribbean islands, southern United States, southern Japan, South America, and Africa. The clinical picture is that of a slowly progressive paraparesis with increased tendon reflexes and Babinski sign; the disorder of spinothalamic control is usually an early change. Paresthesias, reduced vibratory and position senses, and ataxia have been described. A few of the patients have had an associated polyneuropathy, as in Cruikshank's early cases. The upper extremities are usually spared (except for lèves tendon reflexes), as are cerebral and brainstem structures.

The CSF contains small numbers of lymphocytes of T type (10 to 50 per cubic millimeter), normal concentrations of protein and glucose, and an increased content of IgG with antibodies to HTLV-I. The diagnosis is confirmed by the detection in the serum of the antibodies to the virus. Thinness of the spinal cord is evident on MRI, and subcortical cerebral white matter changes may be seen as well. Neuropathologic study has documented an inflammatory myelitis with focal spongiform, demyelinating, and necrotic lesions, perivascular and meningeal infiltrates of inflammatory cells, and focal destruction of gray matter. The posterior columns and corticospinal tracts are the main sites of disease, most evident in the thoracic cord. It is strongly suspected but not established that the disease is due to the cytotoxic effect of the viral infection, but an alternative theory of autoimmune damage has been proposed.

The clinical picture can easily be confused with that of progressive spastic paraplegia of the heredofamilial variety, sporadic motor neuron disease, or the chronic phase of multiple sclerosis. There are also similarities with the AIDS myelopathy described above, but the other features of HIV infection are absent. Tropical spastic paraparesis and HTLV-I are also considered in the chapter on viral disease (page 806). There are anecdotal reports of improvement with intravenous administration of gamma globulin.

**Myelitis Secondary to Bacterial, Fungal, Parasitic, and Granulomatous Diseases**

With few exceptions, this class of spinal cord disease is seldom offered any difficulty in diagnosis. The CSF often holds the clue to causation. In most cases, the inflammatory reaction of the spinal meninges is only one manifestation of a generalized (systemic) disease process. The spinal lesion may involve primarily the pia-arachnoid (leptomeningitis), the dura (pachymeningitis), or the epidural space, e.g., taking the form of an abscess or granuloma; in the last circumstance, damage to the spinal cord is due to compression and ischemia. In some acute forms, both the spinal cord and meninges are simultaneously affected, or the cord lesions may predominate. Chronic spinal epidural abscesses may involve the pial arteries or veins; as the inflamed vessels become thrombosed, infarction (myelomalacia) of the spinal cord results. Chronic meningeal inflammation may provoke a progressive constrictive pial fibrosis (so-called spinal arachnoiditis) that virtually strangulates the spinal cord. In certain instances, spinal roots become progressively damaged, especially the lumbosacral ones, which have a long meningeal course. Posterior roots, which enter the subarachnoid space near arachnoidal villi (where CSF is resorbed), tend to suffer greater injury than anterior ones (as happens in tuberous sclerosis). Interestingly, there are many cases of chronic cerebrospinal meningitis that remain entirely without symptoms until the spinal cord or roots become involved.

The unique myelitis caused by the atypical pneumonia agent Mycoplasma pneumoniae has been conceptualized as a postinfectious immune disease, as discussed on pages 747 and 975. However, portions of the DNA from this organism have been found in the spinal fluid early in the course of illness (using the polymerase chain reaction), suggesting instead a direct bacterial infection of the spinal cord (see Chap. 33). It is not known whether antibiotic treatment alters the course of the illness.

**Syphilitic myelitis** is discussed on page 787. Abscess of the spinal cord (acute bacterial myelitis) is exceedingly rare and is only beginning to be recognized by MRI. At times it stands as a single pyogenic metastasis, but more often there has been spread from a contiguous infected surgical site or a fistulous connection with a superficial abscess or furuncle. **Acute spinal epidural abscess and granuloma** are the more important representatives of this group.

Sarcoid may present as an intramedullary spinal cord mass, as in the cases of Levivier and colleagues. More often the granulomatous lesion, which may be focal or multifocal, may accompany a disease process, with respect to its tendency to relapse and remit and an apparent response to corticosteroids (page 761). An asymmetrical ascending paraparesis and bladder disturbance have been the features in our patients. Usually there is evidence of disseminated sarcoidosis and the CSF is abnormal (increase in cells and protein), but we have encountered several instances of sarcoid restricted to the spinal cord before it was clinically evident in the chest (CT will generally demonstrate hilar adenopathy). We do not usually attempt to define the extent of sarcoidosis in the CSF. The use of angiotensin-converting enzyme levels in the CSF to distinguish sarcoidosis from multiple sclerosis suffers from the lack of normative values for this test, but it is said to be elevated in two-thirds of patients. The MRI is invariably abnormal and the conus may show intramedullary lesions, but the most characteristic finding is a nodular enhancement of the meninges adjacent to a lesion of the cord or nerve roots, similar to that observed in neoplastic meningitis. The diagnosis can be confirmed by mediastinal lymph node biopsy or by the less desirable method of biopsy of the spinal meninges and subdural cord.

A number of other rare granulomatous conditions have on occasion caused an intrinsic or, more often, an extrinsic compressive myelopathy, including brucellosis, xanthogranulomatous meningitis, and Sarcoid. The diagnosis may be suspected if the systemic disease is apparent at the time, but in some instances only the histology of a surgical specimen reveals the underlying process.

**Spinal Epidural Abscess**

This process is worthy of emphasis because the diagnosis is often missed or mistaken for another disease, with disastrous results. Children or adults may be affected. Infection of the epidural space has a wide variety of sources. An injury to the back, often trivial at the time, furunculosis or other skin or wound infection, or a bacteria may permit seeding of the spinal epidural space or of a vertebral body. This gives rise to osteomyelitis with extension to the epidural space. Occasionally, extension is from an infected disc. An epidural abscess or granuloma may also develop in the course of a septicemia or in an addict following injection of therapeutic agents. In other cases organisms may be introduced into the epidural space during spinal surgery or rarely via a lumbar puncture needle during epidural or spinal anesthesia or epidural injections of steroid or other therapeutic agents. The localization in these latter instances is over lumbar and sacral roots. In the cases of cauda equina epidural abscess, back pain may be severe and neurologic symptomatology minimal unless the infection extends upward to the upper lumbar and thoracic segments of the spinal cord. **Staphylococcus aureus** is the most frequent etiologic agent, followed by streptococci, gram-negative bacilli, and anaerobic organisms.

At first, the suppurative process is accompanied only by fever and pain, usually intense, in the back, followed within a day or several days by radicular pain in most cases. Headache and nuchal rigidity are sometimes present; more often there is persistent pain and a disinclination to move the back. After several more days, there is the onset of a rapidly progressive paraparesis and paraplegia or quadriplegia, associated with sensory loss in the lower parts of the body and spastic paraparesis with urinary and fecal retention. Percussion of the spine elicits tenderness over the site of the infection. Examination discloses all the signs of a complete or partial transverse cord lesion, with elements of spinal shock if paralysis has evolved rapidly. The CSF contains a relatively small number of white cells (usually fewer than 100 per cubic millimeter), both polymorphonuclear leukocytes and lymphocytes, unless the needle penetrates the abscess, in which case pus is obtained. The protein content is relatively high (100 to 400 mg/100 mL or more), but the glucose is normal. An elevation of the sedimentation rate and a peripheral neutrophilic leukocytosis are important clues (often neglected) to the diagnosis (Baker et al.).

The foregoing clinical and spinal fluid findings call for immediate MRI imaging or CT, the latter preferably with myelography, to determine the level of the infected mass. If not treated surgically by laminectomy and drainage at the earliest possible time, before the onset of paralysis, the spinal cord lesion, which is due in part to ischemia (compression main of veins), becomes more or less irreversible. Antibiotics in large doses must also be given. Cauda equina epidural abscess without neurologic signs may in many cases be treated solely with antibiotics, although some surgeons favor drainage, which must be undertaken in any case if osteomyelitis develops. When osteomyelitis of a vertebral body is the primary abnormality, the epidural extension may implicate only a few spinal sensory and motor roots, leaving long tracts and other intramedullary structures intact. In some cases with cervical epidural abscesses, stiff neck, fever, and deltoid-biceps weakness are the main neurologic abnormalities.

A slowly progressive and then stabilizing syndrome of incomplete cord compression may occur after apparently successful drainage of an epidural abscess. This is usually caused by the formation of a fibrous and granulomatous reaction at the operative site. Distinguishing this inflammatory mass from residual epidural abscess may be quite difficult, even with enhanced MRI, but persistent fever, leukocytosis, and an elevated sedimentation rate should suggest that surgical drainage of the abscess was incomplete.

**Spinal subdural bacterial infections** also occur and, clinically, are virtually indistinguishable from epidural ones. A clue is provided by the CT myelogram, in which the subdural lesion has a lesser sharp margin and a greater vertical extent. The difference is also apparent on axial MRI. The epidural and subdural infections, if they smolder owing to delayed diagnosis or inadequate therapy, may evolve into a chronic adhesive meningoencephalitis.
In the past, postinfectious myelitis was most often observed in relation to the common exanthems (rubella, rubeola, varicella), the neurologic signs appearing as the sphincter disturbances); and a Brown-Séquard–like syndrome. Variants in our experience have included an almost pure paresthetic illness with posterior column dysfunction and the converse, a symmetrical paraparesis with an incomplete corticospinal and spinothalamic syndrome affecting one side more than the other. These signs evolve over several days, although in a few instances a complete “transverse” involvement of the cord is attained in a matter of hours. More often there is Nonetheless representing the same postinfectious immune process. In most instances that have come under our care in recent years, the MRI has shown T2 signal abnormality in the myelogram. The administration of praziquantel arrested the course of the illness, but the patients were left disabled.

**Meningomyelitis due to Fungus and Parasitic Diseases** A wide variety of fungal and parasitic agents may involve the spinal meninges. Such infections are rare, and some do not occur at all in the United States or are limited to certain geographic areas, particularly among immigrant populations. Actinomyces, Blastomyces, Coccidioides, and Aspergillus may invade the spinal epidural space via intervertebral foramina or by extension from a vertebral osteomyelitic focus. Cryptococcus, which causes meningoencephalitis and rarely a cerebral granuloma, in our experience seldom causes spinal lesions. Hematogenous metastases to the spinal cord or meninges may occur in both blastomycosis and coccidiodomycosis. Occasionally an echinococcal infection of the posterior mediastinum may extend to the spinal canal (epidural space) via intervertebral foramina and compress the spinal cord.

**Schistosomiasis (bilharziasis),** is a recognized cause of myelitis in the Far East, Africa, and South America. The spinal cord is a target for all three common forms of Schistosoma: S. haematobium, S. japonicum, and S. mansoni, but particularly the last of these (see page 780). The schistosomal ova evoke a granulomatous myeloneuropathy. The lesions are destructive of gray and white matter, with ova in arteries and veins leading to obstruction and ischemia (Scrimgour and Gadjeusek). Less often, a localized granuloma gives rise to a compressive cord syndrome and, rarely, the disease takes the form of an acute transverse myelitis with massive necrosis of cord tissue (Queiroz et al. We have studied two patients in whom the spinal cord in the low thoracic and lumbar region was infected approximately 3 weeks after they swam in contaminated water during an African vacation. The CSF showed only a slight elevation of protein, and there was no abnormality in the myelogram. The administration of praziquantel arrested the course of the illness, but the patients were left disabled.

**Myelitis of Noninfectious Inflammatory Type (Acute Transverse Myelitis)**

The spinal cord disorders that make up this category take the form of a leptomeningitis based on either demyelination or necrosis of the tracts in the spinal cord. In their pathogenesis, the critical factor appears to be a disordered immune response to an infection rather than the direct effect of an infectious agent. Varied clinical syndromes are induced, and the basic disease is classified in most textbooks under headings such as acute transverse myelitis, postinfectious myelitis, postvaccinal myelitis, acute multiple sclerosis, and recruting myelitis. While each of these conditions may affect other parts of the nervous system (most often the optic nerves or brain), only the manifest signs are spinal. The aforementioned myelitides or myelopathies are sufficiently distinct to justify their separate classification, for in most cases they run to form; but transitional cases, sharing the clinical and pathologic attributes of more than one disease, are encountered in any large clinical and pathologic material.

**Postinfectious and Postvaccinal Myelitides** The characteristic features of these diseases are (1) their temporal relationship to certain viral infections or vaccinations (see pages 975 to 976); (2) the development of neurologic signs over the period of a few days; and (3) a monophasic temporal course, i.e., a single attack of several weeks’ duration with variable degrees of recovery and no recurrence. These diseases may involve the brain as well as the spinal cord, in which case the process is appropriately designated as acute disseminated encephalomyelitis (ADEM); in others cases the spinal cord is affected predominantly or exclusively—an acute myelitis or inflammatory myelopathy. On the basis of the clinical features of disseminated postinfectious encephalomyelitis and the animal model of experimental allergic encephalomyelitis (EAE), postinfectious myelitis is presumed to be immunologic in nature, reflecting an attack that is more or less confined to spinal cord myelin (see Chap. 36).

The usual history in these cases is for weakness and numbness of the feet and legs (less often of the hands and arms) to develop over a few days, sometimes mimicking the pattern of the Guillain-Barré syndrome. However, an asymmetry of the symptoms and signs, a sensory level on the trunk, or a Babinski sign marks the disease as a myelopathy. Sphincteric disturbances and backache are common in the first days. Headache and stiff neck may or may not be present. There may or may not have been a recent infectious illness, such as a mandible upper respiratory syndrome, but the patient is usually afebrile when the myelopathic symptoms begin. Almost invariably the CSF contains lymphocytes and other mononuclear cells in the range of 10 to 100 (sometimes higher) per cubic millimeter, with slightly raised protein and normal glucose content. In milder cases there may be only 3 or 4 cells per cubic millimeter, making the inflammatory aspect less clear but nonetheless representing the same postinfectious immune process. In most instances that have come under our care in recent years, the MRI has shown T2 signal abnormalities and slight gadolinium enhancement extending over two or three spinal segments (the distinction from multiple sclerosis is discussed below); the cord may be swollen in these regions (Fig. 44-2). Several patients with mild and partial myelitis have had normal MRI studies.

**Figure 44-2 MRI of acute postinfectious myelitis in the sagittals (A) and axial (B) planes. There is T2 signal change and other images showed mild enhancement after gadolinium infusion. The cord is slightly enlarged at the involved level.**

These signs evolve over several days, although in a few instances a complete “transverse” involvement of the cord is attained in a matter of hours. More often there is an incomplete corticospinal and spinothalamic syndrome affecting one side more than the other. Variants in our experience have included an almost pure paresthetic illness with posterior column dysfunction and the converse, a symmetrical paraparesis with analgesia below a level on the trunk but without affection of deep sensation (a syndrome usually associated with cord infarction in the territory of the anterior spinal artery); a variable sensory loss involving the leg and groin on one side or both; a purely lumbosacral or sacral myelopathy (conus syndrome with saddle analgesia and sphincter disturbances); and a Brown-Sequard–like syndrome.

In the past, postinfectious myelitis was most often observed in relation to the common exanthems (rubella, rubeola, varicella), the neurologic signs appearing as the
rash was fading, often with a recurrence of fever. Vaccination against smallpox and rabies was also a frequent cause. The former, of course, is no longer a concern, and rabies vaccine as a cause of myelitic symptoms has virtually disappeared, at least in the United States, with the use of vaccine grown on cultures of human tissue rather than myelinated spinal cord.

In more recent years, practically all human viruses have at one time or another been reported to precede acute myelitis; the large DNA viruses, such as Epstein-Barr and cytomegalovirus, have a proclivity to do so, but hepatitis B, varicella, and enterov- and rhinoviruses have been detected when systematically sought. Mycoplasma is almost unique as a bacterial trigger of the disease, but—as noted earlier—it may also be capable of causing direct infection, leaving the mechanism uncertain. In many instances the connection to a preceding infection is presumed but cannot be proved. Only the associations with EBV, CMV, and Mycoplasma seem certain, based on the regularity of their occurrence. The list of antecedent infections is otherwise much the same as that for the Guillain-Barré syndrome with the notable absence of Campylobacter jejuni, which has not led to myelitis. A pharyngitis, respiratory infection, or conjunctivitis, etc., with or without fever, is likely related if it occurred several days or in a 2- to 3-week period before the onset of neurologic symptoms. Severe headache with or before the fever and neurologic signs suggests Mycoplasma, influenza, or another atypical pneumonic agent, and abnormal liver function tests or severe pharyngitis with cervical adenopathy usually indicates EBV or, less often, CMV infection.

More difficult to understand are the instances of myelitis, including autopsy proven ones, in which the disease develops without an apparent antecedent infection. There is always uncertainty in such cases as to whether the illness is the opening phase of multiple sclerosis (MS) of the type described below, under “Demyelinative Myelitis.” In our cases of transverse myelitis, fewer than half have shown other signs of MS after 20 years (this is a far lower incidence than following a bout of optic neuritis). Also, there is a relapsing form of myelitis, sometimes but not always triggered by an infection, that does not manifest lesions elsewhere in the neuraxis and therefore accounts for an ambiguous relationship to multiple sclerosis. Further discussion of acute transverse myelitis in relation to other demyelinating diseases can be found on page 963.

The pathologic changes take the form of myriads of subpial and perivenular zones of demyelination, with perivascular and meningeal infiltrations of lymphocytes and other mononuclear cells, and para-adventitial pleomorphic histiocytes and microgliaocytes (page 975).

**Treatment** Once symptoms begin, it is doubtful if any treatment other than supportive therapy is of consistent value. One’s first impulse, assuming the mechanism to be an autoimmune disorder, is to administer high doses of corticosteroids—a practice we have followed, but without conviction. Perhaps it is advisable to do so, but there are no trials that have demonstrated the natural course of the illness in a meaningful way. We have also tried plasma exchange and intravenous immune globulin in several patients, with uncertain results, although this approach was seemingly helpful in a few patients.

In general, the prognosis is better than the initial symptoms might suggest. Invariably, the purely myelitic disease improves, sometimes to a surprising degree, but there are examples in which the sequelae have been severe and permanent. Pain in the midthoracic region or an abrupt, severe onset usually indicates a poor prognosis (Ropper and Poskanzer). The authors have several times given a good prognosis for long-term recovery and assurance that no relapse will occur, only to witness a recrudescence of other symptoms at a later date, suggesting that the original illness was one of multiple sclerosis.

**Demyelinative Myelitis (Acute Multiple Sclerosis)** The lesions of acute MS presenting as a myelitis share many of the features of the postinfectious type except that the clinical manifestations of the former tend to evolve more slowly, over a period of 1 to 3 weeks or even longer. Also, their relation to antecedent infections is less certain, and in most recorded examples such events were lacking. The difficulty of distinguishing between an attack of demyelinative and postinfectious myelitis was mentioned above and was emphasized by Ichimura and Shiraki in their study of postrabies inoculation in Japan. In most of their cases, the myelitis took the form of acute MS, but the disease did have the monophasic character and some of the pathologic attributes of the postinfectious variety. However, in other cases of similar onset, the occurrence of subsequent attacks indicated that the basic illness was one of chronic recurrent demyelination, identical to the usual type of MS.

The most typical mode of clinical expression of demyelinative myelitis is with numbness that spreads over one or both sides of the body from the sacral segments to the feet, anterior thighs, and up over the trunk, with coincident weakness and then paralysis of the legs. As this process becomes complete, the bladder is also affected. The sensorimotor disturbance may extend to involve the arms, and a sensory level can be demonstrated on the trunk. The CSF usually shows more dramatic signal changes and gadolinium enhancement than most cases of transverse myelitis, usually extending over several levels (Fig. 44-3). In later imaging studies the involved segments of cord which were initially swollen appear atrophic. The electromyogram (EMG), several weeks or more after the illness has begun, reveals several contiguous denervated myotomes, reflecting damage to the gray matter of those segments. A characteristic feature in most of our cases of necrotic myelopathy without optic neuritis has been a relapsing course, usually with salatory worsening but occasionally punctuated by brief and limited remissions.

**Myelitis (Myelopathy) with Systemic Lupus Erythematosus** A rapidly evolving or subacute myelopathy in association with systemic lupus erythematosus must always be considered in the differential diagnosis of demyelinative myelitis. It is presumed to arise from a microvasculitis of the spinal cord. Proper and Bucknall presented such a case and reviewed 44 others in which a patient with lupus erythematosus developed a transverse myelitis over a period of days. There was back pain at the level of sensory loss, although in the cases we have seen these have been painless. Pleocytosis and elevation of CSF protein were characteristic. The MRI revealed a segmental swelling of the spinal cord. Postmortem examinations of such cases have disclosed widespread vasculopathy of small vessels with variable inflammation and myelomalacia, and, rarely, a vacuolar myelopathy.

Many but not all cases have antiphospholipid antibodies; the relationship of these antibodies to the myelopathy is uncertain (see also page 912). The incidence of lupus myelopathy is not known, but one such case comes to our attention every year or two.

**Acute and Subacute Necrotizing Myelitis and Devic Disease** In every large medical center, occasional examples of this disorder are found among the many patients who present with an acute onset of paraplegia or quadriplegia, sensory loss, and sphincter paralysis. The neurologic signs may erupt so precipitously that a diagnosis of MS cannot be considered. In every large medical center, occasional examples of this disorder are found among the many patients who present with an acute onset of paraplegia or quadriplegia, sensory loss, and sphincter paralysis. The neurologic signs may erupt so precipitously that a diagnosis of MS cannot be considered. In our cases of transverse myelitis, fewer than half have shown other signs of MS after 20 years (this is a far lower incidence than following a bout of optic neuritis). Also, there is a relapsing form of myelitis, sometimes but not always triggered by an infection, that does not manifest lesions elsewhere in the neuraxis and therefore accounts for an ambiguous relationship to multiple sclerosis. Further discussion of acute transverse myelitis in relation to other demyelinating diseases can be found on page 963.

The differential diagnosis of demyelinative myelitis is fully considered in Chap. 36.

**Treatment** Corticosteroids, as outlined for MS (page 973), may lead to a regression of symptoms, sometimes with relapse when the medication is discontinued too soon. Other patients, however, show no apparent response, and a few have even continued to worsen while the medication was being given. Plasma exchange and intravenous immune globulin have reportedly been beneficial in individual cases, particularly in those with an explosive onset (see below). Our results with plasma exchange have been too variable to interpret.

The disease is a variable mixture of acute and chronic myelitis, often with variable residual signs. The relationship of these antibodies to the myelopathy is uncertain (see also page 912). The incidence of lupus myelopathy is not known, but one such case comes to our attention every year or two.

**Myelitis (Myelopathy) with Systemic Lupus Erythematosus** A rapidly evolving or subacute myelopathy in association with systemic lupus erythematosus must always be considered in the differential diagnosis of demyelinative myelitis. It is presumed to arise from a microvasculitis of the spinal cord. Proper and Bucknall presented such a case and reviewed 44 others in which a patient with lupus erythematosus developed a transverse myelitis over a period of days. There was back pain at the level of sensory loss, although in the cases we have seen these have been painless. Pleocytosis and elevation of CSF protein were characteristic. The MRI revealed a segmental swelling of the spinal cord. Postmortem examinations of such cases have disclosed widespread vasculopathy of small vessels with variable inflammation and myelomalacia, and, rarely, a vacuolar myelopathy.

Many but not all cases have antiphospholipid antibodies; the relationship of these antibodies to the myelopathy is uncertain (see also page 912). The incidence of lupus myelopathy is not known, but one such case comes to our attention every year or two.

**Acute and Subacute Necrotizing Myelitis and Devic Disease** In every large medical center, occasional examples of this disorder are found among the many patients who present with an acute onset of paraplegia or quadriplegia, sensory loss, and sphincter paralysis. The neurologic signs may erupt so precipitously that a vascular lesion is assumed. In other cases the disease evolves at a somewhat slower pace, over several days or a week or longer. The main clinical features that distinguish necrotizing myelopathy from the more common types of transverse myelitis are a persistent and profound flaccidity of the legs (or arms if the lesion is cervical), areflexia, and atony of the bladder—all reflecting a widespread panneuritis that involves both the gray and white matter over a considerable vertical extent of the spinal cord—or spinal shock.

A small number of such cases are associated with unilateral or bilateral optic neuritis. This combination of spinal cord necrosis and optic neuritis corresponds to the syndrome described by Devic in 1894 and named neuromyelitis optica (page 966). But nearly all neurologists agree that a similar clinical syndrome involving the optic nerve and spinal cord (usually without necrosis) may be caused infrequently by postinfectious encephalomyelitis and, more often, by MS.

A few or several hundred mononuclear cells per cubic millimeter and increased protein may be found in the CSF, but oligoclonal banding is usually absent. The MRI shows more dramatic signal changes and gadolinium enhancement than most cases of transverse myelitis, usually extending over several levels (Fig. 44-3). In later imaging studies the involved segments of cord which were initially swollen appear atrophic. The electromyogram (EMG), several weeks or more after the illness has begun, reveals several contiguous denervated myotomes, reflecting damage to the gray matter of those segments. A characteristic feature in most of our cases of necrotic myelopathy without optic neuritis has been a relapsing course, usually with salatory worsening but occasionally punctuated by brief and limited remissions. Survival has been the rule, but the neurologic deficits of necrotic myelopathy—unlike those of the demyelinative and postinfectious myelitides described above—tend to be profound and lasting; in a few cases, they have been progressive over weeks or months. None of the treatments we have offered seemed to make a noticeable difference, but some authors have the impression that high-dose corticosteroids, cyclophosphamide, or plasma exchange may have been beneficial in individual cases.
In several cases coming to postmortem examination at variable times after the onset, the acute lesion has proved to be a necrotizing myelitis, not essentially different from the hemorrhagic leukoencephalitis of Hurst or an aggressive form of ADEM, described on page 978, but in a pattern that appears infective, i.e., not respecting the borders of gray and white matter. However, there are also areas of inflammation and demyelination at the edges of the destructive lesions. For this reason the authors agree with Hughes in classifying this condition with the demyelinating diseases. Older lesions will have left the spinal cord cavitated or collapsed over a vertical extent of 5 to 20 cm, often with conical extensions into the gray matter above and below the main area of necrosis. In one of the cases studied by R.D. Adams, in which death occurred many years after the onset of the myelitis, there was an old cavitated, obviously necrotizing lesion and many cerebral ones, the latter typical of MS. Cases of this type emphasize the overlapping relationship between the necrolytic and demyelinating processes. Also, we have been unable to make a clear distinction between the necrotic myelopathy of Devic disease and an identical process occurring without optic neuropathy. In the cases described by Greenfield and Turner as well as by Hughes and in our own (Katz and Roopenian), patients of all ages and both sexes were affected. The optic nerve lesions, when present, tend to be of demyelinating type, much like those of MS.

Under the title “Subacute Necrotic Myelitis,” Fox and Alajouanine and later Greenfield and Turner described a disorder of adult men characterized by an amyotrophic paraplegia that ran a progressive course over several months. An early spastic paraplegia evolved after a few weeks or longer into a flaccid, areflexive one. Sensory loss, at first dissociated and then complete, and loss of spincteric control followed the initial paresis. The CSF protein was considerably elevated but there were no cells. Postmortem examinations in two of the cases of Fox and Alajouanine (11 and 22 months after onset, respectively) and in subsequent ones have shown the lumbosacral segments to be the most severely involved, with progressively less severe affection of the thoracic segments. In the affected areas there was severe necrosis of both gray and white matter with appropriate macrophage and astrocytic reactions. The small vessels seemed to be increased in number; their walls were thickened, cellular, and fibrillary; yet their lumens were not occluded (“angioidplastic”). The veins were also thickened and surrounded by lymphocytes, mononuclear cells, and macrophages. These findings have been difficult to interpret. The importance of spinal venous thrombosis in the pathogenesis has been emphasized, but in the case of Maal and Folks, only one thrombosed anterior spinal vein was seen; in the cases of Fox and Alajouanine, no thrombosed vessels were found. We believe the evidence of venous thrombosis to be unequivocally and are inclined to the view of Antoni and of others, who were impressed with the prominence of large arteries and veins and have even interpreted their pathologic process as an arteriovenous malformation (see further on). However, the more severe involvement of the gray matter, the vascular abnormality simply reflects the neovascular response to spinal cord necrosis. We suggest that only when enlarged and abnormal vessels involve the surface and adjacent parenchyma of the cord (as they did in the cases of Fox and Alajouanine) does the disorder deserve to be designated as Foix-Alajouanine myelopathy; the remaining cases are of the inflammatory-necrotizing type described above.

Rarely, a similar syndrome is produced by an idiopathic granulomatous or necrotizing angiitis that is confined to the spinal cord (Caccamo et al.). In those cases, there has been a persistent and marked pleocytosis and some clinical stabilization with corticosteroids. One of our patients with a similar subacute necrotizing myelitis, seemingly responsive to corticosteroids, persistently had 50 or more cells in the spinal fluid, many of them polymorphonuclear, and died because of inflammatory cerebrospinal hemorrhages; there were multiple occlusions of small vessels surrounding the spinal cord but no well-developed vasculitis. Polyradiculitis nodosa and necrotizing arteritis rarely involve the spinal cord.

Paraneoplastic Myelitis A subacute necrotic myelitis developing in conjunction with a bronchogenic carcinoma was first brought to notice by Mancall and Rosales in 1964. Several dozen cases have been recorded, some in association with lymphomas. The clinical syndrome as we have seen it consists of a rapidly progressive painless loss of motor and then sensory tract function, usually with sphincter disorder. Imaging studies demonstrate an area of T2 signal change or may be normal, in distinction to the nodular enhancing appearance of an intramedullary metastasis or of extradural metastatic disease with cord compression. Actually, in cancer patients, intramedullary metastasis is a more common problem than a paraneoplastic disease as a cause of intrinsic myelopathy. A compressive lesion must always be excluded and, of course, far more frequent than either of these entities, which are discussed in later parts of the chapter.

The CSF may contain a few mononuclear cells and a slightly increased protein, or it may be normal. The lesions are essentially of necrotic type and respect neither gray nor white matter, but the latter is more affected. There is no evidence of an infective-inflammatory or ischemic lesion, for the blood vessels, apart from a modest cuffing with mononuclear cells, are normal. No tumor cells are visible in the CSF, meninges, or spinal cord tissue, and no virus has been isolated. Unlike the case in most of the paraneoplastic neurologic disorders, there is no antineural antibody to act as a diagnostic marker or to connect the neoplasm to the destructive lesion. In particular, this myelopathy does not seem to be a component of the anti-Hu-associated encephalitis-neuropathy spectrum of disease.

In some cases of paraneoplastic myelopathy, the degenerative changes are more chronic, confined to the posterior and lateral funiculi; they are often associated with a diffuse loss of cerebellar Purkinje cells. This latter syndrome has a disproportionately large association with ovarian teratomas. The small vessels seemed to be increased in number; their walls were thickened, cellular, and fibrillary; yet their lumens were not occluded (“angioidplastic”). These findings have been difficult to interpret. The importance of spinal venous thrombosis in the pathogenesis has been emphasized, but in the case of Maal and Folks, only one thrombosed anterior spinal vein was seen; in the cases of Fox and Alajouanine, no thrombosed vessels were found. We believe the evidence of venous thrombosis to be unequivocally and are inclined to the view of Antoni and of others, who were impressed with the prominence of large arteries and veins and have even interpreted their pathologic process as an arteriovenous malformation (see further on). However, the more severe involvement of the gray matter, the vascular abnormality simply reflects the neovascular response to spinal cord necrosis. We suggest that only when enlarged and abnormal vessels involve the surface and adjacent parenchyma of the cord (as they did in the cases of Fox and Alajouanine) does the disorder deserve to be designated as Foix-Alajouanine myelopathy; the remaining cases are of the inflammatory-necrotizing type described above.

Subacute Spinal Neuronitis Whitely and colleagues have drawn attention to a rare but distinctive form of ependymomyelitis of unknown cause, characterized clinically by a spastic, ataxic, and sometimes spastic paraplegia, with or without a sensory level. The CSF protein is increased but there are no cells. This syndrome is, of course, far more frequent than either of these entities, which are discussed in later parts of the chapter.

Subacute Spinal Neuronitis Whitely and colleagues have drawn attention to a rare but distinctive form of ependymomyelitis of unknown cause, characterized clinically by a spastic, ataxic, and sometimes spastic paraplegia, with or without a sensory level. The CSF protein is increased but there are no cells. This syndrome is, of course, far more frequent than either of these entities, which are discussed in later parts of the chapter.

The brunt of the pathologic process falls on the cervical portion of the spinal cord. Widespread loss of interneuronal neurons with reactive gliosis and microglial proliferation, conspicuous lymphocytic cuffing of small blood vessels, and scanty meningeal inflammation are the main findings. Involvement of the white matter is less marked.

The pathophysiology of the rigidity in these cases is not well understood but may be due to the impaired function (or destruction) of Renshaw cells, with the release of toxic myoelastic reflexes (Penry et al.). The painful spasms and dysesthesias relate in some way to neuronal lesions in the posterior roots of the spinal cord and dorsal root ganglia. We agree with Whitely and with Lhermitte and their coworkers that these cases probably represent a rare and obscure form of viral myelitis. Myelonic jerking of the trunk and limbs in a focal or segmental distribution is probably due to neuronal damage that is limited to the spinal cord. We have seen several such cases, usually of regional abdominal or thoracic myoclonus, in otherwise healthy patients and have been unable to determine its cause. Anticonvulsants and antispastic drugs in some combination may partially suppress the myoclonus, and local injection of botulinum toxin has improved the symptoms. Rarely, a similar syndrome complicates vertebral or spinal artery angiography (see below).

VASCULAR DISEASES OF THE SPINAL CORD

In comparison with the brain, the spinal cord is an uncommon site of vascular disease. Blackwood, in a review of 3737 necropsies at the National Hospital for Nervous Diseases, London, in the period 1903 to 1958, found only 9 cases, but in general hospitals such as ours, the incidence is considerably higher. The spinal arteries tend...
not to be susceptible to atherosclerosis, and emboli rarely lodge there. Of all the vascular disorders of the spinal cord, infarction, bleeding, and arteriovenous malformation are the only ones that occur with any regularity, but they are rare in comparison with demyelinating myelitis. In current practice, most cases occur in relation to operations on the aorta, usually the thoracic portion, where the aorta must be clamped for some period of time. An understanding of these disorders requires some knowledge of the blood supply of the spinal cord.

**Vascular Anatomy of the Spinal Cord**
The blood supply of the spinal cord is derived from a series of segmental vessels arising from the aorta and from branches of the subclavian and internal iliac arteries (Fig. 44-4). The most important branches of the subclavian are the vertebral arteries, the segmental branches of which form the rostral origins of the anterior median and posterior and lateral spinal arteries and constitute the major blood supply to the cervical cord. The thoracic and lumbar cord is nourished by segmental arteries arising from the aorta and internal iliac arteries; segmental branches of the lateral sacral arteries supply the sacral cord.

A typical segmental artery divides into an anterior and a posterior ramus (Fig. 44-5). Each posterior ramus gives rise to a spinal artery, which enters the vertebral foramen, pierces the dura, and supplies the spinal ganglion and roots through its anterior and posterior radicular branches. Most anterior radicular arteries are small and some never reach the spinal cord, but a variable number (four to nine), arising at irregular intervals, are much larger and supply most of the blood to the spinal cord. Tributaries of the radiculomedullary supply blood to the vertebral bodies and surrounding ligaments. The venous drainage of the marrow is into the posterior veins forming the spinal plexus. Their importance relates to the pathogenesis of fibrocartilaginous embolism (see further on).

**Infarction of the Spinal Cord (Myelomalacia)**
Ischemic softening of the spinal cord usually involves the territory of the anterior spinal artery, i.e., a variable vertical extent of the ventral two-thirds of the spinal cord. Infarctions in this territory are relatively uncommon, representing 1.2 percent of all strokes (Sandson and Friedman). The resulting clinical abnormalities are generally referred to as the anterior spinal artery syndrome, first described by Spiller in 1909. Atherosclerosis and thrombotic occlusion of the anterior spinal artery itself is quite uncommon, however, and infarction in the territory of this artery is more often secondary to disease of an important extravertebral collateral artery or to disease of the aorta—either advanced atherosclerosis or a dissecting aneurysm—which occludes or shears the important segmental spinal arteries at their origins. We have seen a few instances of myelomalacia in adolescents and young adults in whom no aortic or spinal arterial disease could be demonstrated. An ischemic myelopathy has been reported in cocaine users, including episodes of cord dysfunction resembling transient ischemic attacks. Cardiac and aortic surgery, which requires clamping of the aorta for more than 30 min, and aortic arteriography may occasionally be complicated by infarction in the territory of the anterior spinal artery; more often in these circumstances damage to central neuronal elements is greater than that to anterior and lateral funiculi. Occasionally, polyaerteritis nodosa may cause occlusion of a spinal medullary artery. Systemic cholesterol embolism arising from a severely atheromatous aorta may have the same effect. This type of embolism is prone to occur after surgical procedures, angioplasty, or cardiopulmonary resuscitation. Sometimes the operation precedes the spinal cord infarction by up to 3 weeks, as noted in Dabhog’s series. In almost all such patients, other evidence of widespread embolism can be expected. A quite different progressive ischemic necrosis of the cord occurs in the neighborhood of an arterovenous malformation and is considered later in this chapter (see also the subacute necrotic myelitis of Foix and Alajouanine, described earlier). Infarction of the spinal cord due to fibrocartilaginous embolism is a special type of vascular disease, also discussed further on.

The clinical manifestations of arterial occlusion will, of course, vary with the level and portions of the cord that are infarcted, but common to practically all cases of
infarction in the territory of the anterior spinal artery is pain in the neck or back and the development of motor paralysis and loss of pain and thermal sensation below the level of the lesion, accompanied by paralysis of spinothoracic function. Rarely, infarction is preceded by transient spinal ischemic attacks. The symptoms may develop instantaneously or over an hour or two, but more rapidly than in the myelitides. Radicular pain is sometimes a complaint, corresponding to the upper level of the lesion. Paralysis is usually bilateral, occasionally unilateral, and rarely complete. Except in high cervical lesions, the sensory changes are dissociated; i.e., pain and temperature are preserved, while vibration and position sense are lost (due to interruption of the spinohalamic tracts), but vibration and position sense, two-point discrimination, judgment of degree of pressure, and perception of direction of cutaneous stinging are unpaired (sparing of posterior columns). In this respect the syndrome differs from the acute transverse myelopathy of trauma, but—as mentioned earlier—a similar syndrome can occasionally be produced by a myelitis. In complete cases, the limbs are initially flaccid and areflexic, as in spinal shock from traumatic lesions, followed after several weeks by the development of spasticity, hyperactive tendon reflexes, Babinski signs, and some degree of voluntary bladder control (unless sacral segments have been infarcted). Some patients regain substantial motor function, mainly in the first month but extending over a year (Sandson and Friedman; Cheshire et al.). Infarction in the territory of the posterior spinal arteries is uncommon and does not give rise to a stereotyped syndrome. It may occur with surgery or trauma of the spine or with vertebral artery dissections.

Most spinal cord infarctions can be detected by MRI. After a few days, there are obvious lesions on the T2 image sequences, presumably reflecting edema, over several areas. There may be slight enhancement after infusion of gadolinium. Incomplete infarctions may not be so evident. After several weeks there is myelomalacia, and in the chronic stages the region collapses and is shown to be attenuated on MRI.

A dissecting aneurysm of the aorta—which is characterized by intense interscapular and/or chest pain (occasionally it is painless), widening of the aorta, and signs of impaired circulation to the legs or arms and various organs—gives rise to a number of neurologic syndromes. The most common of these, according to Weisman and Adams, is typically located on the dorsal surface of the cord. The progression of symptoms is due presumably to the chronic venous hypertension and secondary intramedullary ischemic changes, and the clinical effects are also subacute and saltatory in evolution, sometimes painless, although in some cases, as in those of Leech and coworkers, one cannot ascertain the source of the bleeding, even at autopsy. Epidual or subdural bleeding, like epidural abscess, represents a neurologic emergency and calls for immediate radiologic localization and surgical evacuation. Actually, most vascular malformations of the spinal cord do not cause hemorrhage, but instead produce a progressive, presumably ischemic myelopathy, as described below.

Vascular Malformations of the Spinal Cord and Overlying Dura

Hemorrhage into the spinal cord is rare, compared with the frequency of cerebral hemorrhage. The apoplectic onset of symptoms that involve tracts (motor, sensory, or both) in the spinal cord, associated with blood and xanthochromia in the spinal fluid, are the identifying features of hematomyelia. Aside from trauma, hematomyelia is usually traceable to a vascular malformation or a bleeding disease and particularly to the administration of anticoagulants. The same causes may underlie bleeding into the epidural or subdural space and give rise to a rapidly evolving compressive myelopathy. In some cases, as in those of Leech and coworkers, one cannot ascertain the source of the bleeding, even at autopsy. Epidural or subdural bleeding, like epidural abscess, represents a neurologic emergency and calls for immediate radiologic localization and surgical evacuation. Actually, most vascular malformations of the spinal cord do not cause hemorrhage, but instead produce a progressive, presumably ischemic myelopathy, as described below.

Vascular Malformations of the Spinal Cord and Overlying Dura These are well-known lesions, occurring not infrequently and causing both ischemic and hemorrhagic lesions. Some are arteriovenous malformations (AVM) and others more limited fistulas, the distinctions being the size of the nidus of communication between an artery and a vein and the size and location of feeding and draining vessels. The classification of spinal AVMs has been confusing, in part because the enlarged draining veins by which the lesions were identified pathologically are probably a secondary feature. The most useful categorization reflects the appearance and location of the malformation by angiography and by surgical examination. We divide these malformations into three groups: (1) true arteriovenous malformations that may be strictly intramedullary or involve the meninges and surrounding structures such as the vertebral bodies; (2) a variety of intradural perimedullary fistulas; and (3) purely dural fistulas. There is not sufficient pathologic material to determine whether these represent distinct pathologic entities or simply differing degrees and configurations of a common developmental process.

The true AVM, previously referred to as angioma racemosum venosum or dorsal extramedullary arteriovenous malformation, is typically located on the dorsal surface of the lower half of the spinal cord and occurs most often in middle-aged and elderly men (23 of 25 of Logue's cases were male). However, this lesion may occur at any age and at any location in the cord. In only a few cases has there been an associated dermatomal nevus. The clinical picture has been well described by Wyburn-Mason. Acute cramp-like, lancinating pain, sometimes in a sciatic distribution, is often a prominent early feature. It may occur in a series of episodes over a period of years; in others, for weeks, sometimes for months or years. The pain is usually associated with weakness or paralysis of one or both legs and numbness and paresthesias in the same distribution. Wasting and weakness of the legs may introduce the disease in some instances, with uneven progression, sometimes in a series of abrupt episodes. Severe disability of gait is usually present within 6 months, and half of the patients described by Aminoff and Logue were chair-bound within 3 years. The average survival in the past was 5 to 6 years, but the disorder has rarely been fatal in our patients. These lesions infrequently give rise to intramedullary or subarachnoid hemorrhage.

As mentioned, when viewed pathologically, the dorsal surface of the lower cord may be covered with a tangle of veins, some involving roots and penetrating the surface of the cord. The progression of symptoms is due presumably to the chronic venous hypertension and secondary intramedullary ischemic changes, and the abrupt episodes of worsening have been attributed to the thrombosis of vessels. However, angiographic studies sometimes show only a single or a few such dilated draining vessels. Furthermore, there is not sufficient pathologic material to determine whether some of the more prominent venous anomalies represent true venous angiomas (probably they do not). These lesions rarely bleed.

Increasingly, it has been recognized that arteriovenous fistulas that lie within the dura overlying the spinal cord or at times at a distance from the cord are capable of causing a myelopathy, sometimes with several segments distal from the malformation. The majority of spinal AVMs that we have encountered are of this dural type, usually in the region of the thoracic cord and with a connection to the intradural venous system. Some appear to be located in a dural root sleeve and drain into the normal perimedullary coronal venous plexus. The clinical effects are also subacute and saltatory in evolution, sometimes painless, although most of our patients have had a spinal aoehe or sciatica. A caudal myelitis has been reported. These lesions bleed only rarely.

The third type, a pial fistulous arteriovenous communication that involves the superficial aspect of the cord to a variable extent, is the least frequent. In contrast to dorsal arteriovenous malformations, these fistulas tend to involve the lower thoracic and upper lumbar segments or the anterior parts of the cervical enlargement. The patients are often younger, and the sexes are equally affected. The clinical syndrome may also take the form of slow spinal cord compression, sometimes with a sudden exacerbation, or the initial symptoms may be apoplectic in nature, due to either thrombosis of a vessel or a hemorrhage from an associated draining vein that dilates as the abnormal size and shapes into the subarachnoid space or cord (hematomyelia and subarachnoid hemorrhage); the latter complication occurred in 7 of 30 cases reported by Wyburn-Mason.

Any of these lesions, dural or intradural, may be revealed on CT myelography or MRI by the presence of one or more fortuitously discovered enlarged and serpiginous draining vessels in the subarachnoid space; just as often, they are not visualized by these methods. The diagnosis is established through selective angiography, which shows the fistula in the dura overlying the cord or on the surface of the cord itself, but the most conspicuous finding is often the associated early draining vein (Fig. 44-6). As with other spinal cord malformations, demonstration of the fistula may require the painstaking injection of feeding vessels at numerous levels without the suspected lesion, until the main vessel of origin is often some distance away from the malformation. Also, blood flow through the nidus may be so rapid and brief that it is missed. In rare instances the fistula or high-flow arteriovenous malformation lies well outside the cord—for example, in the
In the Klippel-Trenaunay-Weber syndrome, a vascular malformation of the spinal cord is associated with a cutaneous vascular nodule; when the malformation lies in the low cervical region, there may be enlargement of finger, hand, or arm (the hemangiectatic hypertrophy of Parkes Weber). Spinal segmental and tract lesions may occur at any age, but three of our patients were young adults. Vascular occlusion or hemorrhage was responsible. Some of these vascular lesions have been treated by defining and ligating their feeding vessels. In a few reported cases it has been possible to extirpate the entire lesion, especially if it occupied the surface of the cord.

Other vascular anomalies of the spinal cord include aneurysm of a spinal artery with coarctation of the aorta (rare) and telangiectasia, which may or may not be associated with the hereditary hemorrhagic type of Osler-Rendu-Weber. The authors have had under their care over the years several patients with the latter disease who developed acute hemorrhagic lesions of the spinal cord. Also, we have observed several cavernous angiomas of the spinal cord. In two of our cases, an angiographically negative solitary cavernous angioma had been the source of an acute partial transverse myelopathy. The lesions were clearly demonstrable only in the T2-weighted MR images. McCormick and associates have reported similar cases. Characteristically, the cord lesions cause partial syndromes and are followed by considerable recovery of function. There may or may not be blood in the CSF. Rarely, the same disease is responsible for one or more hemorrhagic lesions of the brain. The association of cavernous angiomas with arteriovenous fistulas of the lung is a rare finding, and the latter may be a source of brain abscess. In coarctation of the aorta, the circulation to the lower part of the spinal cord may be deficient, with resultant paresis of the legs, sensory loss, and sphincteric impairment. Or there may be intracranial subarachnoid hemorrhage from a ruptured saccular aneurysm.

**Treatment** By occluding the feeding artery, which is often single, and eliminating the pressure in veins, the course of disease can be arrested and pain reduced (Symon et al). In most of our cases, there has been postoperative improvement in the neurologic state over a few weeks or months. In cases of the racemose AVMs, stripping the enlarged veins along the dorsal cord is no longer considered necessary and may be dangerous. Alternatively, one may obliterate a fistula or an AVM that is limited in size by the use of endovascular techniques, using special catheters and one of a number of types of embolic particles. The procedure is long and painstaking, for the radiologist must identify and embolize all the feeding vessels of the malformation; general anesthesia is utilized in most cases. This approach has certain drawbacks; recanalization occurs in many instances, as does distal occlusion of the venous drainage system. For these reasons, surgical ligation of the arterial supply is still preferred for larger AVMs as the initial procedure. Some surgeons advise a staged approach in which the size of the malformation is first reduced by endovascular techniques. This makes the surgery less complicated. Intradural fistulas are usually treated by endovascular methods. Interventional radiologic techniques have also been used to advantage in the intradural malformations, either as the sole treatment or in combination with surgery. The results of focused radiation have been difficult to evaluate, since most series are too small to judge its effectiveness.

**Fibrocartilaginous Embolism**

In 1961, Naiman and coworkers described the case of an adolescent boy who died of sudden paralysis after an athletic injury and was found to have extensive myelomalacia, due to numerous occlusions of spinal vessels by emboli of nucleus pulposus. Many more such cases have now been observed. Bots and colleagues encountered three cases in one year, and we regularly see one or two such cases each year. The clinical picture is essentially one of spinal apoplexy—the patient experiences the abrupt onset of pain in the back or neck, accompanied by the signs of a transverse cord lesion affecting all sensory, motor, and sphincteric functions and evolving over a period of a few minutes to an hour or more. Occasionally, the syndrome spares the posterior columns thus simulating an anterior spinal artery occlusion. The CSF is normal.

In some of the reported instances the patient had not engaged in excessive activity at the time of onset of spinal cord symptoms. However, this has not been true of our patients, who had been participating in some strenuous activity earlier in the day. A few had fallen and injured themselves on the day of the illness or on preceding days; a direct blow to the back, as occurs during contact athletic sports, was a preceding event in several others. Survival has ranged from hours to months, and some patients survived indefinitely.

At autopsy numerous small arteries and veins within the spinal cord are occluded by typical fibrocartilage, with infarct necrosis of the spinal cord. A ruptured disc of the usual type was not found to be evident in these patients, but high-resolution radiographs in a few of them showed a discontinuity of the cortical bone of the vertebral body adjacent to a collapsed disc and herniation of disc tissue into a vertebral body. A reasonable explanation suggested by Yoganand and colleagues is that the high intravertebral pressure forces the nucleus pulposus material into venules and arteriae of the marrow of the vertebral body, thence into radicular vessels. This unique lesion can sometimes be diagnosed during life by clinical data and MRI of the vertebrae and spinal cord (Tran et al). It has probably been overlooked in many cases of acute ischemic myelopathy.

**Caisson Disease**

Decompression sickness (“the bends”), observed in persons who are subjected to high underwater pressure, affects mainly the upper thoracic spinal cord as a result of nitrogen bubbles that are formed and trapped in spinal vessels. There may be little or no involvement of the brain. Haymaker, who has provided the most complete account of the neuropathologic changes, observed lesions of ischemic type mainly in the white matter of the upper thoracic cord; the posterior columns were more affected than lateral and anterior ones. We have encountered instances in which an almost complete transverse myelopathy was evident soon after the patient resurfaced but improved to some extent, leaving the patient with an asymmetrical and incomplete albeit permanent syndrome. The smallest degree of cord damage is probably a minor myelopathy that affects the anterior or the posterior funiculi, leaving either spasticity of the legs or numbness. Immediate treatment consists of recompression in a hyperbaric chamber; later treatment is symptomatic, with antispastic drugs and physical therapy.

**Spinal Subdural Hemorrhage**

We have had experience with a few instances of spinal subdural hemorrhage that presented with excruciating thoracic back pain of such severity as to cause a bizarre, almost psychotic, reaction (Swann et al). The neck becomes slightly stiff and there may be a headache, suggesting subarachnoid hemorrhage. However, signs of a myelopathy do not appear, indicating that the bleeding is confined to the pliable subdural spaces surrounding the cord. This syndrome is rare and not readily recognized. Lumbar puncture yields dark yellow-brown spinal fluid. The color is imparted by methemoglobin and reflects the presence of adjacent, walled-off blood. Usually there are also some red blood cells in the CSF, suggesting seepage into the subarachnoid space from adjacent clot. CT myelography shows a subdural collection, with characteristic smooth borders; when drained operatively, this is found to be blood clot. Usually no vascular malformation is found and the cause remains obscure. Trauma or anticoagulation underlie a few cases. The symptoms resolve in 1 or 2 weeks, after removal of the subdural hematoma. Small collections may be managed without surgery, in which case corticosteroids may be helpful.

**Figure 44-6** Angiographic injection of a low lumbar radicular vessel demonstrating a vascular blush of a fistula in the dura overlying the lumbar cord (small arrow) and a prominent early-draining vein (large arrow), which was barely seen on a CT myelogram and was not seen on MRI. This dural arteriovenous malformation caused a subacute myelopathy involving the lumbosacral cord.
THE SYNDROME OF SUBACUTE OR CHRONIC SPINAL PARAPARESIS WITH OR WITHOUT ATAXIA

The gradual development of weakness of the legs is the common manifestation of several diseases of the spinal cord. A syndrome of this type—including ataxia of gait, beginning insidiously in late childhood or adolescence, and progressing steadily—is usually indicative of hereditary spinocerebellar degeneration (Friedreich ataxia). Other variants (see Chap. 39) include acute anterior horn cell disease, multiple sclerosis, and AIDS-related encephalopathy. The multiple sclerosis type is being increasingly recognized; syphilitic meningomyelitis is now quite uncommon. In middle and late adult life, cervical spondylisis, subacute combined degeneration of the cord (vitamin B₁₂ deficiency), combined system degeneration of the non–pernicious anemia type, demyelinating myelopathy (MS), radiation myelopathy, tropical spastic paraplegia, spinal arachnoiditis, and spinal syringomyelia, particularly menigiroma, are the important diagnostic considerations. In most forms of subacute and chronic spinal cord disease, spastic paraparesis is much more prominent than posterior column ataxia (Friedreich ataxia and myelopathy due to vitamin B₁₂ deficiency are notable exceptions).

Spinal Multiple Sclerosis

(See also Chap. 36)

Ataxic paraparesis is among the most common manifestations of MS. Asymmetrical affection of the limbs and signs of cerebral, optic nerve, brainstem, and cerebellar involvement usually provide confirmatory diagnostic evidence. Nevertheless, purely spinal involvement may occur, no lesions being found outside the spinal cord even at autopsy. A frequent problem in diagnosis is posed by the older adult patient who is not known to have had MS in earlier life (previous episodes having been asymptomatic or forgotten). The secondary progressive stage in this group is thought to be consequent to recurrent demyelinative attacks. But there is another group in which slowly advancing neurologic deterioration represents the primary manifestation of the disease. The National Hospital Research Group examined 20 cases of the secondary progressive type and 20 of the primary type by gadolinium-enhanced MRI of the spinal cord and brain and found new lesions in only 3 of each group (Kidd et al). They suggest that the progression correlates better with progressive atrophy of the spinal cord than with recurrent demyelinative lesions. In both groups the lesions may be differentiated from cervical disc disease, spondylisis, and tumor. As previously discussed, the main aids in diagnosis are the CSF findings (minor pleocytosis and oligoclonal IgG abnormalities), present in 70 to 90 percent of cases, the demonstration by evoked potential studies of lesions in the optic nerves or in the auditory and sensory tracts, and particularly MRI, which may disclose unsuspected white matter lesions in the spinal cord and brain.

Cervical Spondylisis with Myelopathy

It has been stated, correctly in our opinion, that this is the most frequently observed myelopathy in general practice. Basically a degenerative disease of the spine involving the lower and midcervical vertebrae, it narrows the spinal canal and intervertebral foramina and causes progressive injury of the spinal cord, roots, or both.

Historical Note

Key, in 1838, probably gave the first description of a so-called spondylotic bar. In two cases of compressive myelopathy with paraplegia, he found "a projection of the intervertebral substance, or rather the posterior ligament of the spine, which was thickened and presented a firm ridge which had lessened the diameter of the canal by nearly a third. The ligament, where it passes over the intervertebral substance, was found to be ossified." In 1892, Horsley performed a cervical laminectomy in such a patient; a "transverse ridge of bone" was found to be compressing the spinal cord at the level of the sixth cervical vertebra. Thereafter, operations were performed in many cases of this sort, and the tissues removed at operation were repeatedly misidentified as benign cartilaginous tumors or "chondroma." In 1928, Stookey described in detail the pathologic effects upon the spinal cord and roots of these "ventral extradural chondromas." Peet and Echols, in 1934, were probably the first to suggest that the so-called chondromata represented protrusions of intervertebral disc material. This idea gained wide credence after the publication, in the classic article on ruptured intervertebral disc by Mixter and Barr: Although their names are usually associated with the lumbar disc syndrome, 4 of their original 19 cases were instances of cervical disc disease.

Also of historical importance is Gowen's original account, in 1892, of vertebrolysis exostoses, in which he described osteophytes that protrude from the posterior surfaces of the vertebral bodies and encroach upon the spinal canal, causing slow compression of the cord as well as bony overgrowth in the intervertebral foramina, giving rise to radicular pain. Gowers correctly predicted that these lesions would offer a more promising field for the surgeon than other kinds of vertebral tumors.

For some reason, there was little awareness of the frequency and importance of spondylotic myelopathy for many years after these early observations had been made. A few cases of acute cord injury and acute disc herniation in the cervical region were described. In 1948, Russell Brain, who put cervical spondylisis on the neurologic map, so to speak, he drew a distinction between acute rupture and protrusion of the cervical disc (often traumatic and more likely to compress the nerve roots than the spinal cord) and chronic spinal cord and root compression consequent upon disc degeneration and associated osteophytic outgrowths (hard disc) as well as changes in the surrounding joints and ligaments. In 1957, Payne and Spillane documented the importance of a smaller-than-normal spinal canal in the genesis of myelopathy in patients with cervical spondylisis. These reports were followed by a spate of articles on the subject (see Wilkinson). Rowland's review of the natural history of cervical spondylisis and the results of surgical therapy is a useful modern reference, as is that of Uttley and Monro.

Symptomatology

In the characteristic syndrome consists of varying combinations of the following tetrad: (1) painful, stiff neck; (2) pain in the neck, shoulders, and upper arms (brachialgia) that may be aching or radicular (sharply and radiating); (3) spastic leg weakness with Babinski signs and unsteadiness of gait; and (4) numbness and paresthesias. The latter symptoms typically involve the distal limbs, especially the hands, but are infrequently the earliest symptoms. Variations of these symptoms are elaborated below. Each of the components may occur separately, or they may occur in several combinations and sequences.

With reference to the first of these symptoms, in any sizable group of patients beyond 50 years of age, about 40 percent will be found to have some clinical abnormality of the neck, usually crepitus or pain, with restriction of lateral flexion and rotation (less often of extension). Ball and colleagues, in a survey of 50 patients, all of them over 50 years of age and none with neurologic complaints, found that 75 percent showed radiographic evidence of narrowing of the cervical spinal canal due to osteophytic outgrowths of the posterior vertebral bodies or to narrowing of the intervertebral foramina due to osteoarthropathy at the apophyseal joints; thickening of the ligaments (both the ligamentum flavum posteriorly and the posterior longitudinal ligament anteriorly) adds to the narrowing of the canal. About half of the patients with radiologic abnormalities showed physical signs of root or cord involvement (changes in the tendon reflexes in the arms, briskness of reflexes and impairment of vibratory sense in the legs, and sometimes Babinski signs). The occasional finding of a Babinski sign in older individuals who had never had a stroke or complained of neurologic symptoms may be explained by an otherwise silent cervical osteophytes (Savitsky and Madinick).

In patients with only shoulder and arm symptoms as well as those in whom these symptoms are combined with a disorder of the legs, pain is the most frequent symptom. It is centered in the back of the neck, often radiating to an area above the scapula. When brachialgia is also present, it takes several forms: a stabbing pain in the pre- or postaxial border of the limb, extending to the elbow, wrist, or fingers; or a persistent dull ache in the forearm or wrist, sometimes with a burning sensation. Discomfort may be elicited by coughing, Valsalva maneuver, or neck extension, or neck flexion may induce electrical feelings down the spine (Lhermitte symptom). Rarely, the pain is referred submentally. Frequently patients also complain of numbness or paresthesias, most often in one or two digits, a part of the palm, or a longitudinal band along the forearm. Frequently, patients describe their fingers and hands as feeling constantly swollen. Slight clumsiness or weakness of a hand is another complaint.

The biceps and brachioradial reflexes may be depressed, sometimes in association with an increase in the triceps and finger reflexes. The hand or forearm muscles, if affected, may be wasted. A scapular pull test, with the patient seated and the hands together behind the back, may be indicative of some nerve root irritation.

The third part of the typical syndrome, spastic legs from a compressive myelopathy, most often presents as a complaint of weakness of a leg and slight unsteadiness of gait. The whole leg or the quadriceps feels stiff and heavy and gives out quickly after exercise. Mobility of the ankle may be reduced, and the advancing toe of the leg may be more stiffly extended. Sensation is usually normal, but sometimes tingling or prickling of the feet (all indicative of a lesion of the posterior columns) as well as the Romberg sign are the most conspicuous sensory findings. This imparts a "tabletlike"
unsteadiness to the gait. These sensory defects tend also to be asymmetrical. Rarely the sensorimotor pattern takes the form of a Brown-Séquard syndrome. Infrequently, paresthesias and dysesthesias in the lower extremities and trunk may be the principal symptoms; far less often there are sensory complaints on the face, ostensibly corresponding to compression of the trigeminal sensory tract in the upper cervical cord.

As the myelopathy progresses, sometimes intermittently, both legs become weaker and more spastic. Sphincteric control may then be altered; slight hesitancy or precipitation of micturition are the usual complaints; frank incontinence is infrequent. In the more advanced form of this condition, walking requires the aid of a cane or canes or a walker; in some cases all locomotion ultimately becomes impossible, especially in the elderly patient. Abrupt worsening, even paraplegia or quadriplegia, may follow forceful flexion or extension injuries of the neck, as indicated below.

Pathologic Changes The fundamental lesion is a fraying of the annulus fibrosus, with extrusion of disc material into the spinal canal. The disc becomes covered with fibrous tissue or partly calcified. Another common lesion is bulging of the annulus without extrusion of nuclear material; this may also be associated with the formation of osteophytes and transverse bony ridges. The latter changes, unlike ruptured discs that occur mainly at the C5-6 or C6-7 interspace, often involve higher interspaces and occur at several levels. The adjacent dura mater may be thickened and adherent to the posterior longitudinal ligament. The underlying pia-arachnoid is also thickened and the adjacent laminar hypertrophy may contribute to compression of the cord or the nerve roots. This series of pathologic changes is frequently ascribed to hypertrophic osteoarthritis. However, in lesser degree, the osteophyte formation and ridging are so frequently observed in patients who have no other signs of arthritic disease that this explanation is surely incorrect. Subclinical trauma is far more likely, in the authors' opinion.

When a root is compressed by osteophytic overgrowth, the dural sleeve is thickened and occluded and the root fibers are damaged. Usually the fifth, sixth, or seventh cervical roots are affected in this way, both the anterior and posterior or only the anterior, on one or both sides. A small neurona may appear proximal to the site of anterior root compression.

The dura is ridged and the underlying spinal cord is flattened. The root lesions may lead to secondary wedge-shaped areas of degeneration in the lateral parts of the posterior columns at higher levels. The most marked changes in the spinal cord are at the level(s) of compression. There may be zones of demyelination or focal necrosis at the points of attachment of the denticlate ligaments (which tether the spinal cord to the dura) and zones of necrosis in the posterior and lateral columns as well as loss of nerve cells. The latter lesions, often asymmetrical, are attributed by Hughes to ischemia.

Pathogenesis The particular vulnerability of the lower cervical spine to degenerative change has no ready explanation. Most likely it is related in some way to the high degree of mobility of the lower cervical vertebrae, which is accentuated by their situation next to the relatively immobile thoracic spine.

The mechanism of spinal cord injury would seem to be one of simple compression and ischemia. When the spinal canal is diminished in its anteroposterior dimension at one or several points, the space available for the spinal cord is insufficient. However, the presence and degree of cord injury correlate inexactlly with the anteroposterior dimensions of the spinal canal, since there is considerable variability in the diameter from individual to individual. The range of narrowing that produces symptomatic cervical spondylosis is from 7 to 12 mm (normal, 17 to 18 mm). One must consider, therefore, several additional mechanisms by which the cord might be damaged. The effects of the natural motions of the spinal cord during flexion and extension of the neck are probably important in this respect. Adams and Logue confirmed the observation of O'Connell that, during full flexion and extension of the neck, the cervical cord and dura move up and down. The spinal cord is literally dragged over protruding osteophytes and hypertrophied ligaments; conceivably it is this type of intermittent trauma that progressively injures the spinal cord. It has also been shown that the spinal cord, displaced posteriorly by osteophytes, will be compressed by the infolding ligamentum flavum each time the neck is extended (Stiellmann and Blackwood). Segmental ischemic necrosis resulting from intermittent compression of spinal arteries or from compression (possibly spasm) of the anterior spinal artery has also been postulated. Most neuropathologists favor the idea of intermittent cord compression between osteophytes anteriorly and ligamentum flavum posteriorly, with an added vascular element accounting for the scattered lesions deep in the cord. Trauma from sudden extreme extension, as in a fall, severe whiplash injury, or chiropractic manipulation, or from a lesser degree of retraction of the head during myelography, tooth extraction, or a tonsillectomy may be an additional factor, particularly in patients with congenitally narrow canals.

Diagnosis When pain and stiffness in the neck, brachialgia, and sensorimotor-reflex changes in the arms are combined with signs of myelopathy, there is little difficulty in diagnosis. When the neck and arm changes are inconspicuous or absent, the diagnosis becomes more difficult. The myelopathy must then be distinguished from the late, progressive form of spinal MS. Since posterior vertebral osteophytes and other bony alterations are frequent in the sixth and seventh decades, the question must be answered in any given case is whether the vertebral changes are related to the neurologic abnormality. The finding of some degree of sensorimotor or reflex change corresponding only to the level of the spinal abnormalities is a point that always favors spondylocytic myelopathy. A lack of such corresponding changes and the presence of oligocellular bands and signs of lesions in the optic nerves and brain argue for demyelinative myelopathy. Both MRI and CT myelography become critical in such cases (Fig. 44-7). The MRI tends to overestimate the degree of cord compression by an osteophyte, but clear deformation of the cord into the shape of a bean, obliteration of the surrounding CSF spaces and the signal due to fat surrounding the cord, and T2 signal changes within the cord all support the diagnosis. Contrast myelography with the patient supine and lateral views taken during flexion and extension of the neck are also useful diagnostic procedures. There should be flattening of the cord and considerable encroachment on the CSF space at that level, not simply an impingement or slight deformation of the normal oval shape of the cord.

Figure 44-7 MRI in a patient with symptomatic cervical spondylosis. The spinal cord at C4-5 and C5-6 is flattened on its ventral surface by spondylocytic bars and on its posterior surface by ligamentous hypertrophy. Axial images are required to confirm that the cord is truly compressed and that the subarachnoid space is nearly or completely obliterated.

It is said that spondylotic myelopathy may simulate amyotrophic lateral sclerosis (amyotrophy of arms and spastic weakness of the legs). This has seldom been a diagnostic problem in our experience. We have observed only a few patients with spondylotic myelopathy who exhibited an absolutely pure motor syndrome, i.e., one in which there was no cervical or brachial pain and no sensory symptoms in the arms or impairment of vibratory or position sense in the legs. A pure spastic paraparesis is more likely to be a manifestation of MS, hereditary spastic paraplegia, motor neuron disease (primary lateral sclerosis), HTLV-I myelopathy, or the carrier state of adrenoleukodystrophy.

When imbalance, both perceived by the patient and observed in tests of walking, is a major symptom, spondylosis must be differentiated from a number of acquired large-fiber polyneuropathies, particularly inflammatory or immune types and the more benign sensory neuropathy of the aged (see page 1414). Loss of tactile carrier state of adrenoleukodystrophy.

The special problems of spondylotic radiculopathy are discussed on pages 224 and 227.
**Treatment** The slow, intermittently progressive course of cervical myelopathy with long periods of relatively unchanging symptomatology makes it difficult to evaluate therapy. Assuming that the prevailing opinion of the mechanisms of the cord and root injury is correct, the use of a soft collar to restrict anteroposterior motions of the neck seems reasonable. This form of treatment alone may be sufficient to control the discomfort in the neck and arms. Only exceptionally in our experience has arm and shoulder pain alone been sufficiently severe and persistent to require radicular decompression unless there is a laterally protruded disc.

Many of our patients have been dissatisfied with this passive approach and dislike or refuse to wear a collar for prolonged periods. If posterior osteophytes have narrowed the spinal canal at several interspaces, a posterior decompressive laminectomy with severance of the dentate ligaments helps to prevent further injury. The results of such a procedure are fairly satisfactory (Epstein and Epstein); in fully two-thirds of the patients, improvement in the function of the legs occurs, and in most of the others, progression of the myelopathy is halted. The operation carries some risk; rarely, an acute quadriplegia—due, presumably, to manipulation of the spinal canal and damage to nutrient spinal arteries—has followed the surgical procedure. When one or two interspaces are the site of osteophytic overgrowths, their removal by an anterior approach has given better results and carries less risk. The surgical methods and their relative advantages are reviewed by Ebersold et al.

However, the long-term results after surgical treatment are less than satisfactory. Ebersold and colleagues evaluated the outcome in 84 patients in whom the median duration of follow-up was 7 years. In the group of 33 patients who had undergone anterior decompressive procedures, 18 had improved, 9 were unchanged, and 6 had deteriorated. Of the 51 patients who underwent posterior decompression, 19 had improved, 13 were unchanged, and 19 were worse at their last follow-up examinations. These results, similar to those of most other series, indicate that the long-term outcome is variable and that a significant proportion, even after adequate decompression and initial improvement, have persistent symptoms or undergo later functional deterioration.

**Lumbar Stenosis** This is another spondylotic abnormality, seen with particular frequency in older individuals, particularly men. Usually it declares itself by numbness and weakness of the legs, sometime with poor control of sphincters. There is generally no pain or only a spine ache that fluctuates from day to day. A notable feature is induction or aggravation of the neurologic symptoms upon standing and walking (neurologic claudication). See page 218 for further discussion.

**Ankylosing Spondylitis** This rheumatologic condition of the spine is due to inflammation at the sites of ligamentous insertions into bone that leads to an intense calcification at these and adjacent sites. The sacroiliac joints and lumbar spine are most affected, as discussed on page 220, but as the disease advances, the entire spine becomes fused and rigid. The biomechanics of the rigid spine make it susceptible to fracture. The most common complication is a spinal stenosis and cauda equina syndrome. Bartleson and associates described 14 patients (and referred to 30 others in the medical literature) who, years after the onset of spondylitis, developed sensory, motor, reflex, and sphincter disorders referable to L4, L5, and the sacral roots. Surprisingly, the spinal canal was not narrowed and the caudal sac was actually dilated. Confavreux et al. have presented evidence that enlargement of the lumbar dural sac is due to a defect in resorption of the CSF. There are usually arachnoidal diverticulae of the posterior root sleeves, but no other explanation can be given for the radicular symptoms and signs, which can be verified by electromyography. Surgical decompression has not benefited the patients, nor has corticosteroid therapy. This condition occasionally occurs at higher levels and gives rise to a myelopathy. We have observed similar symptoms in the cervical region and also with root-sleeve diverticulae.

The most hazardous complication of ankylosing spondylitis is compression of the cord itself, in which a seemingly minor trauma has resulted in fracture-dislocation. Fox and colleagues from the Mayo Clinic treated 31 such instances in a 5-year period; the majority of unstable fractures that required surgical fixation were in the cervical region, and several patients had fracture-dislocations at two levels. The instability at the upper spinal levels may be difficult to detect radiologically, and caution should be observed in allowing patients to resume full activity after a neck injury if the cervical spine is seen to be involved by spondylitis. Careful flexion and extension x-ray views usually but not always demonstrate the instability.

Multiple arachnoid cysts in the thoracic or lumbar region have been associated with a surgical cord syndrome in ankylosing spondylitis and in Marfan disease.

**Ossification of the Posterior Longitudinal Ligament (OPLL)** Compressive cervical myelopathy due to this process occurs almost exclusively in patients of Japanese extraction and has been demonstrated to us by colleagues in Hawaii. The clinical signs are much the same as those of cervical spondylitis, but the radiologic appearance is unique. The ligamentous calcification can be seen on plain films, CT scan, and MRI, and may be mistaken for spondylotic change. The ossified areas may enlarge to form bone marrow. Laminoplasty with enlargement of the spinal canal has been successful.

**Paget Disease (Osteitis Deformans)** Enlargement of the vertebral bodies, pedicles, and laminae in Paget disease may result in narrowing of the spinal canal. The clinical picture is one of spinal cord compression. Plasma alkaline phosphatase concentrations are high, and the typical bone changes are seen in radiographs. Usually several adjacent vertebrae of the thoracic spine are affected. Other parts of the skeleton are also involved (see below), which facilitates diagnosis. Posterior surgical decompression, leaving the pedicles intact, is indicated if there is sufficient stability of the vertebral bodies to prevent collapse. Medical management includes the use of nonsteroidal anti-inflammatory drugs for persistent pain; calcitonin to reduce pain and plasma levels of alkaline phosphatase; and cytotoxic drugs such as plicamycin and etidronate disodium to reduce bone resorption (see Singer and Kranke).

**Other Spinal Abnormalities with Myelopathy**

The spinal cord is obviously vulnerable to any vertebral maldevelopment or disease that encroaches upon the spinal canal or compresses its nutrient arteries. Some of the common ones are listed below.

**Anomalies at the Craniocervical Junction** Of these, congenital fusion of the atlas and foramen magnum is the most common. McCrae, who described the radiologic features of more than 100 patients with bony abnormalities at the craniocervical junction, found a partial or complete bony union of the atlas and foramen magnum in 25% of the cases. At the time that the odontoid process was less than 10 mm, there were signs of spinal cord compression. Fusion of the second and third cervical vertebrae is a common anomaly but as well does not seem to be of clinical significance.

**Abnormalities of the Odontoid Process** These were found in 17 cases of McCrae's series. There may be complete separation of the odontoid from the atlas or chronic atlantoaxial dislocation (atlas displaced anteriorly in relation to the axis). These abnormalities may be congenital or the result of injury and are known causes of acute or chronic spinal cord compression and stiffness of the neck.

Rheumatoid arthritis is another cause of atlantoaxial dislocation. The ligaments that attach the odontoid to the atlas and to the skull and the joint tissue are weakened by the destructive inflammatory process. The subsequent dislocation of the atlas on the axis may remain mobile or become fixed and give rise to an intermittent or persistent mild to moderate paraparesis or quadriplegia. Similar effects may result from a forward subluxation of C4 on C5 (see Nakano et al.). Atlantoaxial dislocation is known to be a cause of collapse and sudden death. If the upper cervical cord is compressed, the odontoid process must be removed and C1–C2 decompressed and stabilized. However, the long-term results after surgical treatment are less than satisfactory. Ebersold and colleagues evaluated the outcome in 84 patients in whom the median duration of follow-up was 7 years. In the group of 33 patients who had undergone anterior decompressive procedures, 18 had improved, 9 were unchanged, and 6 had deteriorated. Of the 51 patients who underwent posterior decompression, 19 had improved, 13 were unchanged, and 19 were worse at their last follow-up examinations. These results, similar to those of most other series, indicate that the long-term outcome is variable and that a significant proportion, even after adequate decompression and initial improvement, have persistent symptoms or undergo later functional deterioration.

**Platybasia and Basilar Invagination** Platybasia refers to a flattening of the base of the skull (the angle formed by intersection of the plane of the clivus and the plane...
of the anterior fossa is greater than 135 degrees). Basilar impression or invagination has a somewhat different meaning—namely, an upward bulging of the occipital condyles; if the condyles, which bear the thrust of the spine, are displaced above the plane of the foramen magnum, basilar invagination is present. Each of these abnormalities may be congenital or acquired (as in Paget disease); frequently they are combined. They give rise to a characteristic shortness of the neck and a combination of cerebellar and spinal signs. A normal-pressure hydrocephaus may also develop.

**Tethered Cord** This developmental anomaly is discussed fully in Chap. 38. A progressive cauda equina syndrome with prominent urinary difficulties, and varying degrees of spasticity are the usual presentations.

**Syphilitic Meningomyelitis**

Here, as in MS, the degree of ataxia and spastic weakness is variable. A few patients have an almost pure state of spastic weakness of the legs, requiring differentiation from motor system disease and familial spastic paraplegia. Such a syndrome, formerly called Erd’s spastic paraplegia and attributed to meningovascular syphilis, is now recognized as being nonspecific. In a minority of patients, sensory ataxia and other posterior column signs predominate, and ventral roots are involved in the chronic meningeal inflammation. There may be signs of segmental amyotrophy, hence the term syphilitic amyotrophy of the upper extremities with spastic paraplegia. Confirmation of this diagnosis depends on finding a lymphocytic pleocytosis, an elevated protein and gamma globulin, and a positive serologic reaction in the CSF. Other aspects of this disease and treatment are discussed on page 767.

**Subacute Combined Degeneration of the Spinal Cord (SCD)**

This form of spinal cord disease is due to vitamin B<sub>12</sub> deficiency and is fully described in Chap. 41. Almost invariably it begins with bilateral symptoms and signs of posterior column involvement, which, if untreated, is followed within a matter of several weeks or months by spastic paraparesis due to affection of the corticospinal tracts. Of particular importance is the fact that SCD is a treatable disease and that the degree of reversibility is dependent upon the duration of symptoms before specific treatment is begun. There is a premium, therefore, on early diagnosis.

**Combined System Disease of Non–Pernicious Anemia Type**

This term refers to an intrinsic degenerative disease of the spinal cord, somewhat more common than SCD and affecting the posterior and lateral columns (in this sense, a combined system disease). There is no association with vitamin B<sub>12</sub> or folate deficiency. In this syndrome, in distinction to SCD, signs of corticospinal tract disease usually precede those of the posterior columns and are more prominent throughout the illness, which is slowly and chronically progressive. Little is known of its pathologic basis or cause.

Progressive spastic or spastic-ataxic paraparesis of a chronic, irreversible type may also develop in conjunction with chronic, compensated liver disease (page 1185); with AIDS; in certain cases of adrenoleukodystrophy, particularly in the symptomatic heterozygote, i.e., the female carrier (page 1035); in tropical spastic paraplegia (HTLV-I); in radiation myelopathy; and in adhesive spinal arachnoiditis, which is discussed below.

**Spinal Arachnoiditis (Chronic Adhesive Arachnoiditis)**

This is a relatively uncommon spinal cord disorder that was introduced in relation to the subject of low back pain (page 219). It is characterized clinically by a combination of root and spinal cord symptoms that may mimic intraspinal tumor. Pathologically there is opacification and thickening of the arachnoidal membranes and adhesions between the arachnoid and dura—the result of proliferation of connective tissue. The subarachnoid space is unevenly obliterated. In this sense, the term arachnoiditis is not entirely appropriate, although it seems likely that the connective tissue overgrowth is a reaction to an antecedent arachnoidal inflammation. Some forms of arachnoiditis can be traced to syphilis or to a subacute, therapeutically resistant meningitis of another type. Still others have followed the introduction of a variety of substances, most no longer used, into the subarachnoid space for diagnostic or therapeutic purposes. These include penicillin and other antibiotics, iodinated and other contrast media, and iopanoic acid. At one time, many examples of adhesive arachnoiditis were observed following spinal anesthesia, occurring soon afterward or after an interval of weeks, months, or even years. We observed more than 40 such cases. This complication was eventually traced to a detergent that had contaminated vials of procaine. If enough of the contaminant was injected, an areflexic paralysis of the legs and sphincters of bladder and bowel and sensory loss in the legs developed within a few days, along with considerable pain. More pernicious, however, was a delayed meningoencephalopathy that developed within a few months to a few years, causing a spastic paraparesis, sensory loss, and incontinence of sphincters. Still common is a restricted form of arachnoiditis that complicates a series of operations for lumbar disc disease (lumbar arachnoiditis). Less convincing are cases of arachnoiditis attributed to closed spinal injuries. In many cases no provocative factor can be recognized. A familial form has been reported by Duke and Hashimoto, but we have had no experience with it.

**Clinical Manifestations** Spinal arachnoiditis may occur at any age, although the highest incidence of onset of symptoms is between 40 and 60 years; it is rare below the age of 20. Symptoms may occur in close temporal relation to an acute arachnoidal inflammation or may be delayed for weeks, months, or even years. The commonest mode of onset is with pain in one or more sensory nerve roots, first on one side, then on both, in the lumbofemoral regions. The pain has a burning, stinging, or aching quality that is persistent. The skin is normal, sensitive, and unchanged. Abnormalities of tendon reflexes are common, but weakness and atrophy, the results of damage to anterior roots, are less frequent findings and tend to occur in cases involving the cauda equina. In thoracic lesions, symptoms of root involvement may antedate those of cord compression by months or years. Sooner or later, however, there is involvement of the spinal cord, manifest by a slowly progressive spastic paralysis with axon fiber disturbances.

The localized lumbar arachnoiditis associated with repeated disc surgery (the common variety being seen in chronic pain clinics) is characterized by back and leg pain with other inconstant signs of radiculopathy (loss of tendon reflexes, weakness, and variable degrees of sensory loss), usually bilateral.

The CSF is abnormal during the acute stage in practically all cases of adhesive arachnoiditis. In some there is a moderate lymphocytic pleocytosis, occurring soon after the inciting event, but the striking finding is a partial or complete obliteration of the spinal subarachnoid space, sometimes extreme in degree. In the localized lumbar arachnoiditis, referred to above, the CSF may be normal or show only a slight increase in protein content. The myelographic appearance of arachnoiditis is characteristic (patchy dispersion of the column of dye and a “candle-guttering” appearance that was most evident with oil-based contrast media); MRI reveals a loss of the normal ring of CSF or localized loculations of CSF (see Fig. 11-6). These ancillary procedures and the CSF formula allow one to make the diagnosis with certainty.

**Pathologic Features** In advanced cases the subarachnoid space is completely obliterated and the roots and cord are strangulated by the thickened connective tissue. Subpial nerve fibers of the cord are destroyed to a varying extent, and peripherally placed fibers of the posterior and lateral columns undergo secondary degeneration. Where the pathologic process is confined to relatively circumscribed portions of the cord, the subarachnoid space may be occupied by localized chronic inflammatory exudate (high-protein fluid, meningeitis serosa circumscripta). The rare association of spinal arachnoiditis and syringomyelic cavitation of the cord is considered further on in this chapter.

**Treatment** In the early stages of arachnoiditis, corticosteroids have been given systemically to control the inflammatory reaction and to prevent progress of the disease, but their value is questionable. Surgery may be effective in the rare case of localized “cyst” formation and cord compression. Severe radicular pain can be effectively relieved by posterior rhizotomy, but there is a strong tendency for the pain to return after an interval of several months or a year or two. For chronic adhesive lumbar arachnoiditis, in which diffuse back and limb pain is the most distressing symptom, there is no effective surgical or medical treatment, although relief has been reportedly provided in isolated instances by painstaking microsurgical dissection of the lumbar roots. Administration of corticosteroids, systemic and epidural, has not been consistently beneficial but may be tried. Transcutaneous stimulator treatment and gabapentin may also be tried.

**Subarachnoid Hemorrhage due to Dural Tear**

Exceedingly violent trauma to the spinal canal or skull can be associated with arachnoidal and dural tears; the associated neural injury dominates the picture, and the dural tear may require repair in order to minimize the development of a meningitis. More difficult to understand is the occurrence of spinal cord herniation through an apparently spontaneous rent in the adjacent dura with no injury. We have encountered four such instances in a decade, with a varying degree of success. A vertically oriented tear of limited extent occurs in the ventral dura, usually in the mid- or high-thoracic region, and a segment of the spinal cord protrudes into the epidural space. The result is a painless, subacute, and incomplete spinal cord syndrome, which reaches a plateau and leaves the patient with an asymmetrical spastic paraparesis and variable sensory loss. Orthostatic headache of low-CSF pressure is not part of the syndrome. MRI demonstrates the protruded segment of the cord where it buckles through the dura. Presumably the herniation creates a sufficient degree of local ischemia or mechanical disturbance to account for the myelopathic
symptoms. Surgical replacement of the cord in its proper position and repair of the tear has resulted in partial return of neurologic function (Vallee et al).

**Intraspinal Tumors**

Tumors of the spinal cord are considerably less frequent than tumors that involve the brain; in the Mayo Clinic series of 8784 primary tumors of the CNS, only 15 percent were intraspinal (Sloof et al). In distinction to brain tumors, the majority of intraspinal ones are benign and produce their effects mainly by compression of the spinal cord rather than by invasion. Thus, a large proportion of intraspinal tumors are amenable to surgical removal, and their early recognition, before irreversible neurologic changes have occurred, becomes a matter of utmost importance.

**Anatomic Considerations**

Neoplasms and other space-occupying lesions within the spinal canal can be divided into two groups: (1) those that arise within the substance of the spinal cord, either as a primary neural neoplasm or as a metastasis, and invade and destroy tracts and central gray structures (intramedullary) and (2) those arising outside the spinal cord (extramedullary), either in the vertebral bodies and epidural tissues (extradural) or in the leptomeninges or roots (intradural).

In a general hospital, the relative frequency of spinal tumors in these different locations is about 5 percent intramedullary, 40 percent intradural-extradural, and 55 percent extradural. This percentage of extradural lesions is higher than that encountered in more specialized neurosurgical services (e.g., Elsberg's figures of 7, 64, and 29 percent, respectively), probably because the latter do not include as many patients with extradural lymphomas, metastatic carcinomas, etc., as are seen in general hospitals.

The commonest primary extramedullary tumors are the neurofibromas and meningiomas (Fig. 44-8), which together constitute about 55 percent of all intraspinal neoplasms. They are more often intradural than extradural. Neurofibromas have a predilection for the thoracic region, whereas meningiomas are more evenly distributed over the vertical extent of the cord. The other primary extramedullary tumors are sarcomas, vascular tumors, chordomas, and epidermoid and similar tumors, in that order of frequency.

*Figure 44-8* Gadolinium enhanced MRI of intraspinal meningioma that caused incontinence and leg weakness, including spastic and flaccid elements (combined conus and cauda syndrome).

Primary intramedullary tumors of the spinal cord have the same cellular origins as those arising in the brain (Chap. 31), although the proportions of particular cell types differ. Ependymomas (many of which arise from the filum terminale; page 704) make up 60 percent of the spinal cord cases (Fig. 44-9) and astrocytomas about 25 percent. The astrocytoma is the commonest intramedullary tumor if one excludes tumors arising in the filum terminale. Oligodendrogliomas are much less common. The remainder (about 10 percent) consists of a diverse group of nongliomatous tumors: lipomas, epidermoids, dermoids, teratomas, hemangiomas, hemangioblastomas, and metastatic carcinomas. The hemangioma may be a source of spontaneous hematomyelia. As indicated further on, there is a frequent association between intramedullary tumors (both gliomatous and nongliomatous) and syringomyelia. The basis of this relationship remains obscure.

*Figure 44-9* T1-weighted MRI of an intramedullary thoracic ependymoma, causing expansion of the cord and edema over several segments. There is faint enhancement of the tumor with gadolinium.

Intramedullary growths invade as well as compress and distort fasciculi in the spinal cord white matter. As the cord enlarges from the tumor growing within it or is compressed by a tumor from without, the free space around the cord is eventually consumed, and the CSF below the lesion becomes isolated or loculated from the remainder of the circulating fluid above the lesion. This is indicated by a Froin syndrome (xanthochromia and clotting of CSF) and an interruption of flow of contrast medium in the subarachnoid space (by myelogram). The most informative diagnostic procedure is an MRI, which demonstrates both the intramedullary extent of the tumor and the effect on the surrounding subarachnoid space.

Secondary spinal cord tumors can also be subdivided into intramedullary and extramedullary types. Extradural metastases (carcinoma, lymphoma, myeloma) are the most common of all spinal tumors. They account for the largest group of patients who develop symptoms of myelopathy while being cared for in hospital and are therefore likely to be encountered in the course of providing neurologic consultations. Extradural metastases arise from hematogenous deposits or extend from tumors of the vertebral bodies or from a paraspinal tumor extending via the intervertebral foramina (Fig. 44-10). Secondary extramedullary tumor growths are far more often extradural than intradural. The intradural type takes the form of a meningeal carcinomatosis or lymphomatosis and is considered in Chap. 31.

*Figure 44-10* MRI of multiple spinal metastases from carcinoma of the lung. The metastases exhibit low signal intensity on T1-weighted images. An epidural mass is
Once vertebral and segmental levels of the lesion are settled, there remains the necessity of determining whether the lesion is extradural, intradural-extramedullary, sensory and motor deficits ascend, but they may still be below the lesion. In determining the level of the lesion, the location of the root pain and atrophic paralysis and motor deficits may be most pronounced in those parts of the body farthest removed from the lesion, i.e., in the feet or lumbosacral segments. Later the levels of Symptomatology Patients with spinal cord tumors are likely to present with one of three clinical syndromes: (1) a sensorimotor spinal tract syndrome, (2) a painful radicular-spiral spinal cord syndrome, or (3) rarely, an intramedullary syringomyelic syndrome. Pain and stiffness of the back may antedate signs of spinal cord disease or dominate the clinical picture in some cases of extramedullary tumor. The back pain is usually worse when the patient lies down or may become worse after several hours in the recumbent position and be improved by sitting up. In children, severe back pain associated with spasm of paravertebral muscles is often prominent initially; scoliosis and spastic weakness of the legs come later. Because of this somewhat unusual clinical presentation and the rarity of intraspinal lesions in childhood, spinal cord tumors in this age group may be overlooked. Sensorimotor Spinal Tract Syndrome The clinical picture is related predominantly to compression and less often to invasion and destruction of spinal cord tracts. The signs of compression consist of (1) an asymmetrical spastic weakness of the legs with thoracolumbar lesions and of the arms and legs with cervical lesions, (2) a sensory level on the trunk below which perception of pain and temperature is reduced or lost, (3) posterior column signs, and (4) a spastic bladder under weak voluntary control. The onset of the compressive symptoms is usually gradual and the course progressive over a period of weeks and months, frequently with back pain. With extradural tumors, paralysis usually develops over a period of several days to several weeks, but the tempo of progression may be more rapid or more leisurely. The initial disturbance may be motor or sensory and the distribution asymmetrical. With cervical or foramen magnum lesions, a common sequence of motor impairment is first of an arm, followed by the ipsilateral leg, contralateral leg, and finally the remaining arm ("around-the-clock" pattern). With thoracic lesions, one leg usually becomes weak and stiff before the other one. Subjective sensory symptoms of the dorsal column type (tingling paresthesias) assume similar patterns. Pain and thermal senses are more likely to be affected than tactile, vibration, and position senses. Nevertheless, the posterior columns are frequently involved. Initially the sensory disturbance is contralateral to the maximum motor weakness, but a sharply defined Brown-Séquard syndrome is rarely observed. The bladder and bowel usually become paralyzed coincident with paralysis of the legs. If the compression is relieved, there is recovery from these sensory and motor symptoms, often in the reverse order of their appearance; the first part affected is the last to recover, and sensory symptoms tend to disappear before motor ones. Radicular-Spinal Cord Syndrome The syndrome of spinal cord compression is often combined with radicular pain, i.e., pain in the distribution of a sensory nerve root. It is described as knife-like or as a dull ache with superimposed sharp stabs of pain, which radiate in a distal direction, i.e., away from the spine, and are intensified by coughing, sneezing, or straining. Segmental sensory changes (paresthesias, impaired perception of pinprick and touch) and/or motor disturbances (cramp, atrophy, fascicular twiching, and loss of tendon reflexes) and an ache in the spine, in addition to the radicular pain, are the usual manifestations of a cord compressive-initiative root lesion. Tenderness of spinous processes over the growth is found in about half the patients. These segmental changes, particularly the sensory ones, often precede the signs of spinal cord compression by months if the lesion is benign. Intramedullary Syringomyelic Syndrome No single symptom is unique to intramedullary tumors. Pain is the most common symptom and is almost invariably present with tumors of the filum terminale. Ependymomas and astrocytomas, the two most common intramedullary tumors, usually give rise to a mixed sensorimotor tract syndrome. When the intramedullary tumor involves the central gray matter, a syringomyelic syndrome may result. Theoretically, intramedullary tumors that destroy mainly the gray matter should cause a central cord syndrome, with segmental or dissociated sensory loss, amytrophy, early incontinence, and late corticospinal weakness. Also, on sensory examination, sacral sparing may be found but is of limited value in distinguishing intramedullary from extramedullary lesions. A dissociation of thermal pain and tactile sensory loss over several segments on the trunk is a more dependable sign of an intramedullary lesion. Rarely, for reasons that are difficult to understand, an extramedullary tumor may give rise to a syringomyelic syndrome. Special Spinal Syndromes Unusual clinical syndromes may be found in patients with tumors in the region of the foramen magnum. They may produce a quadriparesis with pain in the back of the head and stiff neck, weakness and atrophy of the hands and dorsal neck muscles, marked imbalance, and variable sensory changes—or, if they spread intracranially, there may be signs of cerebellar and lower cranial nerve involvement. These tumor types are described fully in Chap. 31. Lesions at the level of the lowest thoracic and the first lumbar vertebrae may result in mixed cauda equina and spinal cord symptoms. A Babinski sign means that the spinal cord is involved above the fifth lumbar segment. Lesions of the cauda equina alone, always difficult to separate from those of the lumbosacral plexuses and multiple nerves, are usually attended in the early stages by pain, which is variously combined with a bilaterally asymmetrical, atrophic, areflexic paralysis, radicular sensory loss, and sphincteric disturbance. These must be distinguished from lesions of the conus medullaris (lower sacral segments of the spinal cord), in which there are early disturbances of the bladder and bowel (urinary retention and constipation), back pain, symmetrical hypesthesia or anesthesia over the sacral dermatomes, a lax anal sphincter with loss of anal and bulbocavernous reflexes, impotence, and sometimes weakness of leg muscles. Sensory abnormalities may precede motor and reflex changes by many months. Very rarely, for unclear reasons, tumors of the thoracolumbar cord (intramedullary, as a rule) are associated with elevated spinal fluid protein and hydrocephalus; these respond to shunting and removal of the spinal tumor ( Feldman et al.). Differential Diagnosis Several problems may arise in the diagnosis of spinal cord tumors in addition to those mentioned above. In their early stages they must be distinguished from other diseases that cause pain over certain segments of the body, i.e., diseases affecting the gallbladder, pancreas, kidney, stomach and intestinal tract, pleura, etc. Localization of the pain to a dermatome; its intensification by sneezing, coughing, and straining, and sometimes by recumbency, and the finding of segmental sensory changes and minor alterations of motor, reflex, or sensory function in the legs will usually provide the clues to the presence of a spinal cord-radiculard lesion. Examination of the CSF, CT myelography, and particularly MRI will settle the diagnosis in most instances. If the symptoms and signs of involvement of sensorimotor tracts are present, there is still the problem of locating the segmental level of the lesion. At first the sensory and motor deficits may be most pronounced in those parts of the body farthest removed from the lesion, i.e., in the feet or lumbosacral segments. Later the levels of the sensory and motor deficits ascend, but they may still be below the lesion. In determining the level of the lesion, the location of the root pain and atrophic paralysis is of greater help than the upper level of hypesthesia. Once vertebral and segmental levels of the lesion are settled, there remains the necessity of determining whether the lesion is extradural, intradural-extradural, or intramedullary and whether it is neoplastic. This is important from the standpoint of etiologic diagnosis. If there is a visible or palpable spinal deformity or
radiographic evidence of vertebral destruction, one may confidently assume an extradural localization. Even without these changes, one still suspects an extradural lesion if root pain developed early and is bilateral, if pain and aching in the spine are prominent and percussion tenderness is marked, if motor symptoms below the lesion preceded sensory ones, and if sphincter disturbances were late. However, to distinguish between intradural-extradural lesions and intramedullary lesions on clinical grounds alone may be impossible. The findings of segmental amyotrophy and sensory loss of dissociated type (loss of pain and temperature and preservation of tactile sensation) point to an intramedullary lesion.

Extradural tumors, both primary and secondary, must be differentiated from cervical spondylosis, tuberculous granuloma, sarcoidosis, and certain chronic pyogenic or fungal granulomatous lesions, from lipomas, and from intraspinal neoplastic diseases (for certain lymphomas and myelomas), and the early use of high-dose steroids and analgesics for pain. Seldem is operation necessary as a first resort; Gilbert and his associates have presented convincing evidence that patients who receive high-dose corticosteroids (16 to 60 mg of dexamethasone) and fractionated radiation (500 cGy on each of the first 3 days and then spaced radiation up to 3000 cGy) do as well as surgically treated patients. Sometimes laminectomy and decompression are necessary for diagnosis and, with a rapidly growing tumor, to prevent irreversible compressive effects and infarction of the spinal cord. Cases that have been allowed to progress should probably be operated on if paraplegia has just occurred. If the maximal safe radiation dosage had previously been applied to the spinal column, surgical palliation is also usually undertaken.

The main consideration in the management of epidural metastases is the need for early diagnosis, at a stage when only back pain is present and before neurologic symptoms and signs have appeared. Once neurologic signs appear, the results of treatment are poor. Thus, patients with back pain and vertebral metastases should have MRI or CT myelography and be treated aggressively with radiation (Rodichok et al.; Portenoy et al.). The management of other forms of spinal cord and cauda equina compression is considered in relation to the specific compressive lesions.

Other Rare Causes of Spinal Cord Compression

Intraspinal lipoma (intra- or extradural) should be suspected when there is a protracted evolution of neurologic symptoms and particularly when there is a palpable subcutaneous soft tissue mass, an associated bony abnormality, and myelographic and MRI evidence of a large dural sac and low-lying conus medullaris. Thomas and Miller found 60 such cases (over a period of 40 years) in the files of the Mayo Clinic. Epidural fat deposition with spinal cord or cauda equina compression occurs in Cushing disease and after the long-term use of corticosteroids but also in the absence of these disorders. The clinical picture may suggest discogenic disease (Lipson et al.). Copious amounts of normal adipose tissue are found at laminectomy, and removal of this tissue is curative. Lowering the dose of steroid and caloric restriction will help mobilize the fat and relieve the symptoms.

Arnchond diverticula—intra- or extradural outpouchings from the posterior nerve root—are very rare causes of a radicular-spinal cord syndrome first described by Bechterew in 1893. They tend to occur in the thoracic or lumbosacral regions. The symptoms, in order of decreasing frequency, are pain, radicular weakness and sensory disorder, gait disorder, and sphincteric disturbances (Ciluffo et al.). The frequent association of arachnoid diverticula with osteoporosis, ankylosing spondylitis, and arachnoiditis makes it difficult to interpret the role of the diverticulae themselves. Surgical obliteration of the diverticula has yielded unpredictable results.

Spinal cord compression with paraplegia has also been caused by extramedullary hematopoiesis in cases of myelosclerosis, thalassemia, cyanotic heart disease, myelogenous leukemia, sideropenic anemia, and polycythemia vera (Oustwani et al.). A similar phenomenon occurs with ossification of the posterior longitudinal ligament, as mentioned earlier in the chapter.

Solitary osteochondromas of vertebral bodies and multiple exostoses of hereditary type are other reported causes of spinal cord compression. In the case reported by Buur and Morth, the clinical syndrome was one of pure spastic paraparesis of several months' progression.

Lathyrism

From the interesting historical review of Dastur, one learns that this disease was known to Hippocrates, Pliny, and Galen in Europe, to Avicenna in the Middle East, and to the ancient Hindus. The term lathyrism was applied by Cantani, in Italy, because of its recognized relationship to the prolonged consumption of Lathyrus sativus (chickling vetch, or grass pea).

The disease is still common in some parts of India and Africa. In these districts, during periods of famine, when wheat and other grains are in short supply, the diet may for months consist of flour made of the grass pea. In individuals so exposed there occurs a gradual weakening of the legs accompanied by spasticity and cramps. Paresthesias, numbness, formation in the legs, and frequency and urgency of micturition, impotence, and sphincteric spasms are added. The upper extremities may exhibit coarse tremors and involuntary movements. These symptoms, once established, are more or less permanent but not constantly progressive, and most of the patients live out their normal life span.

Only two reports on the neuropathology of lathyrism were known to Dastur, one by Buzzard and Greenfield in England, and the other by Filiminoff in Russia. Both of their patients had been in a stationary paraplegic state for years. Greenfield noted a loss of ascending and descending tracts in the spinal cord, particularly the corticospinal and direct spinocerebellar tracts. Filiminoff described a loss of myelinated fibers in the posterior and lateral columns. (Unlike the cases of Spencer et al., there had been a loss of pain and thermal sensation in the upper extremities.) The larger Betz cells had disappeared, while anterior horn cells were unaffected. Gliosis and thickening of blood vessels was seen in the degenerated tracts.

The toxic nature of this disease, long suspected, has been confirmed by Spencer and colleagues. They extracted a neuroexcitatory amino acid, beta-N-oxalylaminoalanine (BOAA), from grass peas and were able to induce corticospinal dysfunction in monkeys by giving this substance with a nutritious diet. Subsequently, Hugon and coworkers produced a primate model of lathyrism by feeding monkeys a diet of L. sativus in addition to an alcoholic extract of this legume. These findings tend to negate the importance of several other factors that until now had been thought to be causative—namely, malnutrition, ergot contamination, and toxins derived from Vicia sativa, the common vetch that grows alongside the lathyrus species.

Possibly the more recently described African acute spastic paraplegia called “konzo” has a similar toxic pathogenesis.

Dysraphic and Congenital Tumor Syndromes

See Chap. 38.

Familial Spastic Paraplegia

There are several familiar forms of progressive spastic paraplegia, some beginning in childhood, others in adult life. The pattern of inheritance in our adult cases has been autosomal dominant. A lack of sensory symptoms and signs and sparing of sphincteric function until late in the illness are important diagnostic features. A number of adult cases are “complicated” in the sense that the spastic paraplegia is associated with cerebellar ataxia or dementia. By contrast, primary lateral
syringomyelia with obstruction of the foramen magnum and dilation of the central canal

When a Chiari malformation is associated with syringomyelia and syringobulbia, it may be difficult to separate the effects of the two disorders. Clinical features that

A keyhole-shaped syrinx, which was confined to the upper pons and midbrain and communicated with the fourth ventricle, has been described by

Syringobulbia

Syringomyelia (Syinx)

Syringomyelia (from the Greek syrinx, “pipe” or “tube”) may be defined as a chronic progressive degenerative or developmental disorder of the spinal cord, characterized clinically by painless weakness and wasting of the hands and arms (brachial amyotrophy) and segmental sensory loss of dissociated type (loss of thermal and painful sensation with sparing of tactile, joint position, and vibratory sense, as described below). Pathologically there is cavitation of the central parts of the spinal cord, usually in the cervical region, but extending upward in some cases into the medulla oblongata and pons (syringobulbia) or downward into the thoracic or even the lumbar segments. Frequently there are associated developmental abnormalities of the vertebral column (thoracic scoliosis, fusion of vertebrae, or Klippel-Feil anomaly), of the base of the skull (platybasia and basilar invagination), and particularly of the cerebellum and brainstem (type I Chiari malformation). Approximately 90 percent of cases of syringomyelia have type I Chiari malformation (descent of cerebellar tonsils, see page 1064); conversely, approximately 50 percent of type I Chiari malformations are associated with syringomyelia. In contrast to the frequency of these developmentally related abnormalities is a less frequent but well-described association of syringomyelia with acquired processes such as intramedullary tumor (astrocytoma, hemangioblastoma, ependymoma) and traumatic necrosis of the spinal cord.

Wider experience with the pathology of syringomyelia and better understanding of the postulated mechanisms have led to the following classification, modified from Barnett et al:

Type I. Syringomyelia with obstruction of the foramen magnum and dilation of the central canal

A. With type I Chiari malformation

B. With other obstructive lesions of the foramen magnum

Type II. Syringomyelia without obstruction of the foramen magnum (idiopathic type)

Type III. Other diseases of the spinal cord (acquired types)

A. Spinal cord tumors (usually intramedullary)

B. Traumatic myelopathy

C. Spinal arachnoiditis and pachymeningitis

D. Secondary myelomalacia from cord compression (tumor, spondylosis) or infarction (AVM, etc.)

Type IV. Pure hydromyelia (developmental dilatation of the central canal), usually with hydrocephalus

Historical Note Although pathologic cavitation of the spinal cord was recognized as early as the sixteenth century, the term syringomyelia was first used to describe this process in 1827 by Olivier d’Angers (cited by Ballantine et al). Later, following recognition of the central canal as a normal structure, it was assumed by Vinchow (1863) and by Leyden (1876) that cavitation of the spinal cord had its origin in an abnormal expansion of the central canal, and they renamed the process hydromyelia. Cavities in the central portions of the spinal cord, unconnected with the central canal, were recognized by Halloppaus (1870); Simon suggested in 1875 that these cavities be referred to as syringomyelia.

Clinical Features The clinical picture varies in the four pathologic types listed above, the differences depending not only on the extent of the syrinx but also on the associated pathologic changes, particularly those related to the Chiari malformation. In type I (idiopathic and Chiari developmental syringomyelia), symptoms usually begin in early adult life (20 to 40 years). Males and females are equally affected. Rarely, some abnormality is noted at birth, and occasionally the first symptoms appear in late childhood or adolescence. The onset is usually insidious and the course irregularly progressive. In many instances the symptoms or signs are discovered accidentally (a painless burn or atrophy of the hand), and the patient cannot say when the disease began. Rarely, there is an almost apoplectic onset or worsening; there are cases on record of an aggravation of old symptoms or the appearance of new symptoms after a violent strain or paroxysm of coughing. Once the disease is recognized, some patients remain much the same for years, even decades, but more often there is intermittent progression to the point of being chair-bound within 5 to 10 years. This extremely variable course makes it difficult to evaluate therapy.

The precise clinical picture at any given point in the evolution of the disease depends upon the cross-sectional and longitudinal extent of the syrinx, but certain clinical features are so common that the diagnosis can hardly be made without them. These features are segmental weakness and atrophy of the hands and arms with loss of tendon reflexes and segmental anesthesia of a dissociated type (loss of pain and thermal sense and preservation of the sense of touch) over the neck, shoulders, and axiosyl metastases; there are weakness and ataxia of the legs from involvement of the corticospinal tracts (possibly at their decussation) and posterior columns in the cervical region. Kyphoscoliosis is added in many of the cases, and in nearly one-quarter of them there is an overt cervico-occipital malformation (short neck, low hairline, odd posture of the head and neck, fused or missing cervical vertebrae).

The particular muscle groups that are affected on the two sides may vary. Exceptionally, motor function is spared, and the segmental dissociated sensory loss and/or pain are the only marks of the disease. In a few of the cases, especially those with the Chiari malformation, the reflexes in the arms are preserved or even hyperactive, as might be expected with upper rather than lower motor neuron involvement. Or the shoulder muscles may be atrophic and the hands spastic. In the lower extremities the weakness, if present, is of a spastic (corticospinal) type.

The characteristic segmental sensory dissociation is usually bilateral, but a unilateral pattern is not unknown, and this is true of the amyotrophy as well. The sensory loss has a cuneate or hemispheric distribution, often extending to the face or back of the head and onto the trunk. Although tactile sensation is usually preserved, there are cases in which it is impaired, usually in the region of the most dense analgesia. Exceptionally there is no sensory loss in the presence of amyotrophy, and cases have been recorded in which only a hydrocelesphalus and hydromyelia were present with spastic paraparesis (type IV). If tactile sensation is affected in the arms, joint position and vibratory sense tend also to be impaired. In the lower extremities there may be some loss of pain and thermal sensation proximally and over the abdomen, but more often there is a loss of vibration and position sense which is indicative of a posterior column lesion and is the basis of ataxia. A Horner syndrome may result from ipsilateral involvement of the intermediolateral cell column at the C8, T1, and T2 levels.

When a Chiari malformation is associated with syringomyelia and syringobulbia, it may be difficult to separate the effects of the two disorders. Clinical features that favor the diagnosis of type I syringomyelia with Chiari malformation are nystagmus, cerebellar ataxia, exertional head-neck pain, prominent corticospinal and sensory tract involvement in the lower extremities, hydrocephalus, and cranio cervical malformations. In type I syringomyelia without a Chiari malformation but with some other type of obstructive lesion at the foramen magnum, the clinical picture is much the same, and the nature of the foramen magnum lesion can be determined only by MRI.
The association of syringomyelia with an intramedullary tumor (type III) should be suspected when there is a syringomyelic type of sensorimotor abnormality extending over many segments of the body. With Von Hippel-Lindau disease, the diagnosis hinges on the finding of the characteristic hereditary hemangioblastoma in the syrinx and renal and retinal and cerebellar vascular malformations. In the posttraumatic cases, a traumatic necrosis of the spinal cord that has been stable for months or years begins to cause pain and spreading sensory or motor loss, recognizable most easily in segments above the original lesion (Schurch et al). This has occurred in approximately 3 percent of the cases of the Roschrist and coworkers, more in quadriplegics than in paraplegics. The posttraumatic syrinx is not as well defined as the usual forms of syringomyelia but consists instead of several contiguous areas of gli-lined myelomalacia with differing degrees of cavitation. In some instances of progressive spinal cord symptoms occurring several years after spinal surgery, the lesion has proved to be one of arachnoiditis and cord atrophy and not a syrinx (Avrahami et al).

In the few cases of hydromyelia that have come to our attention, there has sometimes been a long-standing hydrocephalus, often congenital, complicated years later by progressive weakness and atrophy of the shoulders and the muscles of the arms and hands. Segmental sensory loss has been reported in only a few instances. Proof of the existence of this entity in the past has been based on necropsy demonstration of an enormously widened central canal, with or without hydrocephalus. Now it should be easily diagnostically by MRI.

Pathogenesis One theory of the pathogenesis of developmental syringomyelia, of which Gardner was the most persuasive protagonist, is that normal flow of CSF is prevented by a congenital failure of opening of the outlets of the fourth ventricle. As a result, a pulse wave of CSF pressure, generated by systolic pulsations of the choroid plexuses, is transmitted into the cord from the fourth ventricle through the central canal. According to this theory, the syrinx consists essentially of a greatly dilated central canal with a diverticulum that ramifies from the central canal and dissects along gray matter and fiber tracts. The frequency with which syringomyelia is linked to malformations at the craniovertebral junction, i.e., to lesions that could interfere with normal flow of CSF, lent credence to this theory.

There are many instances, however, where Gardner's hydrodynamic theory could not explain the syringomyelia. In some cases the foramina of Luschka and Magendie are found to be patent, and other abnormalities of the posterior fossa or foramen magnum are also not in evidence. Cases have been observed in which two well-developed cavities, one at a cervical and another at a lumbar level, were not connected by any patent channel. Furthermore, in many cases, including several of our own, serial histologic sections have failed to demonstrate a connection between the fourth ventricle and the syrinx in the spinal cord or a widening of the central canal above the syrinx (see also Hughes).

Gardner's theory has been questioned on other grounds. Ball and Dayan calculated the pressure-pulse wave transmitted into the cord to be of so low an order as to be unlikely to produce a syrinx. These authors suggested a somewhat different mechanism, with which we are in accord. In their view, the CSF around the cervical cord is forced during systole against the resistance of the craniovertebral junction, thus creating a hydrodynamic imbalance. This imbalance is further increased by the Virchow-Robin spaces or other subpial channels. Over a prolonged period of time, abetted perhaps by traumatic lesions, small pools of fluid coalesce to form a syrinx; originally the syrinx forms independently of the central canal, but eventually the two may become connected, perhaps because of the secondary enlargement of the central canal. The recent report of patients with syringomyelia and Chiari malformation, lending support to the theory of Ball and Dayan. According to Heiss et al., progression of syringomyelia is produced by the action of the cerebellar tonsils, which partially occlude the subarachnoid space at the foramen magnum and create pressure waves that compress the spinal cord from without and not from within; the pressure waves propagate syrinx fluid caudally with each heartbeat.

A blastomatous formation in the spinal cord, akin to tuberous sclerosis or central von Recklinghausen disease but with a tendency for the abnormal tissue to cavitate, is another suggested explanation of syrinx formation—a view that can be discounted because of the lack of blastomatous tissue in the walls of the syrinx. Still others have suggested that edema is a major pathogenic factor, induced by angiomatous malformations, neoplasms, trauma, arachnoiditis, etc. This hardly exhausts the list of hypotheses, but none of them is easy to confirm, and there is no point in enumerating them all. The authors favor the view that in the most common type of syringomyelia, a cervical cord lesion, occurring in childhood as part of a Chiari malformation or other developmental abnormality, results in an enlarging cavity in the substance of the spinal cord, with secondary dilatation of the spinal canal via a hydrodynamic mechanism within a destructive lesion—as postulated originally by Gordon Holmes and elaborated by Ball and Dayan. We are impressed with the relationship between basilar cranial, cervical spine, and cerebellopinal malformations and hydroxy-syringomyelia and with disturbed hydrodynamics of perispinal CSF as important factors in the pathogenesis. Logue and Edwards have documented several cases of syringomyelia in which the foramen magnum was obstructed by a lesion other than a Chiari formation—dural cyst, localized arachnoiditis, atlantoaxial fusion, simple cerebellar cyst, and basilar invagination (see Williams for a review of the numerous hypotheses).

Irrespective of its mode of origin, the syrinx first occupies the central gray matter of the cervical portion of the spinal cord, where it interrupts the crossing pain and temperature fibers in the anterior commissure at several successive cord segments. As the cavity enlarges, it extends symmetrically or asymmetrically into the posterior and anterior horns and eventually into the lateral and posterior funiculi of the cord. It may enlarge the spinal cord and even widen the interpeduncular spaces. The cavity is lined with astrocytic gli a and a few thick-walled blood vessels, and the fluid in the cavity is clear and has a relatively low protein content, like CSF.

The cavitation is nearly always found in the central portion of the cord and only reaches the thoracic and lumbar portions by extension from the cervical region. Either a cavity or a glial septum may extend asymmetrically into the medulla oblongata, usually in the vicinity of the descending tract of the fifth cranial nerve (syringobulbula).

Diagnosis The clinical picture of syringomyelia is so characteristic that diagnosis is seldom in doubt. No one can obtain spectacular demonstrations of the syrinx, Chiari malformations, and other foramen magnum lesions by MRI in the sagittal plane of the brain and spinal cord (see Figs. 38-4 and 44-12). Also, contrast injection, scanning, performing a myelogram, head position, etc., patient's head position, will reveal the Chiari malformation and usually expose the syrinx; the contrast material fills the syrinx and the central canal directly, probably from the surface of the cord (Ball and Dayan).

Certain rare neuropathies (amyloid, Tangier disease, and Fabry disease) that preferentially affect small fibers in the nerves of the upper extremities can reproduce the dissociated sensory loss that is characteristic of a syrinx, but syringomyelic motor abnormalities are not found in these cases.

Treatment The only therapy of lasting value for type I syringomyelia (related to Chiari malformation) is surgical decompression of the foramen magnum and upper cervical canal. Headache and neck pain are helped most; ataxia and nystagmus tend to persist. Radiation therapy, which was formerly recommended, is of no benefit. The operation advised by Gardner, of plugging the connection between the fourth ventricle and the central canal of the cervical cord, has been abandoned. There have been complications of this operative procedure, and the results appear to be no better than those obtained from simple decompression. The latter operation also carries some risk, especially if there is an attempt to excise the tonsillar projections of the cerebellum. In the series of Logue and Edwards, comprising 56 cases of type I syringomyelia, the occipitocervical pain was relieved by decompression in most patients, but the shoulder-arm pain usually persisted. Upper motor neuron weakness of the legs and sensory ataxia were often improved, whereas the segmental sensory and motor manifestations of the syringomyelia were not. Hankinson has reported good results from decompression in 75 percent of type I cases of syringomyelia. In the retrospective review of 141 adult patients by Stevens and col leagues, a good surgical outcome was achieved in 60 percent of those with minor degree of descent of the cerebellar tonsils but only 12 percent in those with major cerebellar ectopia. A distended syrinx also led to a more favorable outcome. Whether the long-term course of these diseases is altered has not been determined.

Syringostomy or shunting of the cavity has been found in type I and type II (idiopathic) cases, but the results have been unpredictable. Love and Olafson, who performed this procedure in 40 patients of both types (mainly type II), stated that 30 percent had an excellent outcome. Schuch and coworkers obtained improvement of pain and motor weakness in 5 cases out of the 7 cases by stabilization of the spinal cord and syringostomy with placement of a T-tube within the syrinx. In a more recent and comprehensive study of 73 patients with a developmental syrinx operated by Sjogren and Williams, one-half remained clinically stable for a 10-year period. The increased pressure during or after the procedure was often not sustained and of no benefit in most of the cases. The procedure has been found to be of little value in most patients, even those who reported some improvement originally, soon relapsed to their preoperative state, and the disease then progressed in the usual way. An enlarged cervical cord with progressive clinical worsening may merely justify shunting of the cavity.

Surgery for the posttraumatic cases has given more favorable results. With incomplete myelopathy, syringostomy relieved the pain in all the 10 patients of Shannon and associates. Where they performed the myeloplasty to be complete, the cord was transected and the upper stump excised. Sjogren and Williams have also studied 57 such patients and recommend decompressive laminectomy and reconstruction of the subarachnoid space as the most effective of the several procedures that have been used in the management of this complication.

In the cases of syringomyelia with tumor, in which the cyst fluid may be high in protein and viscid (unlike the low-protein fluid of the usual syrinx), the tumor should be
excised if possible. This has been done successfully with hemangioblastomas of the posterior columns and occasionally with epedymomas.

The rare symptomatic purely hydromyelic cases should benefit from ventriculoperitoneal shunts of the hydrocephalus, and a few excellent results are reported. This procedure has also been attempted in type I cases, with unimpressive results unless there is an associated hydrocephalus. Draining the central canal by amputation of the tip of the sacral cord has been unsuccessful and can be harmful.

**CONCLUDING REMARKS**

It is always well to remind oneself that of the more than thirty diseases of the spinal cord, effective means of treatment are available for only a few: spondylitis, extramedullary spinal cord tumors, syphilis (meningomyelitis and tabes), epidural abscess, hematoma and granuloma (tuberculous, fungal, sarcoidosis), perhaps syringomyelia, and subacute combined degeneration and other forms of nutritional myelopathy. Some of the inflammatory myelopathies may respond to immune modulating measures. The physician's major responsibility is to determine whether the patient has one of these treatable diseases.

**CHAPTER REFERENCES**

This is the interface between the finely branched nerve fiber and the muscle fiber, where the electrical activity of the motor nerve is translated into muscle action (The Neuromuscular Junction (Motor End Plate)). It is the most reliable marker of an acquired demyelinating neuropathy; of all the electromyographic changes, it corresponds most closely to the degree of muscle weakness during electrophysiologic examination is termed conduction block (discussed under "Conduction Studies of Nerve"). Repetitive nerve stimulation ("Jolly test") and of needle examination of muscle biopsy are useful aids in diagnosis of denervation.

Conduction Studies of Nerve Roots and Spinal Segments (Late Responses, Blink Responses, Segmental Evoked Responses) is activated by the depolarization of the muscle fiber membrane and is the process by which the nerve impulse is conducted along the length of the nerve fiber. The action potential then spreads in an all-or-none fashion, down the length of the nerve or muscle membrane (see chapter 53). The action potential then repolarizes the membrane to a resting level. During this brief period of repolarization, the nerve and muscle fibers are refractory, at first absolutely then relatively, to another depolarizing stimulus. The intelligent use of ancillary examinations requires some knowledge of the biochemistry and physiology of muscle fiber contraction, nerve action potentials, and neuromuscular conduction. These subjects are therefore reviewed briefly, as an introduction to the descriptions of the laboratory methods and the subject matter of the chapters that follow. The relevant anatomy is presented in later parts of this chapter and in Chapter 3.

Chapter 45: Electrophysiologic Testing and Laboratory Aids in the Diagnosis of Neuromuscular Disease

The Neuromuscular Junction (Motor End Plate)

This is the interface between the finely branched nerve fiber and the muscle fiber, where the electrical activity of the motor nerve is translated into muscle action (Fig. 45-1). The nerve fiber, as it innervates the muscle cell membrane, leaves a small space of 50 μm—the synaptic cleft, between the axolemma and sarcolemma.
In the nerve terminal, a relatively fixed number of packets, or quanta, of acetylcholine (ACh), each packet consisting of about 10,000 molecules, are liberated through an exocytotic process by the arrival of action potentials, but some are also released spontaneously. Arrival of the electrical impulse opens calcium channels in the presynaptic membrane, which serve to bind packets of ACh to the membrane and govern their release. Molecules of ACh diffuse into the synaptic cleft and attach to receptor sites on the postsynaptic membrane. Each impulse triggers the release of approximately 200 quanta of ACh and produces a depolarization of sufficient size to initiate an action potential in the muscle through the same mechanism of a regenerative sodium current described above. Botulinum toxin and a high concentration of Mg ions interfere with the entry of calcium on the presynaptic side and raise the threshold for quantal release. There is also known to be a nonquantal release of ACh through continuous leakage. This appears to play a role in the trophic influence of nerve on muscle.

Each ACh molecule binds to a postsynaptic ACh receptor protein, thereby causing a conformational change in the postsynaptic part of the motor end plate and a local increase in the conductance of Na and K and other small ions. This produces a depolarization known as the end-plate potential. Small (miniature) end-plate potentials (MEPPs) are continuously formed and are too small to be recorded by routine EMG testing, although fortuitous needle placement adjacent to a synapse may detect them. The bound ACh is hydroyzed by cholinesterase, a glycoprotein enzyme that exists in free form in the cleft, its main function is to terminate the action potential and permit the sequential activation of muscle. The postsynaptic membrane, once depolarized, is refractory to another action potential until it is repolarized.

The analysis of a rapid series of electrically elicited muscle contractions is used specifically to analyze the function of the neuromuscular junction. A decrement in the amplitude of muscle action potentials is typical of postsynaptic failure of conduction, and an increment, of presynaptic failure. Myasthenia gravis is the principal disease affecting the neuromuscular junction. The fundamental defect is not a deficiency of ACh or its release, but rather its failure to attach to the postsynaptic receptor, being blocked by an antibody at the receptor site. There are several other synaptic disorders—due to botulism, aminoglycoside antibiotics, and the antibodies of the Lambert Eaton myasthenic syndrome—which impede presynaptic release of ACh. Certain pharmacologic agents interfere with neuromuscular transmission by combining with the cholinergic (nicotinic) receptor on the postsynaptic membrane, thereby competitively blocking the transmitter action of ACh. The curariform drugs, derived from curare and termed nondepolarizing neuromuscular blockers, are the main examples. Other drugs, notably succinylcholine and decamethonium, cause neuromuscular blockade by producing direct depolarization of the end plate and adjacent sarcoplasmic membrane (depolarizing neuromuscular blockers). Agents that inactivate cholinesterase have the opposite effect, i.e., they enhance the action of ACh. The ones in clinical use (for the treatment of myasthenia gravis) are the carbamates neostigmine, physostigmine, pyridostigmine, etc., the effects of which are reversible. The organophosphates are irreversible blockers of cholinesterase function, for which reason they are feared weapons of chemical warfare. Atropine is a potent cholinergic antagonist that is active only at muscarinic sites and therefore has no effect at the neuromuscular junction.

Chemistry of Muscle Contraction

The sarcolemma, the transverse tubules, and the sarcoplasmic reticulum each play a role in the control of the activity of muscle fibers. The structural components involved in excitation, contraction, and relaxation of muscle are illustrated in Fig. 45-2. Following nerve stimulation, an action potential is transmitted by the sarcoplasmic reticulum from the motor end-plate region to both ends of the muscle fiber. Depolarization spreads quickly to the interior of the fiber along the walls of the transverse tubules, probably by a conducted action potential. The transverse tubules and the terminal cisternae of the sarcoplasmic reticulum come into close proximity at points referred to as triads. Here, by a mechanism that is not fully understood, depolarization of the transverse tubules is transmitted to the sarcoplasmic reticulum, which releases Ca stored in its interior. Calcium binds to the regulatory protein tropinin, thereby removing the inhibition exerted by the tropinin-tropomyosin system upon the contractile protein of this actin. This allows an interaction to take place between the actin molecules of the thin filaments and the cross bridges of the myosin molecules in the thick filaments and enables myosin adenosine triphosphatase (ATPase) to split adenosine triphosphate (ATP) at a rapid rate, thereby providing the energy for contraction. This chemical change causes the filaments to slide past each other. Relaxation occurs as a result of active (energy-dependent) Ca reuptake by the sarcoplasmic reticulum.

The pyrophosphate bonds of ATP, which supply the energy for muscle contraction, must be replenished constantly by a reaction that involves interchanges with the muscle phosphagen creatine diphosphate, where high-energy phosphate bonds are stored. These interactions, in both contraction and relaxation, require the action of creatine kinase (CK). Myoglobin, another important muscle protein, functions in the transfer of oxygen, and a series of oxidative enzymes are involved in this exchange. The intracellular Ca, as noted above, is released by the muscle action potential and must be reaccumulated in the cisternae of the sarcoplasmic reticulum before actin and myosin filaments can slide back past one another in relaxation. The reuptake of Ca requires the expenditure of considerable energy. When there is defective generation of ATP, the muscle remains shortened, as in the contracture of phosphorylase deficiency (McArdle disease) or of phosphofructokinase deficiency. The same sort of shortening occurs under normal conditions in some of the “catch muscles” of certain mollusks and is the basis of rigor mortis in
Many glycolytic and other enzymes (transaminases, aldolase, CK) are utilized in the metabolic activity of muscle, particularly under anaerobic conditions. Muscle fibers differ from one another in their relative content of oxidative and glycolytic enzymes; the latter determine the capacity of the muscle fiber to sustain anaerobic metabolism during periods of contraction with inadequate blood flow. Muscle cells rich in oxidative enzymes (type 1 fibers) contain more mitochondria and larger amounts of myoglobin (therefore appearing red), have slower rates of contraction and relaxation, fire more tonically, and are less fatigable than muscle fibers poor in oxidative enzymes. The latter (type 2 fibers) fire in bursts and are utilized in quick phasic rather than sustained reactions. The amount of myosin ATPase activity, which governs the speed of contraction, is low in oxidative-rich fibers and high in glycolytic-rich fibers. The myosin ATPase stain at pH 9.4 has been used to identify these two types of fibers in microscopic sections. Type 1 fibers have a low content of myosin ATPase, and type 2 (phosphorylative-rich) fibers have a high content of this enzyme; hence type 1 fibers stain lightly and type 2 darkly (the reverse reaction occurs at pH 4.6). Other less well differentiated histochromic types have also been identified. All the fibers within one motor unit are of the same type, which is used to advantage to identify the innervation of muscle fibers by a single motor neuron (fiber type grouping) after adjacent neurons have died and denervated their constituent muscle fibers.

The chemical energy required to maintain the various activities of the muscle cell is derived mainly from the metabolism of carbohydrate (blood glucose, muscle glycogen) and fatty acids (plasma free fatty acids, esterified fatty acids, and ketone bodies). There is a lesser contribution from branched-chain and other amino acids, but this may increase during prolonged exercise.

The most readily available source of energy is glycogen, which is synthesized and stored in muscle cells. It provides over 90 percent of the energy needs of muscle under conditions of high work intensity and during the early stages of submaximal exercise. Blood glucose and free fatty acids supplement intracellular glycogen as exercise proceeds. The free fatty acids are obtained from endogenous triglycerides (found in fatty acids), triglycerides released by circulating lipoproteins, and from the lipolysis of adipose tissue. Most of the energy needs of resting muscle are provided by fatty acids.

The enzymatic reactions involved in the transport of these substrates into muscle cells and their intracellular synthesis and degradation during anaerobic and aerobic cell conditions have been thoroughly investigated and most of the enzymes identified. This subject is too complicated to present in a textbook of neurology, but enough is known about these matters to state confidently that there are a number of diseases that can impair the contractile functions of muscle in different ways without destroying the fiber. Specific enzymatic deficiencies under genetic control may affect carbohydrate utilization (myophosphorylase, debrancher enzyme, phosphoketolase, phosphoglycerate mutase, and myoacetate deaminase), fatty acid utilization (carotid and carotinyltransferase deficiencies), pyruvate metabolism, and cytochrome oxidase activity (in the mitochondrial diseases). These enzymatic disturbances are discussed in later chapters.

### Physiology of Muscle Contraction

The contraction of a muscle fiber is to be viewed as both a series of electrochemical events and a mechanical event. The mechanical change far outlasts the electrical one and extends through the period when the muscle fiber is refractory to another action potential. When a second muscle action potential arrives, after the refractory period, the muscle fiber is capable of another action potential but before the muscle has relaxed, the contraction will be prolonged. Thus, at frequencies of anterior horn cell firing of more than 100 per second, the twitches fuse into a sustained contraction or fused tetanus. In most sustained contractions, there is incomplete tetanus, attained by firing rates of 40 to 50 per second. In this fashion the mechanical phenomena are smoothed into a continuous process, even though the electrical potentials present as a series of depolarizations, separated by intervals during which the muscle membrane resumes its resting polarized state.

As pointed out in Chap. 3, the physiology of muscle activity should always be considered in terms of motor units, i.e., the group of muscle fibers within the domain of each anterior horn cell. The strength of muscle contraction is a function of the number and rates of firing of many motor units. The smoothness of contraction depends on the integrated enlistment of motor units of increasing size. The electrical signal of this summated contraction, as recorded at the skin surface over a muscle, is the main feature of the surface EMG and the basis of motor nerve conduction examinations.

Further study involves the insertion into the muscle of a coaxial needle, which samples a multitude of motor units in the vicinity of the electrode. When elicited by a sustained voluntary contraction, the flurry of electrical activity from many units at different distances from the electrodes is referred to as an “interference pattern.” If the motor unit is of the same calibre as the motor nerve, the interference pattern is a compound muscle action potential (CMAP). The CMAP can be visualized on the screen of an oscilloscope or a computer and utilized to measure the speed of motor nerve conduction and the summated amplitudes produced by all the innervating nerve fibers. It can also be converted into an audible noise (see further on, under “Conduction Studies of Nerves” and “Needle Examination of Muscles”).

Biochemical changes may cause not only an impairment of neuromuscular activity (paresis, paralysis) but also excessive irritability, tetany, spasm, and cramp. In the latter instances, spontaneous discharges may occur from an instability of axon polarization; hence a single nerve impulse may initiate a train of action potentials in nerve and muscle, as in the tetany of hypocalcemia and in hemifacial spasm. In tetany, there may also be paresthesias, on the basis of irritability and ectopic discharges of sensory nerve fibers. The common cramps of calf and foot muscles (painless, sustained contractions with motor unit discharges at frequencies up to 200 per second) may be due to increased excitability (or unstable polarization) of the motor axons. Quinine, procainamide, diphenhydramine, and warmth reduce the irritability of nerve and muscle fiber membranes, as do a number of anticonvulsant drugs that act by blocking sodium channels and thereby limiting spontaneous membrane discharges.

To summarize, the muscle fiber, which is wholly dependent on the nerve for its stimulus to contract, may be physiologically activated or paralyzed in a number of ways. The nerve cell may be disinhibited in the anterior horn of the spinal cord, permitting the discharge of continuous action potentials, as in tetany and the “stiff-man” syndrome (page 1565); the nerve fiber may fail to conduct impulses (demyelinating neuropathies) or the number of fibers may be inadequate to produce a fused and sustained contraction (axonal neuropathies); the neuromere may not distribute the nerve impulse simultaneously to all parts of the motor unit (“fitter phenomenon in distal axonal damage or neuromuscular junction diseases); ACh may not be released at the presynaptic region of the neuromuscular junction (as occurs in botulism and in the Eaton-Lambert syndrome) or, once released, ACh may not be inactivated by cholinesterase (physostigmine, organophosphates); the receptor site on the postsynaptic membrane may be destroyed or blocked by antibodies or pharmacologic agents (myasthenia gravis or curare drugs); and, finally, the metabolic or contractile elements of the muscle may not react or, once contracted, may not relax. Similarly, the mechanisms involved in fasciculations, cramps, and muscle spasms may be traced to a number of different loci in the neuromuscular system. There may be an unstable polarization of the nerve fibers, as in tetany and in dehydration or salt depletion, or unexplained hyperirritability in the motor unit, as in amyotrophic lateral sclerosis. The threshold of mechanical activation or electrical reactivation of the sarcolemmal membrane may be reduced, as in myotonia, or impairment of an energy mechanism within the fiber may slow the contractile process, as in hypothyroidism; or a deficiency of phosphorylase, which deprives muscle of its carbohydrate energy source, may prevent relaxation, as in the contracture of McArdle disease. Lesions of the most peripheral branches of nerves, which allow nerve regeneration, may give rise to continuous activity of motor units. This is expressed clinically as a rippling of muscle, or myotonia (see pages 1457 and 1568).

In recent years, new technologies, such as isolation of complementary DNA, have made it possible to isolate each of the proteins and channels involved in nerve and muscle, as in the tetany of hypocalcemia and in hemifacial spasm. In tetany, there may also be paresthesias, on the basis of irritability and ectopic discharges of sensory nerve fibers. The common cramps of calf and foot muscles (painless, sustained contractions with motor unit discharges at frequencies up to 200 per second) may be due to increased excitability (or unstable polarization) of the motor axons. Quinine, procainamide, diphenhydramine, and warmth reduce the irritability of nerve and muscle fiber membranes, as do a number of anticonvulsant drugs that act by blocking sodium channels and thereby limiting spontaneous membrane discharges.

Diffuse muscle weakness or muscle twitching, spasms, and cramps should always raise the question of uremia or an abnormality in serum electrolytes. These disorders reflect the concentrations of electrolytes in the intra- and extracellular fluids. The electrocardiogram (ECG) may reveal alterations of their intracellular levels to this subject are found in the chapters that follow.

### Effects on Muscle of Abnormalities of Serum Electrolytes

#### Hypercalcemia

Hypercalcemia above 12 mg/dL (as in vitamin D intoxication, hyperparathyroidism, carcinomatosis, sarcoid, and multiple myeloma) causes weakness, tetanic muscle spasms, and convulsions; a considerable increase in magnesium levels leads to muscle weakness and depression of central nervous function (confusion). The weakness of muscle may be due, in part at least, to reduced...
release of ACh at the motor end plate.

**Changes in Serum Levels of Enzymes Originating in Muscle Cells**

In all diseases causing extensive damage to striated muscle fibers, intracellular enzymes leak out of the fiber and enter the blood. Those measured routinely are the transaminases, lactate dehydrogenase, aldolase, and creatine kinase (CK). Of these, the concentration of CK in serum has proved to be the most sensitive measure of muscle damage. Since high concentrations of this enzyme are found in heart muscle and brain, raised serum values may be due to myocardial or cerebral infarction as well as to the necrotizing diseases of striated muscle (polymyositis, muscle trauma, muscle infarction, paroxysmal myoglobinuria, and the more rapidly advancing muscular dystrophies). For serum CK levels to be interpretable, one has to be certain that the enzyme being released into the serum is not derived from heart or brain. This can be determined by the quantitation of serum isoenzymes of CK, referred to as MB, MM, and BB (M, muscle; B, brain); their measurement provides a sensitive means for the detection of damage to myocardium (MB), skeletal muscle (MM), and nervous tissue (BB), respectively.

The MM form of CK is found in highest concentration in striated muscle, but there is also 5 to 6 percent MB. Heart contains 17 to 59 percent MB; hence, the diagnosis of myocardial infarction requires that the CK-MM fraction be greater than 6 percent (or that troponin, which is overrepresented in heart muscle, be present in the serum). Embryonic and regenerating muscle contains more CK-MB than mature normal muscle. In patients with destructive lesions of striated muscle, serum values of CK often exceed 1000 units and may reach 40,000 units or more (the upper limit of normal varies from 65 to 200 units, depending on the method). Serum of the normal adult contains only the MM isoenzyme, but in normal children, as much as 25 percent of serum CK may be derived from the MB fraction. Even more interesting is its rise in some children with progressive muscular dystrophy before there is enough destruction of fibers for the disease to be clinically manifest, at least as judged by the relatively crude tests of muscle strength. Moreover, the unaffected female carrier of Duchenne dystrophy may often be identified by an elevated serum level of CK. Alterations of serum enzyme levels are nonspecific for dystrophy since they occur in all types of disease that damage the muscle fiber. Moreover, in the more slowly evolving types of dystrophy, such as that of Landouzy-Déjerine, the serum levels of CK may be normal. It would be expected that the values would always be normal in denervation paralysis with muscular atrophy, but slight elevations are sometimes observed in patients with progressive spinal muscular atrophy and amyotrophic lateral sclerosis. Even vigorous exercise or surgical operations elevate CK, sometimes exceeding 6 percent from the MB fraction. In some individuals, CK may be persistently elevated without evidence of muscle or other diseases. An unexplained alteration of the sarcoclemma with high serum CK occurs in hypothyroidism and in alcoholism.

An isolated elevation of aldolase, the serum enzyme other than CK that is derived predominantly from skeletal muscle, generally has less clinical significance. Measurement in the serum of various transaminases or lactate dehydrogenase is not particularly useful for the diagnosis of muscle disease because of their ubiquitous distribution in many mammalian tissues. Nevertheless, the neurologist should be aware that unexplained elevations in all of the muscle-derived enzymes (CK, LDH, SGOT, etc.) can be caused by invident muscle trauma.

**Myoglobinuria**

The red pigment myoglobin, responsible for much of the color of muscle, is an iron-protein compound present in the sarcoplasm of striated skeletal and cardiac fibers. Of the total body hematrin content, about 25 percent is in muscle, the remainder in red blood corpuscles and other cells. Destruction of striated muscle, regardless of the process—whether trauma, ischemia, or metabolic disease—liberates myoglobin, and because of its relatively small size, the molecule filters through the glomeruli and appears in the urine, imparting to it a burgundy red color. Because of the low renal threshold for myoglobin, excretion of this pigment is so rapid that the serum remains uncolored. In contrast, because of the high renal threshold for hemoglobin, destruction of red blood corpuscles colors both the serum and the urine. Myoglobinuria should thus be suspected when the urine is deep red and the serum is normal in color. It is estimated that 200 g of muscle must be destroyed to color the urine visibly (Rowland). As in hemoglobinuria, the guaiac and benzidine tests of urine are positive. The colored urine does not fluoresce, as it does in porphyria. On spectroscopic analysis, myoglobin shows an absorption band at 581 nm, but the most sensitive method for measuring myoglobin in the urine and serum is by radioimmunoassay methods (Rosano and Kenney). Hyperkalemia, hyperphosphatemia, and hypercalcemia may complicate massive rhabdomyolysis.

Some years ago, the measurement of creatine and creatinine in blood and urine was a standard method of estimating damage to striated muscle. This technique is now seldom used for clinical or research purposes, having been replaced largely by the measurement of CK and its isoenzymes.

**Endocrine Myopathies**

In a number of disorders of the endocrine glands, muscle weakness may be a prominent feature, and occasionally it may be the chief complaint. Although these diseases are discussed in detail in Chap. 51, it should be noted that such weakness, local or generalized, acute or chronic, may occur in the absence of changes in serum electrolytes or enzymes. Specific hormone assays are then necessary for diagnosis. This is particularly true of patients with thyrotoxicosis or Cushing disease and those receiving prolonged corticosteroid therapy. In thyrotoxicosis, muscle paresis may appear without the classic signs of Graves disease.

**ELECTRODIAGNOSIS OF NEUROMUSCULAR DISEASE (ELECTROMYOGRAPHY; EMG)**

It was long ago discovered that muscle would contract when a pulse of electric current was applied to the skin, near the point of entrance of the muscular nerve (motor point). The electrical pulse required is brief, less than a millisecond, and is most effectively induced by a rapidly alternating (faradic) current. After denervation, an electrical pulse of several milliseconds, induced by a constant electrical (galvanic) stimulus, is required to produce the same response. This change, in which the galvanic stimulus remains effective after the faradic one has failed, was the basis of Erb's reaction of degeneration, and varying degrees of this change were later plotted in the form of strength-duration curves. For decades, this was the standard electrical method for evaluating denervation of muscle. Though still valid, it was replaced long ago by nerve conduction studies and by the needle electrode examination. The latter tests, based on the sherringtonian concept of the "motor unit" (page 47), is accomplished by recording the firing characteristics of evoked motor unit potentials (MUPs and CMAPs) and by the insertion into muscle of needle electrodes to measure spontaneous and voluntarily evoked muscle fiber activity. The terms electromyography and electromyogram (EMG) were coined originally to describe only the needle electrode examination but are now commonly used to describe the entire electrodiagnostic evaluation, including the nerve conduction studies, described below.

**Conduction Studies of Nerve**

The main laboratory technique for the study of peripheral nerve function involves the percutaneous stimulation of motor or sensory nerves and recording of the elicited muscle and sensory action potentials. The results of these motor and sensory nerve conduction studies, expressed as amplitudes, conduction velocities, and distal latencies, yield certain quantitative information and additional qualitative observations regarding the waveform and dispersion of electrical impulses.

Hodes and coworkers in 1948 were the first to perform nerve conduction studies in patients. An accessible nerve is stimulated through the skin by surface electrodes, using a stimulus that recruits all available fibers, and the resulting compound action potential is recorded by electrodes on the skin (1) over the nerve more proximally, using orthodromic techniques for sensory fibers stimulated in the digital nerves, (2) over the nerve more distally, using antidromic techniques for sensory nerve conduction studies (this has many technical advantages over orthodromic techniques), (3) over the muscle more distally in the case of motor fibers stimulated in a mixed or motor nerve, and (4) over the nerve more proximally for mixed nerve conduction studies (Fig. 45:3). The second and third techniques are the ones used most often in clinical work. An alternative but much more demanding technique uses "near nerve" needle electrodes to record action potentials as they course through the nerve.
Distal (Terminal) Latencies, Conduction Times, and Conduction Velocities  

The conduction times from the most distal stimulating electrode to the recording site, in milliseconds, as determined from the stimulus artifact to the onset and to the peak of the response, are termed the distal (or terminal) and peak latencies, respectively. *The distal latency (the time to the onset of the compound muscle action potential) is used as a measure of the speed of conduction*  

If a second stimulus is applied to a mixed nerve more proximally (or if recording or stimulating electrodes can be placed more proximally in the case of sensory fibers), a new and longer conduction time can be measured. When the distance (in millimeters) between the two sites of stimulation of motor fibers or recording of sensory fibers is divided by the difference in conduction times (in milliseconds), one obtains a maximal conduction velocity (in meters per second), which describes the velocity of propagation of the action potentials in the largest and fastest nerve fibers. These velocities in normal subjects vary from a minimum of 40 or 45 m/s to a maximum of 65 to 75 m/s, depending upon which nerve is studied (slower in the legs than in the arms; Table 45-1). Values are lower in infants, reaching the adult range by the age of 2 to 4 years and decline again with advancing age. They are diminished also with exposure to cold—a potentially important artifact in these recordings.

Amplitude of the Compound Muscle Action Potential  

In addition to the study of distal latency and conduction velocity, the amplitudes of the evoked muscle action potential yield valuable information about peripheral nerve function. A stimulus that provides the maximal-amplitude muscle potential is used. These amplitudes are a semiquantitative measure of the number of nerve fibers that respond to a given stimulus and are conducted to the various recording points, hence allowing the detection of conduction block and axonal loss. In addition, segmental demyelination, which markedly slows conduction velocities or, in the case of the acquired demyelinating neuropathies, produces dispersion of the action potential and conduction block (see below).

Sensory Nerve Action Potentials  

When motor fibers in a mixed nerve are stimulated, a compound action potential of many hundreds of microvolts can easily be recorded from electrodes on the skin over the muscle. However, when one attempts to measure sensory potentials, where activity must be recorded from nerve fibers themselves, one lacks the "amplification" provided by all the muscle fibers in many motor units, as noted above, and much greater electronic amplification is required. Abnormal sensory potentials are sometimes very small or absent even when powerful computer-averaging techniques are used, and sensory conduction...
measurements may be difficult or impossible to record, particularly in the lower extremities of elderly patients. Table 45-1 gives the range of normal values for sensory nerve action potential amplitudes and velocities.

Conduction Block By stimulating a motor nerve at multiple sites along its course, it is possible to demonstrate segments in which conduction is partially "blocked" or is completely "blocked." From such data one infers the presence of lesions, often demyelinating lesions in motor nerves. This contrasts with the findings in certain of the demyelinating inherited neuropathies, in which all parts of the nerve fiber are altered to more or less the same degree and there is uniform slowing of conduction velocity but no block. Conduction blocks are demonstrated by a reduction in the amplitude of the CMAP that is elicited from proximal nerve stimulation, compared with stimulation at a more distal site, as described earlier. Generally, a 40 percent reduction in amplitude over a short distance, or 50 percent over longer distances, qualifies as a block, the exception being the tibial nerve, in which it is difficult to stimulate all the motor nerve fibers and a drop in amplitude is expected. It is important also to be certain that the reduction in amplitude along the course of the nerve is not due solely to dispersion of the waveform and that the block not be attributable simply to nerve compression at the common sites (fibular head, across the elbow, flexor retinaculum at the wrist, etc.). Conduction block can also be inferred from the finding that muscle action potentials after several denervations have no action potential for several weeks in the same muscle. The finding of conduction block is a central feature in a number of acquired immune demyelinating neuropathies, including Guillain-Barré syndrome, chronic inflammatory demyelinating neuropathy, and multifocal conduction block associated with the GM, antibody, all of which are discussed in Chap. 48.

Focal compression of nerve, as in the entrapment syndromes mentioned above, may produce localized slowing or blocks in conduction, perhaps because of segmental demyelination at the site of compression. The demonstration of such localized changes of conduction affords ready confirmation of nerve entrapment; for example, if the distal latency of the median nerve (A, Fig. 45-3) exceeds 4.5 ms while that of the ulnar nerve remains normal, compression of the median nerve in the carpal tunnel is likely. Similar focal slowing or partial block of conduction may be recorded from the ulnar nerve at the elbow and from the peroneal nerve at the fibular head.

Electrodiagnostic Studies of Nerve Roots and Spinal Segments (Late Responses, Blink Responses, Segmental Evoked Responses) H Reflex and F Wave Information about the conduction of impulses through the proximal segments of a nerve that is not obtainable by routine nerve conduction techniques may be provided by the study of the H reflex and the F wave. In 1918, Hoffmann, after whom the H reflex was later named, showed that submaximal stimulation of mixed motor-sensory nerves, insufficient to produce a direct motor response, produces a muscle contraction (H wave) after a latency that is much longer than the direct motor response. The H reflex is based on the action of spinal interneurons (those involved in the transmission of initial impulses) of delayed muscular response reflects the time required for the impulses to reach the spinal cord along the sensory fibers, synapse with anterior horn cells, and then be transmitted along motor fibers to the muscle (see Fig. 3-1). Thus the H reflex is the electrical representation of the tendon reflex circuit and can be useful because the impulse traverses both the posterior and anterior roots. The H reflex is particularly helpful in the diagnosis of S1 radiculopathy and of polyneuropathies, including predominantly sensory ones, because it generally parallels the state of elicitability of sensory fibers other than the tibial. Stimulation of increasing frequency but low intensity causes a progressive depression and finally obliteration of H waves. The latter phenomenon has been used to study spasticity, rigidity, and cerebellar ataxia, in which there are differences in the frequency-depression curves of H waves.

The F response, so named because it was initially elicited in the foot, was first described by Magladery and McDougall in 1950. It is evoked by a supramaximal stimulus of a motor-sensory nerve. Again, after a latency longer than that for the direct motor response (latencies of 28 to 32 ms in arms, 40 to 50 ms in legs), a second small muscle action potential is recorded (F wave). The F wave is produced by the stimulation of motor fibers that travel antidromically to the anterior horn cells; a small number of anterior horn cells are activated and produce an orthodromic response that can be recorded in a distal muscle. The F response is a more discerning test than the H wave in that the former traverses only the ventral root and can be elicited from any number of muscles. Normal F responses and absent H reflexes can be seen with disease of sensory nerves and roots. The late responses find their main use as corroborative tests that are interpreted in the context of the entire nerve conduction examination (see Wilbourn in the References). The usually elicited late response latencies are given in Table 45-1.

Electrical Blink Responses This special nerve conduction test may be useful in the diagnosis of certain demyelinating neuropathy and other regional processes that affect the trigeminal or facial nerve. The patient's supraorbital (or infraorbital) nerve is stimulated transcutaneously and the reflex closure of both orbicularis oculi muscles is recorded with surface electrodes. Two EMG bursts are observed: the first (R1) appears ipsilaterally 10 ms after the stimulus and the second (R2) ipsilaterally at 30 ms and contralaterally up to 5 ms later. The amplitudes of the responses vary considerably and are not in themselves clinically important. The first response is not visible as a muscular contraction but may serve some preparatory function by shortening the blink reflex delay. R1 is mediated by an oligosynaptic pontine circuit consisting of one to three neurons located in the vicinity of the main sensory nucleus. It has been established that R1 and R2 share the same facial motor neurons.

The elicitation of blink reflexes confirms the integrity of theafferent trigeminal nerve, the efferent facial nerve, and the interneurons in the pons (R1) and caudal medulla (mainly related to the bilateral R2 response). The test may be helpful in identifying a demyelinating neuropathy when the facial and oropharyngeal muscles are affected but the orbicularis oculi is spared. The R2 response is the best indicator of facial nerve function. In cases such as this, the blink reflexes are delayed, sparsely recruited, and contralaterally, as a result of conduction block in the proximal facial nerve. Direct facial nerve stimulation often fails to demonstrate this block because only the distal segment of the nerve is amenable to study. Although this test is rarely necessary for diagnosis, most patients with hereditary neuropathy have blink response abnormalities. The reason for this is that there is a delay in the latency only on the affected side. Large acoustic neuromas may interfere with the trigeminal portion of the pathway and give rise to abnormal responses on the affected side. Diseases of the brainstem have yielded inconsistent results. It is noteworthy that the test is normal in patients with trigeminal neuralgia.

Segmental Motor, Cranial, and Somatosensory Evoked Potentials These techniques are particularly useful in diseases that affect spinal roots. By applying a magnetic stimulus, which induces an electrical impulse, or an electrical stimulus delivered directly by an electrode, over the cranium or lower cervical or lumbar spine, it is possible to activate motor cortex or motor roots and measure the time required to elicit a muscle contraction. In the latter case, the motor point stimulated is below the motor cortex. Muscles are recorded with surface electrodes. Two EMG bursts are observed: the first (R1) appears ipsilaterally 10 ms after the stimulus and the second (R2) ipsilaterally at 30 ms and contralaterally up to 5 ms later. The amplitudes of the responses vary considerably and are not in themselves clinically important. The first response is not visible as a muscular contraction but may serve some preparatory function by shortening the blink reflex delay. R1 is mediated by an oligosynaptic pontine circuit consisting of one to three neurons located in the vicinity of the main sensory nucleus. It has been established that R1 and R2 share the same facial motor neurons.

It has been established that R1 and R2 share the same facial motor neurons.
agents, and it can be partially corrected with anticholinesterase drugs such as neostigmine and edrophonium. Similar but lesser decremental responses may occur in polymyositis, amyotrophic lateral sclerosis, and certain other diseases of the motor unit or motor nerve, particularly with those who are reinnervating nerve twigs following nerve injury.

The presynaptic myasthenic syndrome of Lambert-Eaton, often associated with oat-cell carcinoma of the lung, is characterized by a different type of defect of neuromuscular transmission. During tetanic stimulation (20-50 per-second repetitive stimulation of nerve), the muscle action potentials, which are small or practically absent with the first stimulus, increase in voltage with each successive response until a more nearly normal amplitude is attained (Fig. 45-4B). Exercising the muscle for 10 s before testing will cause a similar posttetanic facilitation (200-fold increases are not uncommon). A less important decremental response to slow stimulation may occur, but it is difficult to discern because of the greatly diminished amplitude of the initial responses. Neostigmine has little effect on this phenomenon, but it may be reversed by guanidine and 3,4-diaminopyridine, which stimulate the release of ACh. The effects of this myasthenic syndrome are similar to those produced by botulinum toxin or by aminoglycoside antibiotics.

The single-fiber EMG, discussed in a later section, is a more sensitive method of detecting failure of the neuromuscular junction.

**Needle Examination of Muscle**

This technique requires the use of monopolar or concentric bipolar needle electrodes, which are inserted into the body of the muscle. With concentric needle electrodes, the tip of the wire that runs in the hollow of the needle is in proximity to many muscle fibers belonging to several motor units; this is the active recording electrode. The shaft of the needle, in contact over most of its length with intercellular fluid and many other muscle fibers, serves as the reference electrode. With monopolar electrodes, the uninsulated needle tip is the active electrode, while the reference electrode may be another monopolar needle electrode placed in subcutaneous tissue or a surface electrode on the skin overlying the muscle being tested. Patients almost invariably find this portion of the test uncomfortable and should be prepared by a description of the procedure. Rapid and brief needle insertion by the skilled examiner makes the test more tolerable.

When an electrical impulse travels along the surface of the muscle toward the recording electrode, a positive potential (by convention) is recorded on the oscilloscope, i.e., the recorded signal is deflected downward (at A in Fig 45-5). When the depolarized zone moves under the recording electrode, it becomes relatively negative and the beam is deflected upward (at B). As the depolarized zone continues to move along the sarcolemma, away from the recording electrode, the current begins to flow outward through the membrane toward the distant depolarized region, and the recording electrode becomes relatively positive again (at C). It then returns to its resting isopotential position. The net result is a triphasic action potential, as in Fig. 45-5. This configuration is typical of the firing of a single fiber.

![Figure 45-5](image)

The electrical activity of various muscles is recorded both at rest and during active contraction by the patient. As indicated above, muscle fibers do not discharge in normally innervated muscle until activated together in motor unit activity, which involves the almost simultaneous contraction of all the muscle fibers innervated by a single anterior horn cell. Although the typical configuration of a motor unit potential (MUP) is triphasic, up to 10 percent of normal MUPs consist of four or more phases (polyphasic potentials); an excess of polyphasic potentials beyond this is pathologic.

Normal muscle in the resting state should be electrically silent; the small tension spoken of as muscle tone has no EMG equivalent. There are, however, two closely related types of normal spontaneous activity and another that is induced by the insertion of the needle itself. One is a low-amplitude, 10- to 20-mV monophasic (negative) potential of very brief (0.5 to 1 ms) duration. These represent single or synchronized MEPPs due to the small number of ACh quanta that are being released at all times. They are normally sparse but are most evident when the recording needle electrode is placed near a motor end plate (end-plate noise). Placement of the needle electrode very close to or in contact with the end plate gives rise to a second type of normal spontaneous activity. The latter is characterized by irregularly discharging high-frequency (50-100-Hz) biphasic (negative-positive) spike discharges, 100 to 300 mV in amplitude (i.e., large enough to cause an isolated muscle action potential). These potentials have been termed "end-plate spikes" and represent discharges of single muscle fibers excited by activity in nerve terminals. These potentials must be distinguished from fibrillation potentials (see below). Insertion of the needle electrode into the muscle injures and mechanically stimulates many fibers, causing a burst of potentials of short duration (<300 ms). This is referred to as normal insertional activity.

When muscle is voluntarily contracted, the action potentials of motor units begin to appear. One can observe the way force is built up by watching the progressive recruitment of MUPs, the initial ones, representing the activity of smaller motor units of (type 1), firing at rates of 5 to 10 per second. With increased force of contraction, there is recruitment of larger, previously inactive motor units as well as an increased rate of firing (40 to 50 per second; see Fig. 45-6A). Since individual MUPs can no longer be distinguished during maximal voluntary contraction, this activity is referred to as a complete interference pattern (Fig. 45-6A, right). This is not only seen as a summated signal pattern but also heard as a mixed high-frequency clicking when the electrical activity is made audible by the EMG machine. As muscles relax, more and more units drop out. If a muscle is weakened by denervation or if electrical conduction is blocked, there will obviously be fewer MUPs, firing at a moderately rapid rate (reduced recruitment, Fig. 47-6B). In contrast, with poor voluntary effort and with upper motor neuron lesions, the MUPs fire in decreased numbers, at slower rates, and often in an irregular pattern (termed poor activation).

![Figure 45-6](image)

**Figure 45-6** Patterns of motor unit recruitment. A. Normal. With each increment of voluntary effort, more and larger units are brought into play until, with full effort at the extreme right, a complete "interference pattern" is seen in which single units are no longer recognizable. B. After denervation, only a single motor unit is recorded despite maximal effort. R is seen to fire repetitively. C. With myopathic diseases, a normal number of units is recruited on minimal effort, though the amplitude of the pattern is reduced. Calibrations: 50 ms (horizontal) and 1 mV in A and B; 200 mV in C (vertical).
In the usual EMG examination, a plan for the study is made based on detailed knowledge of muscular innervation and focusing on the regions affected by weakness and by other major clinical features of the illness. In some patients, as in those with motor neuron diseases or polymyositis, a wider sampling of muscles is required to detect changes in asymptomatic regions.

The Abnormal Electromyogram Clinically important deviations from the normal EMG include (1) increased or decreased insertion activity; (2) the occurrence of abnormal "spontaneous" activity during relaxation (fibrillation potentials, positive sharp waves, fasciculation potentials, cramp potentials, myotonic discharges, myasthenic potentials); (3) abnormalities in the amplitude, duration, and shape of single MUPs; (4) a decrease in the number of MUPs and changes in their firing pattern; (5) variation in amplitude and number of phases of MUPs during voluntary contraction of muscle; and (6) the demonstration of special phenomena, such as electrical silence during obvious shortening of the muscle (true contracture).

Insertional Activity At the moment the needle is inserted into muscle, there is usually a brief burst of action potentials that ceases once the needle is stable provided that it is not in a position to irritate a nerve terminal. Increased insertion activity is seen in most instances of denervation as well as in many forms of primary muscle disease and in disorders that dispose to muscle cramps. In cases of advanced denervation or myopathy, in which muscle fibers have been largely replaced by connective tissue and fat, insertional activity may be decreased and there may be increased mechanical resistance to insertion of the needle electrode.

Abnormal "Spontaneous" Activity With the muscle at rest, spontaneous activity of single muscle fibers and of motor units, known respectively as fibrillation potentials and fasciculation potentials, is abnormal. The two phenomena are often confused. Fibrillation is the spontaneous contraction of a single muscle fiber. It occurs when the muscle fiber has lost its nerve supply and is ordinarily not visible through the skin. Fasciculation represents the spontaneous firing of a motor unit, causing contraction of a group of muscle fibers, and may be visible through the skin. The firing irregularly of a number of motor units, seen as a rippling of the skin, is called myokymia.

Fibrillation Potentials When a motor neuron is destroyed by disease or its axon is interrupted, the distal part of the axon degenerates, a process that takes several days or more. The muscle fibers formerly innervated by the branches of the dead axon—that is, the motor unit—are disconnected from the nervous system. For reasons that are still obscure, the chemosensitive region of the sarcolemma at the motor end plate "spreads" after denervation to involve the entire surface of the muscle fiber. Then, 10 to 25 days after death of the axon, the denervated fibers develop spontaneous activity; each fiber contracts at its own rate and without relation to the activity of neighboring fibers. This spontaneous activity is associated with a totally random conglomeration of brief- or triphasic fibrillation potentials (Fig. 45-7A), having a duration of 1 to 5 ms and rarely exceeding 300 mV in amplitude. When brief spontaneous potentials of this sort are observed firing regularly at two or three different locations outside the end-plate zone of a resting muscle, one may conclude that the fibers are denervated. Usually, fibrillation potentials discharge at an almost regular rate. In some early lesions (less than 6 to 8 weeks), irregularly firing fibrillation potentials may be observed. Diseases such as poliomyelitis, which damage spinal motor neurons, or injuries of peripheral nerves or anterior spinal roots frequently produce only partial denervation of the involved muscles. In such muscles, one electrode placement may record fibrillation potentials at rest from denervated fibers and normal potentials during voluntary contraction from nearby healthy fibers. Fibrillation potentials continue until the muscle fiber is reinnervated by progressive proximal-distal regeneration of the interrupted nerve fiber or by the outgrowth of new axons from nearby healthy nerve fibers (collateral sprouting), or until the atrophied fibers degenerate and are replaced by connective tissue, a process that may take many years. In addition, fibrillation potentials may take the form of positive sharp waves, i.e., spontaneous, initially positive diphasic potentials of longer duration and slightly greater amplitude than the spikes of fibrillation potentials (Fig. 45-7A).

Unfortunately, fibrillation potentials, while characteristic of neurogenic denervation, are not altogether specific; for example, they are seen in muscle diseases such as polymyositis and inclusion body myositis, which presumably damage the neural innervation to small regions of muscle or isolate segments of a muscle fiber from its end plate.

Fasciculation Potentials As stated above, a fasciculation is the spontaneous or involuntary contraction of a motor unit or part of a motor unit. Such contractions may cause a visible dimpling or twitching under the skin, though ordinarily they are of insufficient force to move a joint. Large fasciculations, however, can briefly displace a finger or toe; they occur irregularly and infrequently, and prolonged inspection may be necessary to detect them. The form of the accompanying fasciculation potential, like that of an ordinary MUP, seen on voluntary contraction, is relatively constant. If the motor unit from which the fasciculation arises is otherwise normal, the accompanying fasciculation potential will have three to five phases, a duration of 5 to 15 ms (somewhat less in the facial muscles), and an amplitude of several millivolts (Fig. 45-7B). Fasciculation potentials are evidence of motor nerve fiber irritability, most often the result of reinnervation following nerve or motor neuron damage.

The precise source of fasciculation is still contested. Forster and colleagues, in the 1940s, challenged the original belief that the discharge originated in anterior horn cells by demonstrating that fasciculations persisted after nerve block in amyotrophic lateral sclerosis (ALS) and ceased only with the appearance of fibrillation potentials, signifying wallerian (axonal) degeneration. These observations favored a distal site of generation. Other physiologic and pharmacologic evidence pointed to the first segment of the motor axon, or to the distal axon, or even to the motor point, involving elements of the post synaptic muscle membrane (particularly in the case of benign fasciculations) as the source of the spontaneous electrical activity. It seems that several regions of the axon are capable of spontaneous impulse generation, depending on the underlying disease; most involve the anterior horn cell or the motor root, but distal sites are operative in cases of nerve compression and polymyositis.

Occasional fasciculation potentials—particularly in the calves, hands, and pericentral or paraspinal muscles—occur in many normal persons. They can be almost constant for days or weeks on end, or even for years in some individuals, without weakness or wasting; therefore they need not be taken as evidence of disease (benign fasciculations). Certain quantitative features of fasciculations, such as brief duration and a consistent pattern of firing, favor benign over pathologic discharges. Shivering induced by low temperature and twichings associated with low serum calcium levels are other forms of fasculatory activity.

Fasciculation potentials occur with great frequency in chronic, slowly advancing, destructive diseases of the anterior horn cells, such as ALS and progressive spinal muscular atrophy. In these primary spinal cord diseases, both voluntary MUPs and fasciculation potentials may be of long duration (more than 15 ms) and of increased amplitude, indicating chronic denervation and reinnervation. They are seen often in the early stages of poliomyelitis but only occasionally in the chronic phase of the disease, perhaps because the affected cells die rapidly. When anterior horn cells degenerate once again in older individuals who had had poliomyelitis (postpolio syndrome), fasciculations may return. Occasionally, they are seen with compressive anterior root lesions, such as those caused by a protruded intervertebral disc; large numbers of axons may be affected, with the result that the fasciculations (or even cramps) may be more prominent than with disease of anterior horn cells. Fasciculation potentials in lesser numbers are also observed with chronic nerve entrapments, e.g., ulnar neuropathy at the elbow and other peripheral nerve lesions and some polymyopathies. In all these cases, the damaged neuron or its axon seems to leave intact axons in a state of hyperirritability. The
repetitive axon potentials produce activity in all the muscle fibers that the axon innervates. The blocking of axon conduction by local anesthesia does not abolish the fasciculation, but curare-like drugs do so.

**Less Common Types of Spontaneous Activity** One of these is myokymia (pages 1467 and 1568), a persistent quivering and rippling of muscles at rest ("live flesh"). The EMG picture is distinctive. The spontaneously firing MUPS are called myokymic potentials or discharges and consist of groups of repetitive discharging units, each firing at its own rate, quasi-rhythmically, usually several times per second, followed by an even briefer period of silence. The small motor unit discharges may occur singly or as doublets, triplets, or multiplets. The site of generation of this activity has been contested, possibly because it may arise from several sites, but always the site is peripheral, not central, and is believed to correspond to an alteration in the calcium concentration in the microenvironment of the motor axon. Spontaneous discharges arising in large myelinated fibers have been implicated in the genesis of myokymia; indeed, demyelinating polynuropathies are among the conditions that give rise to this phenomenon. This activity may be blocked by lidocaine infusion around the peripheral nerve and may be diminished by carbamazepine or phenytoin.

In the syndrome of continuous muscle fiber activity or Isaacs syndrome (page 1568), which is actually a generalized form of myokymia, EMG discloses high-frequency (up to 300-Hz) repetitive discharges of varying wave forms.

Focal and segmental myokymias are related, as judged by their EMG patterns. They differ in small ways from the generalized form of myokymia with regard to the timing and duration of the discharges. The focal types refer mainly to facial myokymia, seen most often in multiple sclerosis, Guillain-Barré syndrome, or large cerebellar pontine angle tumors, but it may follow any peripheral nerve injury and regeneration. The EMG patterns are complex, either high-frequency (30- to 100-Hz) recurrent bursts or brief lower-frequency bursts. Segmental myokymia is a common occurrence in radiation injuries of the brachial plexus. The EMG bursts tend to be longer and less frequent than in generalized myokymia, and the interburst frequency is highly variable. The origin of these discharges (also referred to as neuromyotonia) is probably in the distal peripheral nerve, where activity of afferent fibers, possibly via ephaptic transmission, irregularly excites distal motor terminals. This activity persists during sleep and general anesthesia.

The phenomenon of myotonia (see page 1553) is characterized by high-frequency repetitive discharges generally having a positive sharp waveform. These myotonic discharges wax and wane in amplitude and frequency, producing a "dive-bomber" sound on the audio monitor. The discharges can be elicited mechanically by percussion of the muscle or movement of the needle electrode and are also seen following voluntary contraction or electrical stimulation of the muscle via its motor nerve. The MUPS may appear normal during voluntary contraction, but they are not followed by the silence that normally occurs on relaxation; instead, there is a "prolonged afterdischarge" consisting of long trains of fibrillation-like potentials that may take as long as several minutes to subside (Fig. 45-8). These EMG findings, which can be seen with any myotonic disorder, correspond to the clinical failure of voluntary relaxation of muscle following a forceful contraction. If the muscle is activated repeatedly at short intervals, the late discharge becomes briefer and briefer and eventually disappears (Fig. 45-8), as the patient becomes able to relax the exercised muscle ("warm-up" effect). In the paradoxical myotonia observed in some cases of von Eulenburg paramyotonia, Nielsen and colleagues have found a decreasing recruitment pattern and increasing activity after each of a succession of voluntary contractions. This is the converse of what happens in congenital myotonia. As shown by the single-fiber EMG studies of Denny-Brown and Nevin, myotonia is generated by single muscle fibers, and the mechanism of the membrane instability, at least in some forms, seems to involve changes in the chloride conductance. In the stiff-man syndrome, painful muscle spasms and stiffness are generated by a central mechanism; the EMG potentials resemble normal motor units but are abnormal by virtue of continuous firing at rest.

**Figure 45-8** A. Myotonia congenita (Thomsen disease). The five lines are a continuous record of activity in the biceps brachii following a tap on the tendon. The initial response is within normal limits, but it is followed by a prolonged burst of rapid activity, gradually subsiding over a period of many seconds or minutes. B. Same electrode placement as in A. Response to the fifth of a series of tendon taps. "Warm-up" has occurred, and the characteristic prolonged myotonic activity is no longer evident.

Complex repetitive discharges—formerly referred to as bizarre high-frequency discharges and, even earlier, as pseudomyotonia—consist of repetitive spontaneous potentials often having an erratic configuration and starting and stopping abruptly. They are seen in some myopathies, in hypothyroidism, and in certain denervating disorders and are a mark of chronicity (lesions over 6 months old). High-frequency coupling of action potentials into doublets, triplets, or higher multiples of single units, indicating instability in repolarization of the nerve fiber to a muscle, occurs in tetany and in the early stages of myokymia.

The cramp-like contracture of McArdle disease and phosphofructokinase deficiency is associated with electrical silence of contracting muscle. This feature is important in the definition of this syndrome.

**Abnormalities in Amplitude, Duration, and Shape of Motor Unit Potentials** Figure 45-9 (schematically) and Figure 45-10 depict the ways in which disease processes affect the motor unit and the appearance of the MUP in the EMG.

**Figure 45-9** The shaded muscle fibers are functional members of one motor unit, whose axon enters from the upper left and branches terminally to innervate the appropriate muscle fibers. The action potential produced by each motor unit is seen in the upper right: its duration is measured between the two vertical lines. The normal-appearing but unshaded fibers belong to other motor units. A. Hypothetical situation, with five muscle fibers in the active unit. B. In this myopathic unit, only two fibers remain active; the other three (shrunken) have been affected by one of the primary muscle diseases. C. Four fibers which originally belonged to other motor units and had been denervated have now been reinnervated by terminal sprouting from an undamaged axon. Both the motor unit and its action potential are now larger than normal. Note that only under these abnormal circumstances do fibers in the same unit lie next to one another.
Early in the course of denervation, many motor units with functional connections to the spinal cord are unaffected, and though the number of MUPs appearing during contraction is reduced, the configurations of the remaining ones are quite normal. In time, the remaining MUPs often increase in amplitude, perhaps two to three times normor, and become longer in duration and sometimes polyphasic (more than four phases).

Such large and sometimes giant potentials (Fig. 45-9C and Fig. 45-10B) are believed to arise from motor units containing more than the usual number of muscle fibers that are spread out over a greatly enlarged territory within the muscle. Presumably, new nerve twigs have sprouted from nodal points and terminals of undamaged axons and have reinnervated previously denervated muscle fibers, thus adding them to their own motor units. Soon after reinnervation, the MUPs generated will be low in amplitude, extremely prolonged, and polyphasic, findings that constitute a transitional configuration of early reinnervation. These amplitudes disappear as the motor unit is re-established. Increased amplitude is usually associated with very chronic, proximal axon loss, e.g., with remote polymyelitis and chronic cervical radiculopathy. These MUPs are to be differentiated from (1) polyphasic potentials of normal duration, which, as was said, make up as much as 10 percent of the total number of MUPs in normal muscle, and (2) polyphasic MUPs of short duration and low amplitude, which are characteristic of most myopathies and of myastheniagravis and other disorders of neuromuscular transmission.

### The Motor Unit Potential in Myopathy
Diseases such as polymyositis, the muscular dystrophies, and other myopathies that randomly destroy muscle fibers or render them nonfunctional obviously reduce the population of muscle fibers per motor unit, as in Fig. 45-9B. Therefore, when such a unit is activated, its potential is of lower voltage and shorter duration than normal, and it may also appear polyphasic as the compound MUP becomes fragmented into its constituent single-fiber potentials. However, if the propagated muscle fiber action potential in affected muscle fibers is also believed to contribute to the changes of the myopathic MUP. When most of the muscle fibers are affected, the MUPS are very small and of short duration and are recruited out of proportion to the tension generated—so-called increased recruitment. Both types of alterations produce a characteristic high-pitched cracking sound from the audio monitor that has been likened to rain falling on a tin roof. They occur in all forms of progressive muscular dystrophy and are indistinguishable from those of polymyositis, dermatomyositis, and other chronic myopathies. Identical MUP changes can occasionally be seen with other processes that cause disintegration of the motor unit, e.g., early Guillain-Barré syndrome (due to conduction block along some of the terminal nerve fibers), and rarely with disorders of neuromuscular transmission (myasthenia gravis, other myasthenic syndromes), but they are most characteristic of primary muscle disease. Fibrillation potentials are sometimes seen in the myositides, inclusion-body myopathy, and the rapidly progressive muscular dystrophies, perhaps because of segmental necrosis of muscle fibers, which may isolate a segment of the fiber from its nerve supply. In myasthenia gravis, where transmission of impulse fails at the neuromuscular junction, a single MUP may vary in amplitude during sustained weak contraction. Electromyographic recordings of single muscle fibers belonging to the same motor unit disclose varying interpotential intervals on successive discharges; this phenomenon is called “jitter” and increases to the point of actual block, with deficits in neuromuscular transmission (see below).

### Abnormalities of the Interference Pattern
Diseases that reduce the population of functional motor neurons or axons within the peripheral nerve obviously decrease the number of motor units that can be recruited in the affected muscles. The decreased number of motor units available for activation now produce an incomplete interference pattern, which is manifest by a decreased number of units firing at a moderate to rapid rate. A severe reduction in the interference pattern may result in the recruitment of only a single unit (Fig. 45-6B). If muscle power is reduced in diseases such as polymyositis or muscular dystrophy, in which individual muscle fibers are affected, there may be little or no reduction in the number of motor units available for recruitment until the process is far advanced and entire MUPs have been lost due to random loss of all their constituent muscle fibers. Nonetheless, each motor unit will consist of fewer muscle fibers than normal, so more motor units must be activated to reach a certain degree of force. A modest effort can thus produce a full interference pattern despite marked weakness (increased recruitment). Because fewer muscle fibers are firing, the amplitude of the pattern will be reduced from normal. This type of full, highly complex interference pattern of less than usual amplitude in the face of dramatic weakness is the hallmark of myopathy (Fig. 45-6C).

### Motor Unit Counting
This technique, developed by McComas and colleagues, estimates the size of motor units and is thus exquisitely sensitive to changes of denervation and reinnervation. It is carried out by applying a weak stimulus to a motor nerve or motor point and increasing it gradually as the evoked muscle response is recorded. Each quantal increase in the compound evoked response is presumed to be due to the addition of a single motor unit. In reinnervated muscles the additional units are reduced in number and are abnormally large. This technique is used mainly for the investigation of motor neuron disorders. When a normal number and configuration of motor units is found, it has been helpful in distinguishing benign fasciculations from those of serious diseases.

### Single-Fiber Electromyography (SF-EMG)
This is a special technique for the recording of single-muscle-fiber action potentials and is used to measure fiber density and so-called jitter. Fiber density is an index of the number and distribution of muscle fibers within a motor unit. Jitter is the variability of the interpotential interval of successive discharges of two single-muscle-fiber action potentials belonging to the same motor unit. Jitter is due largely to the variability of delay at the branch points and so-called jitter. In myasthenia gravis and other disorders of neuromuscular transmission, especially myasthenia gravis. Fiber density and jitter are often markedly increased in neuropathic disorders that cause denervation with reinnervation. They are usually normal or only slightly increased in myopathic disorders.

The testing is carried out with the patient voluntarily contracting a muscle slightly in order to activate only one motor unit (requiring a great deal of cooperation by the patient) or by stimulating an intramuscular nerve twig (requiring great patience on the part of the examiner). The EMG needle is advanced until two muscle fibers from the same motor unit are recorded. By measuring the interval between the activation of the two muscle fibers (the result of slightly differing lengths of the terminal axons), one determines a mean interpeak interval. Approximately 20 fiber pairs are sampled, and an average of the mean consecutive intervals is derived. In a muscle such as the extensor digitorum communis, the average variation should be no more than 34 ms. The acceptable average is lower for large proximal muscles. One muscle fiber in a pair may fail to fire intermittently as a result of a blocking of conduction. If the sweep is triggered by the firing of the first fiber, a fluctuating latency or failure to discharge of the second fiber potential can be seen on the screen as a movement (jitter) of the second peak. Further details of this technique and its clinical applications are discussed fully by Silverberg and Trontell.

### Imaging of Muscle
Imaging techniques—computed tomography (CT), magnetic resonance imaging (MRI), ultrasonographenable one to measure muscle volume and to recognize qualitative changes in muscle structure (see review of deVisser and Reimers). CT scans of dystrophic muscle show foci of decreased attenuation, representing masses of fat cells. The fatty masses spread gradually from multiple foci and eventually replace muscle fibers. The original shape of the muscle is retained; indeed, an enlarged weak muscle containing mostly fat confirms the clinical impression of pseudohypertrophy. In denervative atrophy, the muscles are obviously small and contain multiple punctate areas of decreased attenuation, which represent interstitial fat. Eventually, large portions of chronically denervated muscle may be replaced by fat. Blood, blood products, and calcium deposits are expressed by increased attenuation in CT. This may be helpful in the diagnosis of muscle trauma and polymyositis.

In MR images, fat and bone marrow have a high signal intensity, while fascia, ligaments, and cortical bone lack signal intensity. In T1-weighted images, normal
muscle has a low signal and dystrophic muscle, a slightly increased signal; in T2-weighted images, dystrophic muscle has a slightly enhanced signal.

Ultrasonography reveals the volume of muscle and epimysial and perimysial septa, which are diminished in neuromuscular diseases. There has also been interest in the diagnostic value of the sounds that can be recorded from the contraction and relaxation of muscle by a sensitive microphone applied to the skin; this technique is experimental.

**Biopsies of Muscle and Nerve**

Muscle biopsy can be of great diagnostic value, but both surgical and microscopic techniques must be exacting. The muscle chosen for study should be accessible; there should be evidence that it has been affected but not totally destroyed by the disease in question; it should not have been the site of a recent injection or EMG study, since the trauma of the needles produces focal necrotizing and inflammatory lesions. Muscle biopsy is helpful in distinguishing the following basic disorders in patients with neuromuscular disease.

1. **Denervation atrophy.** Reduction in the size of muscle fibers with enlargement of intact motor units (due to collateral reinnervation) and degenerative changes in some fibers are the main changes of denervation atrophy. **Group atrophy,** which denotes enlarged motor units where all the fibers in the group are reduced to the same size, is typical of denervation. Normally, the fibers of each motor unit are not clustered, so that when grouping occurs it means that some fibers of a denervated unit have been adopted by an adjacent intact motor unit. This change typifies axonal neuropathies and many spinal cord diseases and is particularly well shown in histochimical stains for ATCase, phosphorylase, and oxidasizes, where the normal mosaic pattern of fiber types is altered, i.e., muscle fibers of similar histochimical type form groups of 15 or more fibers (fiber-type grouping), also a specific feature of denervation. The diagnosis of denervation atrophy can usually be made from the clinical and EMG examinations; seldom is biopsy necessary for this purpose, but it is still utilized in cases of possible ALS, for example, where the diagnosis remains uncertain after other testing.

2. **Segmental necrosis of muscle fibers with myophagia and various manifestations of regeneration.** These are the typical changes in idiopathic polymyositis (in combination with infiltrates of inflammatory cells), and infective polymyositis (in the presence of *Trichinella, Toxoplasma,* etc.). These changes may also be observed in Duchenne and other rapidly progressive muscular dystrophies.

3. **Inflammation and vasculitis.** Lymphocytic infiltration of the endomysium is most characteristic of polymyositis and in dermatomyositis it may be perimysial in addition. The lymphocytic infiltrate is often florid in these two processes, whereas it tends to be less intense in inclusion body myositis. Lesser degrees of inflammation are common in Sjögren syndrome, mixed connective tissue disease, and scleroderma. Numerous other processes—including the infections mentioned above and some dystrophies (especially the fascioscapulohumeral type)—may be associated with an inflammatory process. There is usually myofibrillar destruction in regions of maximal lymphocytic infiltration.

The muscle is a frequent site of inflammatory vascular destruction (vasculitis) in systemic diseases such as polyarteritis nodosa, and for this reason it is often useful to obtain a small sample of muscle adjacent to a nerve biopsy. The finding of a granulomatous myopathy may indicate the presence of systemic sarcoidosis.

4. **Unusual changes of muscle fibers.** Included here are sarcoplasmic masses and disorganized ring or serpentine collections of myofibrils and myofilaments (*Ringbinden*) in myotonic dystrophy; glycogen masses in glycogen storage diseases, rods (nemaline), central cores, aggregates of lipid bodies, and other cytoplasmic changes (such as aggregation and other abnormalities of mitochondria) in certain congenital myopathies; and nuclear and cytoplasmic inclusions (and other changes) that characterize inclusion-body myositis. Application of histochemical methods and electron microscopy are the important techniques in the diagnosis of these disorders.

5. **Alterations in number and size of fibers as a reflection of abnormalities of growth, maturation, and aging.** Many states of dwarfism and congenital myopathies of myotubular type present principally with numerical or volumetric changes, which must be distinguished from denervation, disuse effects, cachexia, and work hypertrophy.

6. **Disorders of the neuromuscular junctions in which nerve fibers and muscle fibers appear to be intact.** Here the abnormality is revealed by performing the more demanding procedure, motor point biopsy (to include the motor end plate), and using electron microscopy and special staining techniques for nerve terminals, cholinesterase, and the outlining of acetylcholine receptors. Myasthenia gravis, botulism, Lambert-Eaton syndrome, and myasthenic syndrome with motor end-plate cholinesterase deficiency fall into this category. Again, biopsy is rarely necessary for diagnosis.

7. **Alterations in the histochemical composition of muscle fibers may be shown by special stains for enzymes and structural proteins that are implicated in disease.** For example, it has become possible to detect the absence or deficiency of specific structural proteins of the muscle membrane that define each of the muscular dystrophies: dystrophin, sarcoglycan, laminin, etc., as discussed in *Chap. 56.* These tests require rapid freezing (in a cryostat) rather than formalin fixation. Also, a number of enzymatic deficiencies that lead to weakness and muscle fatigue may be detected by appropriate histochemical staining (*Chap. 56*).

As a rule, the biopsy procedure requires no more than a cleanly excised block of muscle, 1.0 to 2.0 cm, which is prevented from contracting by a clamp or by tying at full length to a tongue depressor. Percutaneous needle biopsies are now being done frequently and may be adequate for the diagnosis of neuromuscular diseases and for their study over a period of time. In general, the needle biopsy is far less satisfactory than an open biopsy. The study of the muscle biopsy requires special care in removal, transport, and fixation techniques. These are discussed in detail by *Engel.*

Sural nerve biopsies, processed for study by thin-section phase and electron microscopy and supplemented by study of teased fiber preparations, can provide valuable histopathologic data. Even with ordinary microscopy, one may find evidence of focal inflammation or angitis, amyloidosis, leprosy, or sarcoid. These procedures are most valuable in the diagnosis of inflammatory and vasculitic neuropathies. They are helpful, also, in the study of palpably enlarged nerves. In children, the nerve biopsy may reveal the histologic features of metachromatic or globoid leukodystrophy, giant axonopathy, or neuroaxonal dystrophy. Nerve biopsy is relatively unhelpful in most other poly-neuropathies and should be used with prudence because the procedure itself is not without complications, such as the occasional occurrence of wound infections, painful stump pseudoneuromas, persistent dysesthesias of the heel, and thrombophlebitis.

In diseases that involve only the motor nerves, it is sometimes useful to sample a fascicle of the superficial radial nerve or the nerve to the extensor digitorum brevis, which denotes enlarged motor units where all the fibers in the group are reduced to the same size, is typical of denervation. Normally, the fibers of each motor unit are not clustered, so that when grouping occurs it means that some fibers of a denervated unit have been adopted by an adjacent intact motor unit. This change typifies axonal neuropathies and many spinal cord diseases and is particularly well shown in histochimical stains for ATCase, phosphorylase, and oxidasizes, where the normal mosaic pattern of fiber types is altered, i.e., muscle fibers of similar histochimical type form groups of 15 or more fibers (fiber-type grouping), also a specific feature of denervation. The diagnosis of denervation atrophy can usually be made from the clinical and EMG examinations; seldom is biopsy necessary for this purpose, but it is still utilized in cases of possible ALS, for example, where the diagnosis remains uncertain after other testing.

**Laboratory Tests in the Study of Muscle and Nerve Disease** None of the results of the diagnostic laboratory procedures described above may be taken as an infallible index of a specific disease of muscle. Each procedure is subject to technical error and the findings to misinterpretation. A biopsy specimen may be excised from an unaffected muscle or portion of a muscle and, because of this sampling error, be negative in the face of clinical evidence of obvious disease.

Rough excision and improper fixation and staining may produce artifacts that may be misinterpreted as marks of disease when, in fact, the muscle (and nerve) is microscopically normal. Similarly, EMG study may fail to record fibrillations in obviously denervated muscle, particularly in slowly progressive disorders. Also, in some of the muscles of the feet, fibrillations and fasciculations may be found in normal asymptomatic older individuals (*Falsck and Alaranta*). As in the study of all disease, laboratory data have significance only if evaluated in the light of the clinical findings.

In this one chapter, an attempt is made to provide an overview of the very large and difficult subject of peripheral nerve disease. Since the structure and function of the peripheral nervous system are relatively simple, one might suppose that our knowledge of its diseases would be complete. Such is not the case. For example, when a group of patients with chronic polyneuropathy were investigated intensively in a highly specialized center for the study of peripheral nerve diseases, a suitable explanation for their condition could not be found in 24 percent (Dyck et al., 1981). Moreover, the physiologic basis of many neuropathic symptoms continues to elude experts in the field, and in many of the neuropathies the pathologic changes have not been fully determined.

In the last few decades there has been a surge of interest in diseases of the peripheral nervous system, which promises to change this state of affairs. Electron-microscopic studies, new quantitative histometric methods, and refined physiologic techniques have already expanded our knowledge of the structure and function of peripheral nerves, and rapidly advancing techniques in the fields of immunology and molecular genetics are beginning to clarify entire categories of neuropathic disease. Also, during the last decade or two, effective forms of treatment for several peripheral neuropathies have been introduced, making accurate diagnosis imperative. For these reasons, clinicians now find the peripheral neuropathies among the most challenging categories of neurologic disease.

GENERAL CONSIDERATIONS

It is important to have a clear concept of the extent of the peripheral nervous system (PNS) and the mechanisms whereby it can be affected by disease. The PNS includes all neural structures lying outside the pial membrane of the spinal cord and brainstem with the exception of the optic nerves and olfactory bulbs, which are but special extensions of the brain. The parts of the PNS within the spinal canal and attached to the ventral and dorsal surfaces of the cord are called the spinal nerve roots; those attached to the ventrolateral surface of the brainstem are the cranial nerve roots, or just cranial nerves.

The dorsal (afferent or sensory) roots consist of central axonal processes of the dorsal root and cranial ganglion cells. On reaching the spinal cord and brainstem, they extend for variable distances into the dorsal horns and posterior columns (funiculi) of the cord and into the spinal trigeminal and other tracts in the medulla and pons before synapsing with secondary neurons. The peripheral axons of the dorsal root ganglion cells are the sensory nerve fibers. They terminate as freely branching or specialized corpuscular endings—i.e., the sensory receptors—in the skin, joints, and other tissues. The ventral (efferent, or motor) roots are composed of the emerging axons of anterior and lateral horn cells and motor nuclei of the brainstem; they terminate on muscle fibers or in sympathetic or parasympathetic ganglia. From these ganglia also issue the axons that terminate in smooth muscle, heart muscle, and glands. They are thin and lack a myelin covering. Traversing the subarachnoid space, where they lack well-formed epineurial sheaths (Fig. 46-1), the cranial and spinal roots (both sensory and motor) are bathed in and susceptible to substances in the cerebrospinal fluid (CSF), the lumbosacral roots having the longest exposure. The sensory nerve fibers also vary greatly in size and the thickness of their myelin covering; based on these dimensions, they are classified as type A, B, or C (see Chap. 8).

Figure 46-1 Diagram showing the relationships of the peripheral nerve sheaths to the meningeal coverings of the spinal cord. The epineurium (EP) is in direct continuity with the dura mater (DM). The endoneurium (EN) remains unchanged from the peripheral nerve and spinal root to the junction with the spinal cord. At the subarachnoid angle (SA), the greater portion of the perineurium (P) passes outward between the dura mater and the arachnoid (A), but a few layers appear to continue over the nerve root as part of the root sheath (RS). At the subarachnoid angle, the arachnoid is reflected over the roots and becomes continuous with the outer layers of the root sheath. At the junction with the spinal cord, the outer layers of the root sheath become continuous with the pia mater (PM). (From Haller FR, Low FM. Am J Anat 131:1, 1971, by permission.)
Pathogenic Mechanisms in Peripheral Nerve Disease

Pathologic processes may be directed at any one of several groups of nerve cells whose axons constitute the nerves, i.e., the cells of the anterior or lateral horns of the spinal cord, the dorsal root ganglia, or sympathetic or parasympathetic ganglia. Each cell type exhibits specific vulnerabilities to disease processes, and if destroyed—as are the motor nerve cells in poliomyelitis—there results a secondary degeneration of the axons and myelin sheaths of these cells. Neuropathic symptoms may also be induced by alterations of function and structure of the ventral and dorsal columns (funiculi) of the spinal cord, which contain the fibers of exit and entry of anterior horn and dorsal root ganglion cells, respectively. The myelin of these centrally located fibers is constituted differently from that of the peripheral nerves, being enveloped by oligodendrocytes rather than Schwann cells, and the fibers are supported by astrocytes rather than fibroblasts. Because of the intimate relation of the roots to the CSF and to specialized arachnoidal cells (the arachnoidal villi), a pathologic process in the CSF or leptomeninges may damage the exposed spinal roots. Destruction of anterior root results in wallerian degeneration (see below) of the motor fibers in peripheral nerves; destruction of posterior roots results in wallerian degeneration of the posterior columns of the spinal cord but not of peripheral sensory nerves. The continuity of the latter is maintained by spinal ganglion cells and their peripheral extensions (the sensory nerves). Disease of the connective tissues may affect the peripheral nerves that lie within their sheaths. Diffuse or localized arterial diseases may injure nerves by occluding their nutrient arteries. In a large category of immune-mediated neuropathies, nerves are damaged by a cellular or humoral attack on various components of myelin. Some of the immune-mediated diseases are also characterized by the binding of circulating antibodies to the specialized regions at the nodes of Ranvier, causing a block of electrical conduction with or without damage of adja-cent axons or myelin. Also, a complement-dependent humoral immune reaction against the radicular or peripheral axolemma has been delineated. Toxic agents that selectively damage the Schwann cells or their membranes, the myelin sheaths, or the axons may specifically affect axons by poisoning their cell bodies, the axolemma, or the lengthly and complex axonal transport apparatus. Finally, one might suppose that axons of the motor or sensory nerves, sympathetic fibers of varying diameter and length, or the end organs to which they are attached would each have its own particular liability to disease.

Many of this is theoretical and somewhat speculative. At present we can cite only a few examples of diseases or intoxicants that utilize these potential pathways exclusively: diphtheria, in which the bacterial toxin acts directly on the membranes of the Schwann cells near the dorsal root ganglia and adjacent parts of motor and sensory nerves (the most vascular parts of the peripheral nerve); polyarteritis nodosa, which causes widespread occlusion of vasa nervorum, resulting in multifocal nerve infarction; tubers dorsalis, in which there is a tropenomal meningoradiculitis of the posterior roots (mainly of the lumbar-sacral segments) that lie next to the arachnoidal villi where CSF is resorbed; doxorubicin intoxication, wherein protein synthesis of dorsal root ganglion cells is blocked, with subsequent neuronal destruction; poisoning with arsenic, which combines with the apoplastic of the largest sensory and motor nerves via sulfhydryl bonds; and vincristine toxicity, which damages the microtubular transport system. Analogous anatomic pathways are probably implicated in other diseases by mechanisms that remain to be divulged.

Pathologic Reactions of Peripheral Nerve

Pathologically, several distinct processes are recognized, although they are not disease-specific and may be present in varying combinations in any given patient. The major ones are segmental demyelination, wallerian degeneration, and axonal degeneration (diagrammatically illustrated in Fig. 46-2). The myelin sheath is the most susceptible element of the nerve fiber, for it may break down as part of a primary process involving the Schwann cells or myelin, or it may be damaged secondarily, consequent to disease affecting its axon. Focal degeneration of the myelin sheath with sparing of the axon is called segmental demyelination. Demyelination of myelin secondary to axonal disease has been called medullary-axonic and may occur either proximal or distal to the site of axonal interruption (wallerian degeneration) or as part of a “dying-back” phenomenon in more generalized, metabolically determined polyneuropathies (axonal degeneration). The latter form of degeneration affects distal parts of the axons in peripheral nerves and in some instances the terminal parts of the central axons in the posterior columns of the spinal cord. Destruction of axons results within several days in a degeneration of all the myelin distal to the point of injury. The myelin breaks down into blocks or ovoids in which lie fragments of axons (the digestion chambers of Cajal). Secondary degeneration of myelinated fibers due to destruction of the nerve cells has been called neuronopathy rather than neuropathy, here also the myelin breaks up into fragments that are then converted, through the action of macrophages, into neutral fats and cholesterol esters and carried by these cells to the bloodstream. Disease may cause either motor or sensory neuronopathy; in the former case the anterior horn cell is affected primarily (motor neuron disease, or motor neuronopathy), and in the latter, the sensory ganglion cell (ganglionopathy). These pathologic reactions are more easily understood if one considers certain features of cytoskeletal structure and function of nerve cells and their axons. The axon contains longitudinally oriented neurofilaments and microtubules, which are separated but interconnected by cross bridges. Their main function involves the transport of substances from nerve cell body to axon terminal (anterograde transport) and from the distal axon back to the cell body (retrograde transport). Thus, when the axon is severed, organelles cannot be transmitted to the distal axon for the purpose of renewing membrane and neurotransmitter systems. By means of retrograde axonal transport, the cell bodies receive signals to increase their metabolic activity and to produce growth factors and other materials needed for axonal regeneration. The histopathologic changes in the nerve cell body that are due to axonal interruption (swelling of the cell cytoplasm and marginalization and dissolution of the Nissl substance) are called chromatolysis or axonal reaction. The important point is that despite the destructive changes in the nerve fibers, the nerve cells, while altered in

![Figure 46-2](https://example.com/fig46-2.png)

Diagram of the basic pathologic processes affecting peripheral nerves. In wallerian degeneration, there is degeneration of the axis cylinder and myelin distal to the site of axonal interruption (arrow), and central chromatolysis. In segmental demyelination, the axon is spared. In axonal degeneration, there is a distal degeneration of myelin and axis cylinder as a result of neuronal disease. Both wallerian and axonal degeneration cause muscle atrophy. Further details in text. (Courtesy of Dr. Arthur Asbury.)
In segmental demyelination, recovery of function may be rapid because the intact but denuded axon needs only to become remyelinated. The newly formed internodal segments are thinner than normal and of variable length. By contrast, with wallerian or axonal degeneration, recovery is slower, often requiring months to a year or more, because the axon must first regenerate and then reconnect to muscle, sensory organ, blood vessel, etc., before function returns. When the regenerating axon becomes myelinated, the internodal segments are inappropriate short, one old internode being replaced by three or four new ones. Recurrent demyelination and remyelination lead to "onion bulb" formations and enlargement of nerves, the result of proliferating Schwann cells and fibroblasts that encircle the axon and its thin myelin sheath.

When a nerve is severed by a crude destructive lesion involving nerve fibers and connective tissue sheathing, the continuity is interrupted and may not be reestablished. Regenerating axonic filaments then take aberrant courses and, with fibroblastic scar formation at the end of the central portion of the interrupted nerve, they form a pseudoneuroma. When nerve cells are destroyed, no recovery of their function is possible except by collateral regeneration from axons of intact nerve cells.

These relatively few pathologic reactions cannot in themselves differentiate the hundred or more diseases of the peripheral nerves; but when they are considered in relation to the selective effects on various types and sizes of fibers, the topography of the lesions, and the time course of the process, they furnish a set of criteria whereby many diseases can be distinguished. There are also special pathologic changes that characterize certain diseases of the peripheral nervous system. For example, in acute demyelinating polyneuropathy of the Guillain-Barré type, there are endoneurial infiltrations of lymphocytes, plasma cells, and other mononuclear cells in the roots, sensory and sympathetic ganglia, and nerves; frequently the infiltrates and destruction of myelin have a perivenous distribution. In polyarteritis nodosa, a characteristic finding is a transmural inflammation with the destruction of the perineurium and endoneurium of peripheral nerves—and less often with rupture of vessels and hemorrhage into nerves—are the dominant findings. Deposition of amyloid in the endoneurial connective tissue and walls of vessels, affecting the nerve fibers secondarily by compression or ischemia, are the distinctive features of amyloid polyneuropathy. In one of the inherited polyneuropathies of childhood, the axons are enlarged by tightly packed masses of neurofilaments. The now rare diphtheritic polyneuropathy is typified by the predominant axonopathic character of the nerve fiber change, the location of this change in and around the roots and sensory ganglia, the subacute course, and the lack of inflammatory reaction. Other polyneuropathies (paraepinephrine, nutritional, porphyric, arsenical, and uremic) are topographically symmetrical but are not presently distinguishable from one another by histopathologic means. The least is known about the familial types of polyneuropathy; although genetic factors are clearly involved, their biochemical mechanisms and pathology are just beginning to be studied.

Concerning the pathology of the mononeuropathies, our knowledge is also incomplete. Compression of nerve, producing local or segmental ischemia, violent stretch, and laceration of nerves are understandable mechanisms, and their pathologic changes have been reproduced in animals. Tumor infiltration and vasculitis with ischemic infarction of nerve account for some cases. Infections localized to single nerves, only leprosy, sarcoid, and herpers zoster represent identifiable disease states. For the acute multifocal neuropathy, the pathologic changes have yet to be defined, since they are usually benign, reversible states that provide no opportunity for complete pathologic examination.

SYMPTOMATOLOGY OF PERIPHERAL NERVE DISEASE

There are a number of motor, sensory, reflex, autonomic, and trophic symptoms and signs that are more or less typical of peripheral nerve disease. Grouping them into syndromes based on their temporal and topographic features has proved to be of value in clinical diagnosis.

Impairment of Motor Function

Whereas anesthetic agents, nerve toxins, cooling, and ischemia may temporarily cause weakness or paralysis, persistent impairment of motor function occurs over days, weeks, or months. The most significant effects of these is due to loss of reflexes, which is a type of axonopathy or functional denervation, rather than true degeneration of the nerve fibers and denervated muscle fibers. This process begins in 6 to 12 months; in 3 to 4 years, most of the denervated fibers will have degenerated. If reinervation takes place within a year, motor function and muscle volume may be restored. Atrophy of weak or paralyzed muscles proceeds slowly over several months, its degree being proportional to the number of damaged motor nerve fibers, specifically, system motor system, as discussed on page 1153. Paraparesis may occur with any of the generalized polyneuropathies, infections and inflammations of the cauda equina, as occurs with Lyme disease, cytomegalovirus, herpes simplex, and with neoplastic nerve root infiltrations. Bilateral and other cranial nerve paralyses are most likely to occur in GBS, with neoplasic invasion, and also with collagen vascular diseases, HIV infection, herpes virus, sarcoidosis, Lyme disease, or one of the rare metabolic neuropathies (Refsum, Bassen-Kornzweig, Tangeri, and Riley-Day).

A predominantly bibrachial paralysis is an unusual presentation of neuropathic disease but may occur as an initial event in Guillain-Barré disease as well as in the Sjögren syndrome, chronic immune or paraneoplastic neuropathies, lead neuropathy, Tangeri disease, and rarely, as a familial brachial neuritis. However, the most frequent cause of bilateral palsy is disease of the motor nerves themselves, specifically, system motor system, as discussed on page 1153. Paraparesis may occur with any of the generalized polyneuropathies, infections and inflammations of the cauda equina, as occurs with Lyme disease, cytomegalovirus, herpes simplex, and with neoplastic nerve root infiltrations. Bilateral and other cranial nerve paralyses are most likely to occur in GBS, with neoplasic invasion, and also with collagen vascular diseases, HIV infection, herpes virus, sarcoidosis, Lyme disease, or one of the rare metabolic neuropathies (Refsum, Bassen-Kornzweig, Tangeri, and Riley-Day).

Atrophy of weak or paralyzed muscles proceeds slowly over several months, its degree being proportional to the number of damaged motor nerve fibers; the maximum degree of denervation atrophy occurs in 90 to 120 days and reduces muscle volume by 75 to 90 percent. Atrophy is also a consequence of disease; it occurs over many weeks and in itself does not reduce muscle volume by more than 25 to 30 percent. Atrophy, therefore, does not coincide with or correspond to acute paralysis and is least prominent in the acute demyelinating neuropathies. In chronic axonal neuropathies, the degrees of paralysis and atrophy tend to correspond. Ultimately there is degeneration and loss of the denervated muscle fibers. This process begins in 6 to 12 months; in 3 to 4 years, most of the denervated fibers will have degenerated. If reinervation takes place within a year, motor function and muscle volume may be restored.

Tendon Reflexes

The rule is that diminution or loss of tendon reflexes is an invariable sign of peripheral nerve disease. In the small-fiber neuropathies, however, tendon reflexes may sometimes be retained, even with marked loss of perception of painful and thermal stimuli and loss of autonomic function. This discrepancy is attributable to the fact that the afferent arc of the tendon reflexes utilizes the large heavily myelinated fibers. Conversely, reflexes can be diminished out of proportion to weakness because of involvement of the large afferent fibers that innervate the muscle spindles. Slowing of conduction velocities in sensory fibers may impair or abolish the reflex by dispersing the afferent volley of impulses initiated by the tendon tap. This concept is borne out in cases of peripheral neuropathy by the general concordance between axonopathy and a loss of proprioceptive and joint-position senses; the large nerve fibers from spiral antennae are of the same type and size as those mediating these forms of sensation, and they tend to be affected together by disease of the nerve or its roots. By contrast, a loss of sensory functions that are dependent on large fibers, in the presence of preserved reflexes, implicates the central projections from the sensory ganglion cells in the posterior columns of the spinal cord. Early in an acute neuropathy, the reflexes may be diminished but not absent and may become perceptibly more reduced from day to day.

Sensory Loss

(See also pages 167 to 172) Most polyneuropathies cause impairment of both motor and sensory functions, but one may be affected more than the other. In GBS for example, paralysis is more prominent than sensory loss. In most of the toxic and metabolic neuropathies, sensory loss exceeds weakness; and in sensory neuropathies, there is virtually no motor deficit. These differences are emphasized in the descriptions of individual peripheral nerve diseases.

Sensory Loss in Polyneuropathies

In the polyneuropathies, even more than motor function, is affected asymmetrically in the distal segments of the limbs, and more in the legs than in the arms (see Chap. 9). In most polyneuropathies, all sensory modalities (touch-pressure, pain and temperature, vibratory, and joint position senses) are impaired or eventually lost, although one modality may seemingly be affected out of proportion to the others, or superficial sensation may be impaired more than deep sensation. Vibratory sense is often affected more than position and tactile senses. As the neuropathy worsens, there is spread of sensory loss from the distal to more proximal parts of the
limbs and, rarely, to the lower abdomen and face.

A relatively rare form of sensory loss affects the trunk, scalp, and face; this pattern is characteristic of sensory ganglionopathy. The esclouteon region of the lower abdomen may be involved as part of severe axonal neuropathy and should not be mistaken for the pattern of segmental truncal loss seen with ganglionopathies or a sensory level that occurs with spinal cord disease.

Another pattern of neuropathic sensory loss is notably—a loss of pain and temperature sensation with either sparing or lesser impairment of touch-pressure, vibratory, and position senses. This resembles the dissociated sensory disturbance of syringomyelia except that it is predominantly lumbosacral (originally it was referred to as "lumbosacral syringomyelia"). This pseudosyringomyelic dissociation of sensation may extend over the arms, trunk, and even cranial surface. Thévenard was the first to question its spinal basis, and it is now generally agreed that most such examples are due to hereditary sensory or certain acquired small-fiber neuropathies, such as primary amyloidosis, congenital absence of pain, Riley-Day syndrome, and Tandger disease. Usually the unmyelinated autonomic fibers are also interrupted. Exceptionally, as in one of the families studied by Adams and associates, all forms of sensation may be lost over the entire body, while motor and other sensory functions are preserved. More often, universal sensory loss is attributive functions acquired disease affecting the sensory ganglia (sensory neuropathy). Usually this is a paraneoplastic syndrome, but it may also be due to a toxic or immune disease (e.g., in Sjögren disease or scleroderma).

Paresthesias, Pain, and Dysesthesias These abnormalities of sensation have been described in Chap. 9. They tend to be especially marked in the hands and feet. "Pins and needles," stabbing, tingling, prickling, electrical, Novacain-like, and band-like sensations are the adjectives used most frequently to describe these abnormalities. Some sensory neuropathies are attended only by these paresthesiae and by numbness; if the symptoms are slight, there may be no objective sensory loss. Others are extremely painful. The pains may be described as burning, aching, sharp or cutting, or crushing, or they may resemble the lightning pains of tabes dorsalis, vibration sensation (anodynia) or loss of temperature and pain sensation in the area of sensory loss. Under these conditions, the given stimulus induces not only an aberrant sensation but also one that radiates and persists after the stimulus is withdrawn. As remarked on pages 145 and 163, the patient's reaction may seem to indicate a hypersensitivity ("hyperesthesia"), but more often the sensory threshold is actually raised and only the sensory experience or response is exaggerated (hyperesthesia).

These paresthesiae and dysesthesias are particularly common in certain types of diabetic and alcoholic-nutritional neuropathy. Mainly they affect the feet ("burning feet") and less often the hands; they are confined to limited regions of the body in herpes zoster, in some cases of diabetic and other types of vascular neuropathy, and in certain sensory neuropathies of obscure nature. A particularly intense form of burning pain typifies causalgia, due to a partial lesion (usually traumatic) of the ulnar, median, posterior tibial, peroneal, or occasionally some other nerve (pages 148 and 1438).

The mechanism of sensory paresthesiae and nerve pain is not fully understood. It has been theorized that a loss of large touch-pressure fibers disinhibits the pain system, which is present in the posterior columns of the spinal cord, against this explanation is the lack of pain in Friedreich ataxia, in which the larger neurons degenerate, and also in certain purely sensory polyneuropathies, where only the perception of tactile stimuli (large fibers) is lost. A more likely explanation, supported by microneurographic recordings after release of tourniquet compression, is that dysesthetic pain results from autogenic ectopic discharges arising at many sites along the regenerating nociceptive or sensory fibers or their terminal receptors, as described in Chap. 8. In contrast to dysesthetic pain, it has been postulated that the deep, aching pain of sciatica or brachial neuritis (nerve trunk pain) arises from irritation of the normal endings (nevi nervorum) in the sheaths of the nerve trunks themselves (Asbury and Fields).

Sensory Ataxia and Tremor Proprioeptive deafferentation with retention of a reasonable degree of motor function is the basis of ataxia of gait and of limb movement, as discussed in Chap. 9. An action tremor of fast-frequency type may also appear during certain phases of a polyneuropathy. Shahnani and coworkers have the impression that it is due to either a loss of input or slowed nerve conduction from some of the muscle-spindle afferents. Corticosteroid therapy enhances the tremor. A particularly severe form of slower tremor is common with clumsiness in certain neuropathies that affect large afferent fibers, specifically in the autonime, anti-melanin-associated glycophopil (MAG) neuropathy and in some cases of chronic inflammatory demyelinating polyneuropathy (CIDP). During action, the tremor may at times be so coarse as to resemble the intention tremor of cerebellar disease.

Ataxia without weakness is characteristic of tabs dorsalis, a purely posterior root, but this syndrome can be nearly duplicated by diabetic polyneuropathy, which affects posterior roots as well as nerves (diabetic pseudotabes), by a variant of the Guillain-Barré syndrome (Fisher syndrome as well as a variant that produces almost pure ataxia), and by sensory neuropathy (ganglionopathy). The ataxia in some instances is virtually indistinguishable from that caused by cerebellar disease, but lacking are other features of cerebellar dysfunction. Several chronic sensory neuropathies have prominent ataxic features, and the movements, though strong, are rendered ineffective by virtue of the deep sensory loss alone. Characteristic of the sensory (atatic) ataxic gait are the brusque, flinging, slapping movements of the legs.

Deformity and Trophic Changes In a number of chronic polyneuropathies, the feet, hands, and spine become deformed. This is most apt to occur when the disease begins during childhood. Austin pointed out that foot deformity is found in 30 percent of patients with hereditary hypotrophic polyneuropathy and spine curvature in 20 percent. In early life, the feet are pulled into a position of talipes equinus (plantar deviation) because of the disproportionate weakness of the peroneal and peroneus longus and the long flexors to shorten the foot, lengthen the arch, and flex the distal phalanges. The result is the claw foot—to lie en griffe of the French. The claw hand has a similar basis. In early childhood, unequal weakening of the paraverterbral muscles on the two sides of the spine leads to kyphoscoliosis.

Denervation atrophy of muscle is the main trophic disturbance resulting from interruption of the motor nerves. Analgesia of distal parts makes them susceptible to burns, pressure sores, and other forms of injury that are easily infected and heal poorly. In an anesthetic and immobile limb, the skin becomes tight and shiny, the nails curved and ridged, and the subcutaneous tissue thickened. Hair growth is diminished in denervated areas. If the autonomic fibers are interrupted, the limb is warm and pink. Repeated injuries and chronic subcutaneous and osteomyelitic infections may result in a painless loss of digits and the formation of plantar ulcers (Charcot's joints). These are prominent features of the recessive form of hereditary sensory neuropathy, and we have observed them in dominant forms as well. In certain familial and other chronic polyneuropathies, analgesic joints, when chronically traumatized, may disintegrate (Charcot arthropathy), as occurs in tabes dorsalis and syringomyelia.

The pathogenesis of the trophic changes is not fully understood. Apart from anaesthesia, a critical factor may be inappropriate neural regulation of the distal vasculature, which interferes with normal tissue responses to trauma and infection. All and colleagues relate the ulcer formation to loss of C fibers, which mediate both pain and autonomic reflexes. However, paralyzed limbs, especially in hystera, if left dependent, are often cold, swollen, and pale or blue. These are probably secondary disease effects, as pointed out long ago by Lewis and Pickering. Erythema and edema, burning pain, and cold sensations have been evoked by peripheral nerve irritation, particularly of C and A-d fibers.

Autonomic Dysfunction Anhidrosis and orthostatic hypotension, the two most frequent manifestations of autonomic dysfunction, may be major features of certain types of neuropathy. The most prominent forms are those that occur most frequently in amyloidosis and certain other hereditary neuropathies, diabetic polyneuropathies, and several congenital types. In addition, they are central features of an acute pure autonomic polyneuropathy called pandsyautonomic (Young et al, Low et al) and can be a prominent feature of GBS. These conditions are described in detail in Chap. 26.

Other manifestations of autonomic paralysis are small or medium-sized unreactive pupils that are unusually sensitive to certain drugs (pages 296 and 563); lack of sweat, tears, and saliva; sexual impotence; weak bowel and bladder sphincters with urinary retention or overflow incontinence; and weakness and dilatation of the esophagus and colon. Also, the normal variability of heart rate is lost and there may be pain from paralytic ileus or dyscoordinated peristalsis as well as achlorhydria and hypoaesthesia. Some of these abnormalities are found in diabetic and amyloid polyneuropathy. In general these autonomic disturbances correlate with diabetic polyneuropathy involving autonomic nerves, and in other neuropathies involving sensory nerves, there is loss of sensory innervation in the same zones as sensory loss. This is not true of radicular diseases because the autonomic fibers join the spinal nerves more distally. Such losses may also be demonstrated by special tests, as described in Chap. 26.

Fasciculations, Cramps, and Spasms In most polyneuropathies, fasciculations and cramps are not important findings. Occasionally one observes a state of mild motor polyneuropathy that, upon recovery, leaves the muscles in a state variably referred to as myokymia, continuous muscular activity, and neuromyotonia (see Chap. 45 and Chap. 54). All the affected muscles ripple and quiver and occasionally cram. Use of the muscles increases this activity, and there is a reduction in their muscle tone. Fasciculations as a clinical sign constitute the essential feature of fasciculations syndrome and may be gratifyingly relieved by carbamazepine or phenytoin. It raises the question of a terminal nerve conduction abnormality. Other closely related phenomena are spasms (e.g., hemifacial spasm) or involuntary movements of the toes and feet. The latter, referred to by Spillane and colleagues as the syndrome of painful limbs and moving toes, is attributed by Nathan to ectopic discharges in sensory roots, ganglia, or nerves, evoking both pain and organized movements. Other possible mechanisms are
ephaptic cross transmission, segmental hyperactivity from deafferentation, and neuronal sprouting and reinnervation. In yet other instances, the muscle activity induces odd postures or slow writhing movements that Jankovic and van der Linden have likened to dystonia. The precise pathophysiology of these seemingly spontaneous asynchronous activities of motor neurons is not known. Stimulation of a motor nerve, instead of causing a brief burst of action potentials in the muscle, results in a prolonged or dispersed series of potentials lasting several hundred milliseconds. Also, the distal latencies are prolonged. Evidently, branched axons involved in collateral innervation have an unstable polarization that may last for years.

**APPRAOCH TO THE PATIENT WITH PERIPHERAL NEUROPATHY**

The clinician is faced with two problems: (1) establishing the existence of disease of the peripheral nervous system, and (2) ascertaining its nature and the possibilities of treatment. The former is not difficult when one becomes familiar with the symptomatology of peripheral nerve diseases, described above. At the outset it must be determined whether the pattern of neurologic findings corresponds to one of the following:

- **Polyneuropathy**
- **Polyradiculopathy**
- **Neuronopathy—motor or sensory**
- **Mononeuropathy**
- **Multiple mononeuropathies (mononeuropathy multiplex)**
- **Plexopathy (involvement of multiple nerves in a plexus)**

A brief definition of each of these neuropathic states follows: (1) In a *polyneuropathy*, weakness is relatively symmetrical from the beginning and progresses bilaterally; reflexes are lost in affected parts, but particularly at the ankles; sensory complaints and loss of sensation are most pronounced distally, in the feet before the hands in most cases. (2) A *polyradiculopathy* (implicating multiple spinal roots) differs from a polyneuropathy in that the pattern of neurologic signs is asymmetrical, causing weakness and sensory loss that may be proximal in one limb and distal in another, and involving muscles and sensory zones that can only be explained on the basis of root disease; pain in the distribution of one or more roots is a common feature. (3) In *sensory neuropathy*, the sensory ganglion cells rather than the peripheral sensory nerves are predominantly affected. This gives rise to symptoms and signs of sensory loss in both a proximal and distal distribution, often including the scalp, thorax, abdomen, and buttocks as well as the extremities; sensory ataxia is a common accompaniment. *Motor neuropathy* is essentially a disorder of the anterior horn cells causing weakness, fasciculations, and atrophy in a widespread distribution. (4) A *mononeuropathy* is the most circumscribed form of peripheral nerve disease, reflected by weakness and sensory loss in the territory of a single peripheral nerve. Certain constellations of signs serve to differentiate mononeuropathy from a radiculopathy—for example, weakness in dorsiflexion and eversion of the foot is referable to the peroneal nerve; however, if inversion of the foot, innervated by the tibial nerve, is also affected, then the L5 root is implicated. (5) Plexopathies (brachial or lumbosacral) may create the most confusing patterns of involvement: only one limb is affected but not necessarily in a pattern involving several adjacent nerve roots. Knowledge of the innervation of the involved muscles usually clarifies the situation.

Of the multitude of diseases of peripheral nerves, certain ones almost always manifest themselves by one or another of above-described patterns. Thus the pattern of the neuropathy sets limits on the etiologic possibilities. Also, in the analysis of a polyneuropathy it is important to determine whether the process is predominantly motor with less sensory involvement (motor-sensory), or the converse (sensorimotor), or purely sensory, motor, or autonomic (see Table 46-1). The time course of the disease is also informative. An acute onset (i.e., rapid evolution) is nearly always diagnostic of an inflammatory, immunologic, toxic, or vascular etiology. The other extreme, a polyneuropathy evolving slowly over many years is indicative of a hereditary or, rarely, a metabolic disease. Most of the toxic, nutritional, and systemic diseases of nerve develop subacutely or “early chronically” over several weeks and months.

The etiologic diagnosis of both polyneuropathy and mononeuropathy multiplex is facilitated further by determining whether the myelin sheath or the axon is primarily involved (demyelinating disease or axonopathy). Sometimes the neurologic examination is sufficient to make this distinction, but it can be made with greater precision by utilizing nerve conduction studies and needle examination of muscles by electromyography (EMG). The latter also helps to distinguish primary disorders of muscle (myopathies) from disorders that are secondary to denervation and those due to neuromuscular block. The electrical examinations of nerve and muscle are described fully in Chap. 45. In a few instances, the EMG abnormalities are so characteristic as to virtually define a group of neuropathies, e.g., the chronic demyelinating motor neuropathies with multifocal conduction block (page 1411). The EMG and conduction studies refine the diagnosis within each of the main categories of neuropathic disease, at times greatly reducing the number of possible etiologic diagnoses. Other useful laboratory procedures are (1) biochemical tests to identify the metabolic, nutritional, or toxic states that produce neuropathy; (2) CSF examination (increase in protein and in cells that indicate radicular or meningeal involvement); (3) nerve and muscle biopsy; (4) measurement of immunoglobulins and antineuronal antibodies that relate to immune-mediated neuropathies; and (5) newly available genetic testing for several of the inherited neuropathies.

Once having established that the patient has a disease of the peripheral nerves and having ascertained its clinical and electrophysiologic pattern and time course, one must then attempt to determine its nature. This is accomplished most readily by allocating the case in question to one of the categories in Table 46-1, in which the peripheral nerve diseases are classified syndromically, according to their mode of evolution and clinical presentation. Having categorized the neuropathic syndrome in this way, one then seeks to identify the case in question with a particular disease in that category. These are listed in the sections that follow.

Our use of the terms acute, subacute, and chronic must be explained. By acute we mean evolution in terms of days and subacute, in weeks. We divide chronic into two groups: early chronic—in which the neuropathy evolves over a period of several months to a few years, and late chronic—more than several years.

Diseases of the peripheral nerves are considered in the most comprehensive fashion in the two-volume monograph *Peripheral Neuropathy*, edited by Dyck and colleagues. Also recommended are more concise monographs on this subject by Schaumburg and associates and by Asbury and Thomas and the recently published atlas on the pathology of peripheral nerve by King.

**SYNDROME OF ACUTE MOTOR PARALYSIS WITH VARIABLE DISTURBANCE OF SENSORY AND AUTONOMIC FUNCTION**

A number of subtle differences separate the polyneuropathies comprised by this category: (1) acute inflammatory demyelinating or the less frequent axonal, type (Guillain-Barré syndrome), (2) some angitic polyneuropathies, (3) porphyria, (4) certain toxic polyneuropathies, and (5) acute sensory and autonomic polyneuropathies. Of these various acute polyneuropathic diseases, the Guillain-Barré demyelinating syndrome, because of its frequency and gravity, is most demanding of the physician's attention.

**Guillain-Barré Syndrome (Landry-Guillain-Barré-Strohl Syndrome, Acute Inflammatory Polyneuropathy)**

This acute polyneuropathy, generally referred to as Guillain-Barré syndrome or GBS, occurs in all parts of the world and in all seasons; it affects children and adults of all ages and both sexes. A mild respiratory or gastrointestinal infection precedes the neuropathic symptoms by 1 to 3 weeks (sometimes longer) in about 60 percent
of the patients. In recent years, it has come to be appreciated from serologic studies that the enteric organism Campylobacter jejuni is the most frequent identifiable preceding infection. Other, less common antecedent events or associated illnesses include viral exanthems and other viral illnesses (cytomegalovirus (CMV), Epstein-Barr virus (EBV), human immunodeficiency virus (HIV)), bacterial infections other than Campylobacter (Mycoplasma pneumoniae, Lyme disease), exposure to variola virus, and in association with acute lymphoblastic leukemia. An increased incidence of GBS and an acute onset with subsequent influenza vaccination program has been associated with a marginal increase. Trauma and surgical operations may precede the neuropathy, but a causal association remains uncertain.

Historical Background

The earliest description is probably that of Warrington and Olivier, in 1834. Other important landmarks are Landry's report (1859) of an acute, ascending, predominantly motor paralysis with respiratory failure, leading to death; Osler's (1892) description of a febrile polynévrite; the account by Guillain, Barré, and Strohl (1916) of a benign polynévrite with albuminocytologic dissociation in the CSF (increase in protein without cells); and the elaboration of the clinical picture by many British and American investigators. The first comprehensive account of the pathology of GBS was that of Hasegawa and Kornhahn (1949), who stressed that essential to the diagnosis of the disease was the initial electrophysiologic examination. Subsequently, Asbury and Cornblath (1969) described the characteristic inflammatory cell infiltrates and perivenous demyelination that establish the essential lesion, from the beginning of the disease, as a perivasculary mononuclear inflammatory infiltration of the roots and nerves. (For details of the historical and other aspects of this disease, see the monographs by Ropper and colleagues, and by Hughes.)

Incidence

Our experience with this disease has shown it to be nonseasonal and nonepidemic. Year after year, between 15 and 25 patients have been admitted to each of our institutions. Females are only slightly more susceptible. The age range of 160 consecutive, prospectively studied patients was 8 months to 81 years, with attack rates highest in persons 50 to 74 years of age. The reported incidence rate worldwide has varied from 0.4 to 1.7 cases per 100,000 persons per year; the latter figure is probably the more accurate.

Symptomatology

The usual case of GBS is readily identified. Paresis and numbness are frequent and early symptoms, but occasionally they are absent throughout the illness. The major clinical manifestation is weakness, which may not be more or less symmetrically over a period of several days or a week or two, rarely somewhat longer. Proximal as well as distal muscles of the limbs are involved, usually the lower extremities before the upper ("Landry's ascending paralysis"); the trunk, intercostal, neck, and cranial muscles may be affected later. The weakness can progress to total motor paralysis with death from respiratory failure within a few days. More than half of the patients complain of pain and an aching discomfort in the muscles, mainly those of the hips, thighs, and back. Objective sensory loss occurs to a variable degree over the first days and in a few is barely detectable; when such loss is present, deep sensibility (touch-pressure-vibration) tends to be more affected than superficial (pain-temperature).

Reduced and then absent tendon reflexes are consistent findings. Rarely, only the ankle reflexes are lost during the first week of illness. At an early stage, the arm muscles may be weak enough to elicit the leg muscles or are spared entirely. Facial diplegia occurs in about half of all cases, and other cranial nerve palsies, if they occur, usually come later, after the arms are affected; infrequently they are the initial signs. Disturbances of autonomic function (situs tachycardia and less often bradycardia, facial flushing, fluctuating hypertension and hypotension, loss of sweating or episodic profuse diaphoresis) are common, but rarely do these abnormalities persist for more than a week or two. Urinary retention occurs in about 15 percent of patients soon after the onset of weakness, but catheterization is seldom required for more than a few days.

Variants of the Typical Pattern

Portions of the clinical picture frequently appear in isolated or abortive form and cause diagnostic confusion. Whereas in most patients the paralysis ascends from legs to trunk, arms, and cranial muscles and reaches a peak of severity within 10 to 14 days, occasionally the pharyngeal-cervical-brachial muscles are affected first, creating difficulty in swallowing as well as neck and proximal arm weakness (Ropper, 1989). Palsy, sometimes with ophthalmpoplegia may be added. Moreover, this pattern may persist without the development of limb weakness. The differential diagnosis is then from myasthenia gravis, diphtheria, and botulism and from a lesion affecting the central portion of the cervical spinal cord and lower brainstem. A syndrome comprising complete ophthalmpoplegia with ataxia and areflexia and thought to be a variant of GBS was described by Fisher. A purely ophthalmpoplegic form also exists; it may be contributed with pharyngeal-cervical-brachial weakness, as mentioned above. The ophthalmpoplegia, whether occurring alone or with weakness or ataxia of other parts, is uniformly associated with a specific antineuronal antibody, anti-GQ1B. The ophthalmpoplegic pattern nates the possibility of myasthenia gravis, botulism, diphtheria, tick paralysis, and basilic artery disease. Bilateral but asymmetrical facial and abducens weakness, coupled with distal paresthesias or with proximal leg weakness, are other variant common variants in our experience (Ropper, 1994). The tendon reflexes may be absent initially at the ankle or at the knees. Lyme disease and sarcoidosis are then considerations in diagnosis. Paraparetic, ataxic, and purely motor forms of the illness have also been observed.

A few cases will continue to evolve for 3 to 4 weeks or even longer. From this group a chronic form of demyelinating neuropathy (chronic inflammatory demyelinating polyneuropathy, or CIDP) often emerges and is described further on.

Numerous phenomena related to dysautonomia occur, and there are important complications secondary to immobilization and respiratory failure, as discussed further on, under "Treatment." At the onset of illness, the temperature is normal, and lymphadenopathy and splenomegaly, if they occur, are related to a preceding viral infection.

Laboratory Findings

The most important laboratory aids are the electrodiagnostic studies and the CSF examination. The CSF is under normal pressure and is occasionally xanthochromic or contains a small amount of blood. The protein content of the CSF is normal throughout the illness, except during the first few days of symptoms, but then it begins to rise, reaching a peak in 4 to 6 weeks. The increase in CSF protein is probably a reflection of the widespread inflammatory disease of the nerve roots, but high values have no clinical or prognostic significance. In a few patients (10 percent or less), the CSF protein values are normal throughout the illness. Among patients with the Fisher syndrome and other restricted forms of GBS, there is a much higher proportion with normal protein values.

Nerve conduction studies are a dependable and early diagnostic indicator of GBS, and in instances with a typical clinical and EMG presentation, one can dispense with the CSF analysis. Although a limited electrodiagnostic examination may be normal early in the illness, a more thorough study, which includes measurement of muscle action potentials, slowed conduction velocity, or conduction block in motor nerves. Prolonged distal latencies (reflecting distal conduction block) and late responses, almost invariably shows abnormalities in an affected limb within days of the first symptom. Also early on, features that indicate widespread axonal involvement are found. In the few patients with pleocytosis, the number of cells decreases rapidly, in a matter of 2 to 3 days; a failure to do so should suggest an alternative diagnosis. We have been able to relate an occasional pleocytosis with the clinical features of GBS or their severity. Usually, the protein content is normal during the first few days of symptoms, but then it begins to rise, reaching a peak in 4 to 6 weeks. The increase in CSF protein is probably a reflection of the widespread inflammatory disease of the nerve roots, but high values have no clinical or prognostic significance. In a few patients (10 percent or less), the CSF protein values are normal throughout the illness. Among patients with the Fisher syndrome and other restricted forms of GBS, there is a much higher proportion with normal protein values.

Abnormalities of liver function occur in less than 10 percent of patients, probably reflecting a recent or ongoing viral hepatitis, usually due to the CMV or Epstein-Barr viruses. The presence of a moderate increase in liver enzymes is not of clinical significance in most patients. In recent years, it has come to be appreciated from serologic studies that the enteric organism Campylobacter jejuni is the most frequent identifiable preceding infection. Other, less common antecedent events or associated illnesses include viral exanthems and other viral illnesses (cytomegalovirus (CMV), Epstein-Barr virus (EBV), human immunodeficiency virus (HIV)), bacterial infections other than Campylobacter (Mycoplasma pneumoniae, Lyme disease), exposure to variola virus, and in association with acute lymphoblastic leukemia. An increased incidence of GBS and an acute onset with subsequent influenza vaccination program has been associated with a marginal increase. Trauma and surgical operations may precede the neuropathy, but a causal association remains uncertain.

Pathologic Findings

These have had a relatively consistent pattern and form. Even when the disease is fatal within a few days, virtually all cases have shown perivascular lymphocytic infiltrates. Later the characteristic inflammatory cell infiltrates and perivenous demyelination are combined with segmental demyelination and a variable degree of wallerian degeneration. Intranuclear inclusions in the early stages of the disease. Subsequent to involvement of the peripheral nerve, sparse infiltrates of inflammatory cells (lymphocytes and other mononuclear cells) may also be found in lymph nodes, liver, spleen, heart, and other organs.

Variations of this pattern of peripheral nerve damage have been observed, each perhaps representing a different immunopathology. Rarely, in a clinically typical case, there may be widespread demyelinating changes and only a perivascular infiltrate of lymphocytes and macrophages. Patients in whose electrophysiologic tests display severe axonal damage early in the illness (the acute axonal type of GBS, discussed below), the pathologic findings corroborate the predominantly axonal nature of the disease, with secondary myelin damage and little inflammatory response. An occasional case has shown an inflammatory process with axonal damage rather than demyelination ( Honovar et al). The acute axonal form is described further on.

Pathogenesis and Etiology

Most of the evidence suggests that the clinical manifestations of this disorder are the result of a cell-mediated immunologic reaction directed at peripheral nerve. Wakman and Adams demonstrated that a peripheral nerve disease (experimen-tal allergic neuritis or EAN), clinically and clinically...
pathologically indistinguishable from GBS, develops in animals about 2 weeks after inoculation with peripheral nerve homogenate. Brostoff and colleagues suggested that the antigen in this reaction is a basic protein, designated P1, found only in peripheral nerve myelin. Subsequent investigations by these authors indicated that the neuritogenic factor was a specific peptide in the P1 protein. It has become evident that there is no unifying antigen-antibody reaction and that any number of myelin and axonal elements may be involved in the immune reaction. The pathologic steps in this proposed reaction are diagrammatically illustrated in Fig. 46-3. Hartung and colleagues have found high levels of soluble interleukin (IL)-2 receptors, shed from activated T cells, and IL-2 itself in the serum of patients with acute GBS, reflecting activation of these cells. As noted below, complement also seems to be a necessary factor in the initial attack on myelin.

**Figure 46-3 Diagram of probable cellular events in acute inflammatory polyneuropathy (GBS).** A. Lymphocytes attach to the walls of endothelial vessels and migrate through the vessel wall, enlarging and transforming as they do so. At this stage no nerve damage has occurred. B. More lymphocytes have migrated into the surrounding tissue. The first effect upon the nerve is breakdown of myelin, the axon being spared (segmental demyelination). This change appears to be mediated by the mononuclear exudate, but the mechanism is uncertain. C. The lesion is more intense, polymorphonuclear leukocytes being present as well as lymphocytes. There is interruption of the axon in addition to myelin sheath damage; as a result, the muscle undergoes denervation atrophy and the nerve cell body shows central chromatolysis. If the axonal damage is distal, the nerve cell body will survive, and regeneration and clinical recovery is likely. If, as in D, axonal interruption has occurred proximally because of a particularly intense root or proximal nerve lesion, the nerve cell body may die and undergo dissolution. In this situation, there is no regeneration, only the possibility of collateral reinervation of muscle from surviving motor fibers. (From Asbury et al., 1969, by permission.)

Although the transmission of EAN by T cells sensitized to myelin is strong evidence of their role in GBS, antilymylin antibodies probably play a significant part in initiating the disease. The serum from patients with GBS damages myelin in tissue cultures, in which it induces a characteristic (“vesicular”) form of myelin destruction. Subepineurial injection of serum from GBS patients into the sciatic nerve of rats leads to local demyelination and electrical conduction block. The studies of Koski and associates of complement-dependent myelin damage by IgM antilymylin antibodies in GBS provides the best evidence that antilymylin antibodies are able to initiate myelin destruction even if T cells and macrophages ultimately effect the damage. Indeed, the very earliest change that could be detected by Hafer-Macko and colleagues was the deposition of complement on the ablaxial surface of the Schwann cell (inner layer of myelin). A number of autoantibodies are detected inconsistently in patients with GBS, the most prominent being anti-GQ b, which is found in almost all patients with ophthalmoplegia. Approximately 15 percent of patients will have anti-GM1 antibodies early in their course, corresponding in most instances to a predominantly motor presentation, the highest titers usually being associated with Campylobacter infections. It would therefore seem that casting GBS exclusively as a humoral or a cellular immune disease is an oversimplification. Several animal diseases—such as coonhound paralysis, Marek’s disease of chickens (a viral neuritis), and cauda equina neuritis of the horse—resemble GBS superficially but do not share its main clinical or pathologic features.

An unanswered question is what initiates the immune reaction in humans. All attempts to isolate a virus or microbial agent from nerves or to demonstrate one by electron microscopy have failed, and it is more likely that a variety of agents—viral, bacterial (particularly C. jejuni), certain vaccines, and perhaps neural injury itself—are all capable, in susceptible individuals, of precipitating a response against autologous peripheral myelin. The occurrence of GBS in patients with AIDS or with EBV or CMV infections simply indicates that these agents too might induce such an autoimmune response without implicating a direct viral infection of nerve.

**Differential Diagnosis GBS** is not only one of the most frequent types of acute polyneuropathy seen in a general hospital but also the most rapidly evolving and potentially fatal form. Any polyneuropathy that brings the patient to the brink of death from respiratory failure within a few days will usually be of this variety. However, several other neurologic conditions must be distinguished from GBS.

The immediate problem is to differentiate GBS from acute spinal cord disease (marked by sensorimotor paralysis below a level on the trunk and sphincteric paralysis). Confusion may occur with acute lesions of the cord in which tendon reflexes are initially lost (spinal shock), or with neurotoxic myelopathy, where a permanent loss of tendon reflexes follows destruction of spinal neurons (pages 966 and 1313). Several rules of thumb are useful in distinguishing GBS from a cervical myelopathy: in GBS, the facial and respiratory muscles are usually involved if there is generalized paralysis; the fingertips should be pareshic; only sensory symptoms have ascended to the level of the midcables; marked sensory loss proximal to the hands or feet is unusual early in the illness; and tendon reflexes are almost invariably lost within 24 h in limbs that are too weak to resist gravity.

Another problem arises in distinguishing generalized GBS or the Fisher variant from basilar artery thrombosis. The presence of reactive pupils, areflexia, and F-wave abnormalities in GBS and of lively reflexes and Babinski signs in the case of brainstem infarction dependably separates the two disorders.

A predominantly motor paralysis is the major characteristic of GBS, for which reason the differential diagnosis also includes polymyositis, now usually caused by enteroviruses other than the polio agent; here the infectious agent is marked by fever, meningeal symptoms, early pleocytosis, and purely motor and usually asymmetrical areflexic paralysis.

Ptotis and ocuclmot or weakness, features of GBS in some cases, may cause confusion with acute myasthenia gravis (MG), but in the latter disease there are no sensory symptoms and tendon reflexes are unimpaired. The mandibular muscles remain relatively strong in GBS, whereas the exercised jaw hangs open in MG. Botulism may also simulate GBS, but pupillary reflexes are lost early in the former (this also occurs in advanced cases of GBS), and there is usually a bradycaudry, which is unusual for GBS. Tick paralysis may be nearly impossible to distinguish from GBS unless one finds the tick (page 1277); both cause an acute ascending paralysis. Both also sometimes cause ataxia and may paralyze eye movements, but sensory loss is not usually a feature of tick paralysis and the CSF protein remains normal. Infection of shellfish or reef fish contaminated with saxitoxin, ciguatoxin, or tetrodotoxin (ciguatera) is another cause of acute facial-brachial paresthesias, weakness, tardyneap, and iridoplegia lasting a few days—symptoms that resemble the cranial nerve variants of GBS (page 1276).

In critically ill patients, a number of neuromuscular disorders may arise that must always be distinguished from GBS. These include the so-called polyneuropathy of critical illness (page 1388): an accelerated neuropathy of renal failure that is seen mainly in diabetic patients receiving peritoneal dialysis (both discussed further on); acute hypophosphatemia induced by hyperalimentation; polymyopathy produced by the administration of high-dose corticosteroids (page 1522); and the prolonged effects of neuromuscular blocking drugs, resulting in the accumulation of their metabolites in patients with renal failure and acidosis.

**Treatment** in severe cases, respiratory assistance and careful nursing are paramount, since the disease remits naturally and the outlook for recovery is favorable in the majority of cases. About 30 percent of our patients have needed the assistance of mechanical ventilation. However, since the patient’s condition may deteriorate unpredictably and rapidly, virtually all cases must initially be admitted to the hospital for observation of respiratory function. Measurement of maximal inspiratory force and expiratory vital capacity suffices for bedside guidance to the adequacy of diaphragmatic strength and the likelihood of respiratory failure. As in polymyelitis, the strength of the neck muscles and trapezius, which share the same segmental innervation as the diaphragm, tends to parallel respiratory strength. A very rough estimate of breathing capacity may be obtained by having the patient count quickly on one deep breath. The ability to reach 20 generally corresponds to a vital capacity of greater than 1.5 L. If a downward trend in these measurements is recognized and the vital capacity reaches 12 to 15 mL/kg, endotracheal intubation and mechanical ventilation should be considered. There is usually a slight rise in the respiratory rate at this time. This degree of impaired ventilation usually occurs before the first sign of dyspnea appears and before there is any elevation of arterial carbon dioxide content, but it generally coincides with tachycardia and a slight decrease in arterial oxygen tension (Pao2 less than 85 mmHg). If respiratory failure arises gradually, over days or longer, there is often slight tachycardia, diaphoresis, restlessness, and tachypnea. Attempts to forestall the need for a positive-pressure ventilator by the use of negative-pressure cuirass-type devices have generally been unsatisfactory. Patients with oropharyngeal weakness may require intubation even earlier to prevent asphyxiation, but mechanical ventilation is not always required at the same time.
These types of treatment demand that the patient be admitted to an intensive care unit staffed by personnel skilled in maintaining ventilation and airway patency.

The major aspects of the treatment in severely affected patients involve the management of cardiovascular autonomic instability and attempts to forestall the many general medical problems that attend any critical illness. Hypotension from dysautonomia, which occurs in about 10 percent of severely affected patients, is treated with intravenous volume infusion and the use of vasopressor agents for brief periods. Extremes of hypotension are managed by short-acting and titratable antihypertensive medications, such as intravenous labetalol. This choice of antihypertensive is important, since these episodes may be rapidly succeeded by a precipitous drop in pressure. Prevention of electrolyte imbalance, gastrointestinal hemorrhage, and particularly pulmonary embolism in patients who are bedbound (by the use of subcutaneous heparin or pneumatic compression boots) all require careful attention. Adynamic ileus is a problem in some cases, manifest first by abdominal pain coincident with nasogastric tube feeding and by bloating; it may lead to bowel perforation if feeding is continued. A number of patients become hypotensive, usually from SIADH but occasionally from a natriuresis, and the drop in sodium may be exaggerated by positive-pressure mechanical ventilation. The distinction between these two conditions determines the course of treatment: fluid restriction or salt replacement.

Failure to effectively clear the tracheobronchial airways and the need for prolonged mechanical ventilation are the usual indications for tracheostomy. In most cases this procedure can be postponed until the end of the second third week of intubation. However, in patients who become rapidly quadriplegic and ventilator-dependent, tracheostomy may be needed earlier. Once tracheostomy is performed, careful tracheal toilet and treatment of pulmonary and urinary tract infections by the use of appropriate antibiotics are required. Prophylactic antibiotic treatment is not recommended. Under these conditions the mortality from the disease can be reduced to 3 percent or less (Ropper and Kehne).

The decision to discontinue respiratory aid and to remove the endotracheal or trachotomy tube is based on the degree of recovery of respiratory function. The weaning process begins when the tidal capacity reaches approximately 10 mL/kg, and can be sustained for a few hours. Physical therapy (aggressive movement and positioning of limbs to prevent pressure palsies and, later, mild resistance exercises) should begin once the patient can comfortably undertake it.

Plasma Exchange and Immune Globulin Specific therapy of GBS includes the use of plasma exchange and intravenous immune globulin (IVIg). Our practice has been to observe the patient closely for several days, even if mildly affected. If the patient becomes unable to walk unaided or if he shows a significant reduction in vital capacity or signs of severe oropharyngeal weakness, plasma exchange or IVIg (not both) is instituted promptly.

Three large randomized trials comprising more than 500 patients have clearly established the usefulness of plasma exchange in the evolving phase of GBS. In patients who are treated within 2 weeks of onset, there is a reduction in the period of hospitalization, in the length of time that the patient requires mechanical ventilation, and in the time required to achieve independent ambulation. However, when plasma exchange is delayed for 2 weeks or longer after the onset of the disease, the procedure has, with a few notable exceptions, been of little value. The most important predictors of responsiveness to plasma exchange therapy are the patient's age (responders are younger) and the preservation of motor compound muscle action potential amplitudes prior to instituting treatment (McKhann et al). One study found that the overall condition of patients treated in this way was better at 6 and 12 months after treatment; other studies have been equivocal on this point.

The regimen we use removes a total of 200 to 250 mL/kg of plasma in four to six treatments on alternate days or over a shorter period if there is no coagulopathy. The replacement fluid is saline combined with 5% albumin. The need for large-bore venous access usually requires the insertion of subclavian or internal jugular catheters, and this may be the main source of complications (pneumothorax, infection, hemorrhage). In many patients, however, treatment can be instituted through the antecubital veins. During the procedure, hypotension, hypoprothrombinemia with bleeding (usually epistaxis), and cardiac arrhythmias may occur. Some groups prefer to use the level of fibrinogen, which is greatly reduced by the treatment, as a gauge to the risk of potential hemorrhage before beginning the next exchange. Reactions to the citrate that is used to prevent blood from clotting in the plasma exchange machine are common but can be obviated by the cautious addition of calcium to the intravenous return line. Hepatitis and AIDS are not risks if plasma is replaced with albumin and saline rather than pooled plasma.

The Dutch Study Group has found that the intravenous administration of immune globulin (0.4 g/kg per day for 5 consecutive days) is as effective as plasma exchange and is both easier to administer and probably safer because there is no need for large intravenous access (van der Meche et al). Their results have been confirmed by an Italian study by Feo et al. which used two subgroups of treatment and evaluated the results of the greater severity subgroup. In the latter trial there was a trend toward a better outcome in patients who received plasma exchange, and results were even better in a group who were treated with plasma exchange followed immediately by 5 days of immune globulin infusions; in both instances, however, the differences failed to attain statistical significance. Most patients tolerate IVIG treatment well. Renal failure, proteinuria, and aseptic meningitis, reflected most often by severe headache, are rare complications. The only serious reactions we have encountered were in those few patients who concomitantly lacked IgA and in whom pooled gamma globulin caused anaphylaxis and inflammatory local venous thrombosis.

After the use of either plasma exchange or IVIG, 5 to 10 percent of patients who initially improve will have a relapse that becomes apparent several days to 3 weeks after completion of treatment. If there was a good response to initial therapy, the same treatment may be repeated or the alternative treatment may be tried; either can be successful. A few such patients relapse repeatedly and have a course more suggestive of chronic inflammatory demyelinating polyneuropathy (see further on). In some such patients under our care the disease stabilized after several months in response to the administration of corticosteroids, either alone with very gradual tapering of the dose over several months, or in combination with repeated courses of IVIG or plasma exchanges.

The value of corticosteroids in the treatment of GBS has been disputed for decades. Many clinicians were persuaded of their benefits. However, two randomized controlled studies, one with conventional-dose prednisolone and the other with high-dose methylprednisolone, have failed to demonstrate any beneficial effect (Izquierdo et al). Although corticosteroids can be recommended as routine treatment for acute GBS, we have observed a few instances in which the administration of intravenous high-dose corticosteroids seemingly halted the progress of the disease.

Prognosis As already indicated, 3 to 5 percent of patients do not survive the illness, even in the best-equipped hospitals. In the early stages, death is most often due to cardiac arrest, perhaps related to dysautonomia, adult respiratory distress syndrome, or some type of accidental machine failure. Later in the illness, pulmonary embolism and other complications (usually bacterial) of prolonged immobilization and respiratory failure are the main causes.

The majority of patients recover completely or nearly completely (with mild motor deficits in the feet or legs). In about 10 percent of patients, however, the residual disability is pronounced; this occurs in those with the most severe and rapidly evolving form of the disease, when there has been evidence of widespread axonal damage (see below), and in those requiring early and prolonged mechanical ventilatory assistance. A consistent predictor of residual weakness is the EMG finding of severe reduced amplitudes of muscle action potentials and widespread denervation, both indicative of axonal damage. In patients with respiratory failure, the average period of machine-assisted respiration has been 22 days and the period of hospitalization approximately 50 days (these were twice as long prior to the introduction of plasma exchange and IVIG). As a rule, older adults recover more slowly and have more residual weakness.

The commonest residual difficulties are weakness of the lower leg muscles, numbness of the feet and toes, and mild facial weakness. A few patients are left with a sensory ataxia; when this occurs, it tends to be severe and has been quite disabling. Distal neuropathic pain and persistent autonomic problems occur but are infrequent. Many of these latter symptoms are attributed with little evidence to the illness and should be addressed on their own merits—fatigue and asthenia, muscle cramps, dizziness, breathlessness, etc.

The speed of recovery varies but its pace is steady. Often it occurs within a few weeks or months; however, if axons have degenerated, their regeneration may require 6 to 18 months or longer. Little or no real improvement can be expected in disabilities that have lasted 2 or 3 years.

Some 5 to 10 percent of patients suffer one or more recurrences of acute polyneuropathy. Also, an illness that in the beginning appeared to be an acute inflammatory polyradiculoneuropathy may fail to stabilize and continue to progress steadily, or there may be an incomplete remission followed by a chronic, fluctuating, slowly progressive neuropathy. These chronic forms of inflammatory neuropathy are described in a later section of this chapter.

Acute Axonal Form of Guillain-Barré Syndrome Feasby et al. and colleagues drew attention to an acute polyneuropathy clinically similar to GBS but characterized pathologically by widespread and severe axonal degeneration. They described five patients, all of them with a particularly rapid evolution of polyneuropathy and poor recovery. Unlike the common form of GBS, muscle atrophy in these patients was apparent relatively early in the disease (weeks), reflecting widespread axonal damage. The defining EMG features are said to be the presence of numerous electrically inexcitable motor nerves and accompanying signs of denervation. Others, however, have noted that the inability to excite a motor nerve is not unique and may signify a distal demyelinating block, from which complete recovery is possible...
Postmortem examinations in these cases have disclosed severe axonal degeneration in nerves and roots, with minimal inflammatory changes and only minimal demyelination early in the disease. Prominent in some of these cases were deposits of complement and the presence of macrophages in the periaxonal space; axonal degeneration was a prominent component of the axonal neuropathy. In some cases from typical GBS if only to lower expectations for the response to immune treatments and for the ultimate clinical outcome.

Critical Illness Polyneuropathy

An acute or subacute symmetrical polyneuropathy is a frequent development in critically ill and septic patients, particularly in those with failure of multiple organs (Zochodne et al.). This type of neuropathy may pose a major difficulty in weaning the patient from the ventilator as the underlying critical illness comes under control. The neuropathy, predominantly sensory, is toxic in clinical, immunologic, and pathologic boundaries of GBS. Certainly, there is a degree of axonal damage in all severe cases, even if the predominant process is demyelinating. At present it is useful to distinguish these cases from typical GBS if only to lower expectations for the response to immune treatments and for the ultimate clinical outcome.

Acute Uremic Polyneuropathy

An accelerated neuropathy in chronically uremic patients has been known for some time but has not been generally recognized as a cause of acute and subacute weakness that simulate GBS (Ropper et al.). Most patients are diabetics in stable end-stage renal failure that is being treated with peritoneal dialysis. In contrast to the better-characterized chronic uremic neuropathy (page 1413), generalized weakness and distal paresthesias progress over one or more weeks to a bedbound state. More aggressive dialysis or a change to hemodialysis has little immediate effect, although kidney transplantation is curative. Electrophysiologic studies show some demyelinating features but usually not a conduction block. There is raised CSF protein concentration (not unexpectedly, for there is usually an element of diabetic neuropathy). A few cases have been reported that are clinically indistinguishable from an inflammatory demyelinating polyneuropathy, including, in some of them, a response to plasma exchange or gamma globulin. The cause of this acute neuropathy, like that of the more common chronic form, is not understood.

Acute Sensory Neuropathy and Neuropathy

Sternman and colleagues described three adult patients with rapidly evolving sensory ataxia, areflexia, numbness, and pain, beginning in the face and spreading to involve the entire body. In each case, the symptoms began within 4 to 12 days following the institution of penicillin therapy for a febrile illness. Mainly proprioceptive sensory loss evolved in a subacute or chronic manner is known to occur as a paraneoplastic phenomenon, described further on in this chapter, or in association with the Sjögren syndrome, scleroderma, or lupus erythematosus, paraproteinemia, and HTLV-I infection. Certain drugs and other agents, especially cisplatin and excessive intake of pyridoxine, also cause a sensory neuronopathy. A process also to be distinguished from sensory neuronopathy is a rare form of the Guillain-Barré syndrome that involves predominantly the large sensory fibers. In the latter there is usually some degree of proximal weakness, and the sensory changes do not extend to the face and trunk.

Diphtheritic Polyneuropathy

Some of the neurotoxic effects of Corynebacterium diphtheriae and the mode of action of the exotoxin elaborated by the bacillus are described in Chap. 32. Local acute or subacute polyneuropathy may evolve when the patient is treated, and there was obtained its maximum severity within a week of onset, after which it stabilized and improved very little. Electrical studies showed absent or slowed sensory conduction but no abnormalities of motor nerve conduction or signs of denervation. In two of these patients, the CSF protein content was elevated to 126 and 175 mg/dL, respectively. Follow-up observations (for up to 5 years) disclosed no neoplastic or immunologic disorder. A toxic disorder, akin to that produced experimentally by doxorubicin and pyridoxine, was postulated. Lacking pathology, it was assumed, from the permanence of the condition, that sensory nerves were destroyed (sensory neuronopathy). A subsequent study by Windebank et al. emphasized the asymmetrical and brachial patterns of symptoms in some patients and an initial affection of the face in two. In contrast to Sternman’s cases, the CSF was usually normal. Eight patients had a spontaneous resolution of the disease. The authors viewed the process as a neuropathy. In subsequent reports of such cases antibiotics were not implicated. Probably, some instances are immune-postinfectious in nature. The same pattern of sensory loss evolving in a subacute or chronic manner is known to occur as a paraneoplastic phenomenon, described further on in this chapter, or in association with the Sjögren syndrome, scleroderma, or lupus erythematosus, paraproteinemia, and HTLV-I infection. Certain drugs and other agents, especially cisplatin and excessive intake of pyridoxine, also cause a sensory neuropathy. A process also to be distinguished from sensory neuropathy is a rare form of the Guillain-Barré syndrome that involves predominantly the large sensory fibers. In the latter there is usually some degree of proximal weakness, and the sensory changes do not extend to the face and trunk.

Porphyria Polyneuropathy

Porphyria Polyneuropathy

Porphyria is inherited as an autosomal dominant trait and is not associated with cutaneous sensitivity to sunlight. The metabolic defect is in the liver and is marked by increased production and urinary excretion of porphobilinogen and of the porphyrin precursors--aminolevulinic acid. The peripheral and central nervous systems may also be affected in another hepatic type of porphyria (so-called variegate type). In the latter type, the skin is markedly sensitive to light and trauma, and porphyrins are at all times found in the stools. Both of these hepatic forms of porphyria are to be distinguished from the rare erythropoietic (congenital photosensitive) porphyria, in which the nervous system is not affected.

The seminal study of acute intermittent porphyria was made by Waldenstrom in 1937. The initial and often the most prominent symptom is moderate to severe colicky abdominal pain. It may be generalized or localized and is unattended by rigidity of the abdominal wall or tenderness. Radiographs show intestinal distention and spasms. Constipation is frequent. Attacks last for days to weeks and repeated vomiting may lead to inanition. In latent forms, the patient may be asymptomatic or...
complain only of slight dyspepsia.

The disease is characterized by recurrent attacks, often precipitated by drugs such as sulfonamides, griseofulvin, estrogens, barbiturates, phenytoin, and the succinimide anticonvulsants. The possibility of sensitivity to these drugs must always be kept in mind when convulsions are being treated in the porphyric patient. The first attack rarely occurs before puberty, and the disease is most likely to threaten life during adolescence and early adulthood. An acute polyneuropathy that appears for the first time in mid- or late adult life is not likely to be porphyric.

The neurologic manifestations are usually those of a polyneuropathy involving the motor nerves more severely than the sensory ones; less often both sensory and motor nerves are affected more or less equally, and sometimes autonomic nerves as well. The symptoms may begin in the feet and legs and ascend, or they may begin in the hands and arms (sometimes asymmetrically) and spread in a few days to the trunk and legs. Occasionally the weakness predominates in the proximal muscles of the limbs and limb girdle muscles, in which case there is loss of knee jerks with preservation of reflexes at the ankles. Sensory loss, often extending to the trunk, is present in half the cases. Facial paralysis, dysphagia, and ocular palsies are features of only the most severe cases, then simulating GBS. The CSF protein content is normal or slightly elevated. The course of the polyneuropathy is variable. In mild cases the symptoms may regress in a few weeks. Severe cases may progress to a fatal respiratory or cardiac paralysis in a few days, or the symptoms may advance in a sallatory fashion over a period of several weeks, resulting in a severe sensorimotor paralysis that improves only after many months.

A disturbance of cerebral function (confusion, delirium, visual field defects, and convulsions) is likely to precede the severe rather than the mild forms of polyneuropathy, and it may not appear at all. The cerebral manifestations usually subside in a few days to weeks, though one of our patients was left with a lasting homonymous hemianopia.

Tachycardia and hypertension are frequent in the acute phase of the disease, and fever and leukocytosis also may occur; these are said to reflect the activity of the pathologic process.

In general, the prognosis for ultimate recovery is excellent; though relapse of the porphyria may result in further involvement of the peripheral nervous system (see discussion of relapsing polyneuropathy, further on), but death may result from respiratory paralysis or cardiac arrest and sometimes from uremia and cachexia.

In sum, the most characteristic clinical features are acute onset, initial abdominal pain, psychotic symptoms, predominant motor neuropathy, often an early bibrachial distribution of weakness, truncal sensory loss, and tachycardia. Rarely the neuropathy develops without other symptoms.

The pathologic findings in the peripheral nervous system vary according to the stage of the illness at which death occurs. If the patient dies in the first few days, the myelinated fibers may appear entirely normal, those with neuronal relationship may be destroyed. If symptoms had been present for weeks, degeneration of both axons and myelin sheaths will be found in most of the peripheral nerves. The relation between the abnormality of porphyrin biosynthesis in the liver and nervous dysfunction has never been explained satisfactorily.

Diagnosis is confirmed by the demonstration of large amounts of porphobilinogen and d-aminolevulinic acid in the urine. The urine turns dark when standing due to the formation of porphobilin, an oxidation product of porphobilinogen.

Treatment consists of respiratory support, use of beta-blocking agents, (propranolol) if tachycardia and hypertension are severe, intravenous glucose to suppress the heme biosynthetic pathway, and pyridoxine (100 mg twice a day) on the supposition that vitamin B6 depletion has occurred. The use of intravenous glucagon and intravenous hematin (4 mg/kg daily for 3 to 14 days) is recommended as the most direct and effective therapy (Windebank and Bonkovsky).

Prevention is of the utmost importance, since attacks can be precipitated by porphyrinogenic drugs, the most common of which are the barbiturates.

**Acute Toxic Polyneuropathies**

As indicated in Chap. 43, the peripheral nerves may be affected by a wide variety of toxins, including metals, drugs, and industrial solvents. As a general rule, the neuropathies induced by these agents fall into the early chronic category (to be discussed further on). Certain drugs, however—notably triorthocresylphosphate (TOCP) and other organophosphates (page 1281), thallium, and rarely arsenic—produce a polyneuropathy that may be fatal in a matter of days. It should be stressed that organophosphate neuropathy almost never occurs without severe anticholinergic effects immediately after exposure. Severe and permanent motor paralysis is caused by TOCP, this ultimately proves to be due to involvement of both upper and lower motor neurons.

Thallium salts, when taken in sufficient amount, may produce a clinical picture resembling that of GBS or an acute sensory polyneuropathy. If the salts are taken orally, there is first abdominal pain, vomiting, and diarrhea, followed within a few days by pain and tingling in the toes and fingertips and then rapid weakening of muscles of the limbs, initially the distal ones. As the weakness progresses, the tendon reflexes diminish. Pain sensation is reduced more than tactile, vibratory, and position sense.

Persistent acral pain with allodynia has been a major feature in three of the five cases we have examined; in two patients there was no weakness, only sensory loss and ataxia. All cranial nerves except the first and eighth may be affected; facial palsies, ophthalmoplegia, nystagmus, optic neuritis with visual impairment, and vocal cord palsies are prominent abnormalities, but only in the most severely affected patients. The CSF protein rises to more than 100 mg. Death may occur in the first 10 days, due to cardiac arrest. The early onset of painful paresthesias, sensory loss, and pain localized to joints, back, and chest as well as rapid loss of hair (within a week or two) help differentiate this neuropathy from GBS, porphyria, and other acute polyneuropathies. Relative preservation of reflexes is noteworthy, and a rapidly evolving, complete alopecia is a striking feature. Patients with lesser degrees of intoxication may recover completely within weeks or months. Thallium salts act like potassium, and a high intake of potassium chloride hastens the excretion of thallium; chelating agents are of unproven value.

Some cases of arsenical and possibly mercurial polyneuropathy may develop acutely, and this is true also of the eosinophilia-myalgia syndrome due to intoxication with contaminated L-tryptophan. More often these neuropathies evolve subacutely, for which reason they are discussed further on.

In this regard to the category of polyneuropathy, it must be pointed out that many instances of neuropathy are imputed with little substantiation to a toxic cause by patients and unskeptical physicians. Before making such an attribution, it is useful to ask whether the clinical features were compatible with the known neurotoxicity of an environmental agent or drug; whether the severity of symptoms was consistent with degree of exposure; whether the associated systemic signs of intoxication were present; if other individuals similarly exposed had been affected; and whether symptoms stabilized or improved once the patient had been removed from the presumed source of exposure. Failure to satisfy these precepts generally signifies some disorder other than exposure to a toxin.

**Other Acute Polyneuropathies**

On rare occasions, a vasculitic polyneuropathy associated with lupus erythematosus, polyarteritis nodosa, and related disorders may develop as rapidly as GBS, and rarely arsenic—produce a polyneuropathy that may be fatal in a matter of days. It should be stressed that organophosphate neuropathy almost never occurs without severe anticholinergic effects immediately after exposure. Severe and permanent motor paralysis is caused by TOCP; this ultimately proves to be due to involvement of both upper and lower motor neurons.

Thallium salts, when taken in sufficient amount, may produce a clinical picture resembling that of GBS or an acute sensory polyneuropathy. If the salts are taken orally, there is first abdominal pain, vomiting, and diarrhea, followed within a few days by pain and tingling in the toes and fingertips and then rapid weakening of muscles of the limbs, initially the distal ones. The CSF protein rises to more than 100 mg. Death may occur in the first 10 days, due to cardiac arrest. The early onset of painful paresthesias, sensory loss, and pain localized to joints, back, and chest as well as rapid loss of hair (within a week or two) help differentiate this neuropathy from GBS, porphyria, and other acute polyneuropathies. Relative preservation of reflexes is noteworthy, and a rapidly evolving, complete alopecia is a striking feature. Patients with lesser degrees of intoxication may recover completely within weeks or months. Thallium salts act like potassium, and a high intake of potassium chloride hastens the excretion of thallium; chelating agents are of unproven value.

Some cases of arsenical and possibly mercurial polyneuropathy may develop acutely, and this is true also of the eosinophilia-myalgia syndrome due to intoxication with contaminated L-tryptophan. More often these neuropathies evolve subacutely, for which reason they are discussed further on.

In this regard to the category of polyneuropathy, it must be pointed out that many instances of neuropathy are imputed with little substantiation to a toxic cause by patients and unskeptical physicians. Before making such an attribution, it is useful to ask whether the clinical features were compatible with the known neurotoxicity of an environmental agent or drug; whether the severity of symptoms was consistent with degree of exposure; whether the associated systemic signs of intoxication were present; if other individuals similarly exposed had been affected; and whether symptoms stabilized or improved once the patient had been removed from the presumed source of exposure. Failure to satisfy these precepts generally signifies some disorder other than exposure to a toxin.

**Pure Autonomic Polyneuropathy**

Since the first description of such a case by Young and colleagues, a number of similar ones have been recorded (Low et al). The condition is described in detail in Chap. 26. Some success has been achieved by treatment with intravenous immune globulin, similar to that used in GBS.

**SYNDROME OF SUBACUTE SENSORIMOTOR PARALYSIS**
Subacute Symmetrical Polyneuropathies

Placed in this category are neuropathic conditions that evolve over a period of several weeks to months and, after reaching their peak of severity, tend to persist for a variable period. Admittedly, as intimated earlier, the dividing line between such cases and neuropathies that evolve over a somewhat shorter or longer period is indistinct; there are diseases of nerve that overlap both the acute and the early chronic categories. In contrast to the acute polyneuropathies, most of those that are subacute are of axonal type. However, a subacute inflammatory-demyelinating type, essentially a slow form of GBS, evolving over 4 to 8 weeks, does occur, as documented by Hughes and coworkers. Similarly, some instances of diphtheritic neuropathy evolve subacutely, but most develop rapidly. A symmetrical syndrome of subacute sensory neuropathy due to a drug (phenytoin) and nutritional deficiency, to a remote effect of cancer (paraneoplastic as described below), or to poisoning with arsenic, lead, or to any number of drugs used for therapeutic purposes (cisplatin, nitrofurantoin, isoniazid, etc.). Occasionally other drugs, metals, and industrial solvents can be incriminated; these are discussed in Chap. 43.

Nutritional Deficiency Neuropathy

In the western world, nutritional polyneuropathy is usually associated with alcoholism. As indicated in Chap. 41, all data point to the identity of alcoholic neuropathy and neurotoxic beriberi. A nutritional factor is responsible for both, though in any given case it often remains unclear whether the deficiency is one of thiamine, pellagra, pantothenic acid, folic acid, or a combination of the B vitamins. We have not been able to define a form of polyneuropathy that is attributable to the direct toxic effect of alcohol, though claims of such an entity have been made. Neurotoxic beriberi and other forms of deficiency neuropathy (Strachan syndrome, pellagra, vitamin B12 deficiency, and malabsorption syndromes) are described fully in Chap. 44.

Paraneoplastic Polyneuropathy (See also page 727.) Although capable of a number of clinical presentations, most often this takes the form of a predominantly distal, symmetrical sensory or sensorimotor polyneuropathy occurring as a remote effect of carcinoma, lymphoma, or multiple myeloma. Severe weakness and atrophy, ataxia, and sensory loss of the limbs may advance over several months to the point where the patient is confined to a wheelchair or bed; usually the CSF protein content is moderately elevated. All these symptoms may occur several months or even a year or longer before a malignant tumor is found.

A mixed sensorimotor polyneuropathy is four to five times more frequent than a purely sensory one. The latter syndrome, described originally by Denny-Brown, is characterized by a loss of all modalities of sensation spreading from the distal to the proximal segments of the extremities and eventually to the trunk and face. There is subsequent axonal and motor involvement, but the neuropathy is relatively mild. It has been appreciated recently that the sensory loss in the beginning may have a multifocal distribution. The sensory loss reaches its peak in a few months, occasionally in weeks, and in a few instances the development has been as rapid as that of GBS. The pathologic changes are those of an inflammatory and destructive neurotoxic neuropathy (ganglionopathy) and are part of a more widespread neoplastic affection of the peripheral nervous system related to the anti-Hu antibody (also termed antineural neuronal antibody) that is most typical of small-cell cancer of the lung. In a series of 71 patients with sensory neuropathy reported by Dalmau and colleagues, more than half were associated with symptomatic inflammatory lesions in the temporal lobes (limbic encephalitis, page 727), the brainstem, and rarely the anterior horn neurons of the spinal cord. Other more distinctive paraneoplastic syndromes such as cerebellar degeneration or Lambert-Eaton myasthenic syndrome were found in isolated cases, and there were signs of dysautonomia in 28 percent. The CSF protein is moderately elevated but acellular and shows high titers of the anti-Hu antibody. Sensory potentials are usually abnormal and some SFEMG abnormalities are present in all nerves after a few weeks but may be spared early on. The localization of anti-Hu to the several affected regions of the nervous system and to the tumor itself suggests that the lungs tumors are typically small or inedible because the antibody suppresses tumor growth. Clinically, serum anti-Hu testing is useful in distinguishing paraneoplastic varieties of sensory neuropathy and neurotoxic neuropathies from those due to postinfectious or immune disorders, such as Sjögren syndrome, and from HIV infection. The finding of high antibody titers should lead to detailed radiologic and bronchoscopic examinations.

An unusual assortment of polyneuropathies may be associated with non-Hodgkin lymphomas of both T- and B-cell types and with several related conditions such as Castleman disease (angiofollicular lymphoid hyperplasia), angiocentric T-cell lymphoma (and the related angioimmunoblastic granulomatosis, page 700), hypersensitivity lymph node hyperplasia (angioimmunoblastic or immunoblastic lymphoproliferative disease), and Kimura disease (lymphoid hyperplasia mainly involving skin). In most of these neuropathies, particularly the one associated with Castleman disease, there is a paraproteinemia, often polyclonal, thereby relating this group to the paraproteinemic neuropathies and to osteoelastic myeloma, discussed below. In several of our cases the neuropathic manifestations have appeared simultaneously with the other systemic features of the disease (eg, fever, lymphadenopathy, and abdominal pain). In one of 18 patients with a subacute neuropathy and another became dependent for sustained improvement on immune globulin; most of the others stabilized or worsened, and the authors concluded that the treatment was of doubtful value.

The pathology of the paraneoplastic polyneuropathies has not been completely defined. In the purely sensory type, there is not only a loss of nerve cells in the dorsal root ganglia but an inflammatory reaction in the anterior horn cells (Hughes and coworkers). Similarly, some instances of diphtheritic neuropathy evolve subacutely, but most develop rapidly. A symmetrical syndrome of subacute sensory neuropathy due to a drug (phenytoin) and nutritional deficiency, to a remote effect of cancer (paraneoplastic as described below), or to poisoning with arsenic, lead, or to any number of drugs used for therapeutic purposes (cisplatin, nitrofurantoin, isoniazid, etc.). Occasionally other drugs, metals, and industrial solvents can be incriminated; these are discussed in Chap. 43.

The pathology of the paraneoplastic polyneuropathies has not been completely defined. In the purely sensory type, there is not only a loss of nerve cells in the dorsal root ganglia but an inflammatory reaction in the anterior horn cells (Hughes and coworkers). Similarly, some instances of diphtheritic neuropathy evolve subacutely, but most develop rapidly. A symmetrical syndrome of subacute sensory neuropathy due to a drug (phenytoin) and nutritional deficiency, to a remote effect of cancer (paraneoplastic as described below), or to poisoning with arsenic, lead, or to any number of drugs used for therapeutic purposes (cisplatin, nitrofurantoin, isoniazid, etc.). Occasionally other drugs, metals, and industrial solvents can be incriminated; these are discussed in Chap. 43.
a slight sensory loss in the radial territory of the hand. Less commonly, foot drop is observed, occurring alone or in combination with weakness of the proximal arm and shoulder girdle muscles. As pointed out in Chap. 43, lead neuropathy seldom occurs in children, in whom lead poisoning usually results in an encephalopathy. Although the neuropathy has been known since ancient times, details of the pathology are obscure. Axonal degeneration with secondary myelin change and swelling and chromatolysis of anterior horn cells has been described. Lead accumulates in the nerve and may be toxic to Schwann cells or to endothelial capillary cells, causing edema.

The diagnosis is established by the history of lead exposure, the predominant and restricted motor involvement, the associated medical findings (anemia, basophilic stippling of red cell precursors in the bone marrow, a “lead line” along the gingival margins, colicky abdominal pain, and constipation), and the urinary excretion of lead and coproporphyrins. Blood lead levels of more than 24 μg/dl are abnormal, and patients with lower levels, doubling of the 24-h urinary lead excretion following an infusion of the chelating agent CaNa₂EDTA indicates a significant degree of lead intoxication. Coproporphyrin in the urine is abnormal in any amount, but it may be found in porphyria, alcoholism, and iron disorders, as well as in lead intoxication. Treatment consists of terminating the exposure to lead and eliminating lead from the bloodstream and the bones. For this purpose, penicillamine, which is safe and can be administered orally, is preferable to dimercaprol [British antidote (BAL)] or EDTA.

Other Metals and Industrial Agents Chronic poisoning with thallium and sometimes with lithium, gold, mercury, and platinum (in the antineoplastic agent cisplatin) may produce a sensorimotor polyneuropathy similar to arsenical polyneuropathy; these intoxications are discussed in Chap. 43. A predominantly motor neuropathy is known with occupational exposure to metallic mercury and mercury vapor, but the connection to the mercury content in dental amalgam has been vastly overstated. Exposure to manganese, bismuth, antimony, zinc, and copper may give rise to systemic signs of poisoning; some of them affect the central nervous system, but one cannot be certain that any of them specifically involves the peripheral nerves.

A distal, symmetrical sensorimotor (predominantly sensory) axonopathy may follow exposure to certain hexacarbon industrial solvents. These include n-hexane (found in contact cements, thus affecting “glue sniffers” who inhale the vapors), methyl-n-buty1 ketone (used in the production of plastic-coated and color-printed fabrics); dimethylaminopropionitrile (DMAPN), used in the manufacture of polyurethane foam); the fumigant methyl bromide; and the gas sterilant ethylene oxide. Operating room nurses are affected by the latter when the agent is absorbed through the skin, leaving a characteristic rash at exposed sites (usually the wrists, where a surgical gown ends). A mild peripheral neuropathy and central nervous system changes of memory loss and headaches have been reported by Brashear and colleagues. Also there is a risk to operating room personnel of nitrous oxide neurotoxicity; but at the present time the neuropathy has most often resulted from its repeated use as a euphoriant. The process is said to have the clinical and electrophysiologic features of a distal axonopathy but is more likely a myeloneuropathy related to impairment of vitamin B₁₂ metabolism. Presumably the neuropathy occurs in marginally vitamin B₁₂-deficient individuals. The associated macrocytic anemia is reversed by the administration of B₁₂, but the neurologic illness is little affected (page 1218).

Detailed accounts of the clinical and experimental neurotoxicology of these agents can be found in the recent monograph of Spencer and Schaumburg.

Drug-Induced Neuropathies A number of medications, the main ones described below, are sources of polyneuropathy of predominantly sensory type. Most are dose-dependent and are therefore more or less predictable after particularly large doses of the drug have been used (e.g., in chemotherapy) or after prolonged administration for other reasons. Often, in the latter case, the patient fails to connect his sensory symptoms to drug toxicity.

Antineoplastic Drugs Among the chemotherapeutic agents in current use, cisplatin and carboplatin are known to evoke a predominantly sensory polyneuropathy, which begins several weeks after completion of therapy and affects the lower limbs. Proprioception and vibratory sensation are most severely impaired, and there may be degeneration in the posterior columns—the basis for a Lhermitte symptom in this form of toxicity. Some patients develop acrodynia and episodic color changes in the fingertips and toes, suggesting that autonomic nerves are also involved. Others exhibit a sensory ataxia and pseudooedema. The severity of histopathologic changes in the peripheral nervous system corresponds to the concentration of plantinum in these tissues, the highest concentrations being found in dorsal root ganglia.

The taxanes paclitaxel (Taxol) and the more potent docetaxel (Taxotere), both cited as inhibitors of the depolymerization of neurotubules, are used mainly in the treatment of ovarian cancer. They produce a sensory polyneuropathy similar to that of cisplatin. The nerve lesion regressess slowly with a reduction in dosage (see also page 1285). Pathologic studies have shown a distal axonopathy affecting mainly large fibers.

Peripheral neuropathy commonly complicates the use of vincristine, an antineoplastic widely used in the treatment of the lymphomas and leukemia (page 1283). Paresthesias are the commonest symptoms, but objective sensory loss is uncommon. Loss of ankle jerks is also an early manifestation. Weakness usually precedes objective sensory loss. Weakness is observed in the extensor muscles of the fingers and wrists, later in the dorsiflexors of the toes and feet; if the dosage of vincristine is not reduced, weakness may spread rapidly to involve the proximal muscles of the limbs. In patients receiving large doses of the drug, foot drop may develop. The weakness is usually mild, but in the past occasional patients became quadriparetic and bedbound. Adults are more severely affected than children, as are persons with pre-existing polyneuropathies. The neuropathy is strictly dose-related, and reduction in dosage is followed by improvement of neurologic symptoms, although this may take several months. Many patients are then able to continue the use of vincristine in low dosage, such as 1 mg every 2 weeks, for many months.

Antimicrobial Drugs As mentioned in Chap. 43, isoniazid-induced polyneuropathy was a common occurrence in the early 1950s, when this drug was first used for the treatment of tuberculosis. Symptoms of neuropathy appeared between 3 and 35 weeks after treatment was begun and affected about 10 percent of patients receiving therapeutic doses (10 mg/kg daily).

The initial symptoms are a symmetrical numbness and tingling of the toes and feet, spreading, if the drug is continued, to the knees and occasionally the hands. Aching and burning pain in these parts then becomes prominent. In addition to sensory loss, examination discloses a loss of tendon reflexes and weakness in the distal muscles of the legs. Severe degrees of weakness and loss of deep sensation are observed only rarely.

Isoniazid (INH) produces its effects on the peripheral nerves by interfering with pyridoxine metabolism, perhaps by inhibiting the phosphorylation of pyridoxine (the collective name for the B₆ group of vitamins) and decreasing the tissue levels of its active form, pyridoxal phosphate. The administration of 150 to 450 mg of pyridoxine daily, in conjunction with isoniazid, completely prevents the neurotoxic disorder. The same mechanism is probably operative in the neuropathies that occasionally complicate the administration of isoniazid-related substances such as ethionamide, used in the treatment of tuberculosis, and the now little-used antibiotic agent hydralazine. Paradoxically, the prolonged administration of extremely high doses of pyridoxine may actually cause a disabling, predominantly sensory neuropathy (Schaumburg et al).

A relatively mild sensory neuropathy (causal paresthesia) associated with optic neuropathy occasionally complicates methotrexate (used in the treatment of Crohn disease and anaerobic infections) may have the same effect. A predominately motor neuropathy may be induced by the chronic administration of dapsone, a sulfone used to treat leprosy and certain dermatologic conditions. Stilbamidine, used in the treatment of kala azar, may produce a purely sensory neuropathy, mainly in the distribution of the trigeminal nerves.

The introduction in 1952 of nitrofurantoin for the treatment of bladder infections was soon followed by reports of neurotoxicity attributable to this drug. The earliest symptoms are pain and tingling paresthesias of the toes and feet, followed shortly by similar sensations in the fingers. If the drug is not discontinued, this disorder may progress to a severe, symmetrical sensorimotor polyneuropathy. Patients with chronic renal failure and azotemia are particularly prone to neurotoxicity from nitrofurantoin, presumably because diminished excretion results in high tissue levels of the drug. To make matters worse, the uric acid level rises, the uric acid level rises, the uric state exacerbates the problem, and the drug is responsible for a clinically similar polyneuropathy, so that the distinction between uricemic and nitrofurantoin neuropathy in the presence of chronic renal failure may be impossible. The neuropathologic studies of Lhermitte and colleagues disclosed an axonal degeneration in peripheral nerves and sensory roots.

Cardiac Drugs Amiodarone, a drug that is commonly used for treating angina pectoris and ventricular tachyarrhythmias, induces a motor-sensory neuropathy in about 5 percent of patients after several months of treatment. Perhexiline maleate, another drug for the treatment of angina pectoris, may also cause a generalized, predominantly sensory polyneuropathy in a small proportion of patients. Affected persons show a striking neuronal lipodiosis. Patients taking niacin to lower blood cholesterol levels may experience intense distal and truncal paresthesias, but no neuropathy has been identified.

Disulfiram (Antabuse) The development of a sensorimotor neuropathy similar to that produced by isoniazid is sometimes associated with the chronic use of disulfiram in the treatment of alcoholism. Its neurotoxic effects have been attributed to the action of carbon disulfide, which is produced during the metabolism of the drug, and is known to produce polyneuropathy and sometimes an optic neuropathy in workers in the visco rayon industry. Pathologic data, though scant, tend to
discredit this notion, insofar as disulfiram produces a wallerian type of axonal degeneration, whereas carbon disulfide neuropathy is characterized by swollen (giant) axons and those that are filled with neurofilaments (Boudin et al).

**Other Agents** Some patients who have taken phenytoin may show absence of ankle and patellar reflexes, a mild, distal symmetrical impairment of sensation, a reduced conduction velocity in the peripheral nerves of the legs, and, rarely, weakness of the distal volitional musculature. Colchicine has long been known to cause a myopathy, but a few cases of predominantly axonal sensory neuropathy have also been reported. Triorthocresyl phosphate and acrylamide are potent peripheral nerve poisons. Both of these drugs cause a "dying-back" polyneuropathy (axonal degeneration) and have been used experimentally to produce this effect. Thalidomide, which can produce sensory polyneuropathy, had been withdrawn from clinical use but is now being used again experimentally for graft-versus-host disease and resistant erythema nodosum, leprous eruptions, and aphthous stomatitis, particularly in AIDS patients—also as an experimental anti-neoplastic agent for vascular tumors. The thalidomide polyneuropathy is dose-dependent and can be anticipated at certain levels of administration. Severe botulinum poisoning and the prolonged use of neuromuscular blocking agents is said to leave some patients with a distal axonopathy or a myopathy, but these must be rare. Residual effects of this polyneuropathy are seen in patients in whom the latter has been present for a long time. It has also been observed that vasculitic myoneuropathy has been used in nonprescription drugs for insomnia (page 1490). In several instances that we have seen, this syndrome has caused quadriplegia and simulated GBS. There may be an eosinophilic infiltrate in nerves, but the neuropathy is probably the result of a direct toxic mechanism. The ingestion of adulterated rapeseed oil (toxic oil syndrome) produces the same effects. A sensory neuropathy resulting from excessive pyridoxine ingestion, alluded to above, is still seen among individuals who take large doses of vitamin supplements. Amiodarone is capable of producing parenteral us, but this effect seems to be idiosyncratic and infrequent. Vancor, a phenylthiourea rodenticide, has been used from time to time as a suicidal agent. It gives rise to a profound sensory and autonomic polyneuropathy with abdominal pain and hyperglycemia due to acute pancreatitis.

As a rare complication of gold therapy, a predominantly motor polyneuropathy has been reported, as mentioned in Chap. 43. In most cases the cumulative dose of gold has exceeded 1 g, but in a few instances the neuropathy has occurred with 0.5 g. Painful distal burning is the initial complaint, and weakness and wasting follow; the onset of weakness, although usually insidious, can be abrupt enough to simulate GBS. There have been trigeminal, facial, and oculomotor palsies. One of the unusual features is a marked rise in CSF protein concentration.

**Subacute Asymmetrical and Multifocal Polyneuropathies (Mononeuropathy Multiplex)**

Several systemic conditions are commonly accompanied by a subacute affection of multiple individual nerves, occurring almost simultaneously and giving rise to a distinctive clinical syndrome. The most notable examples of this syndrome are diabetes of polyneuropathy, are associated with diabetes mellitus, polyarteritis nodosa, cryoglobulinemia and other vasculitides such as the Liptus syndrome, and the uncommon form of idiopathic vasculitis that is confined to the peripheral nervous system. Less frequently, sarcoidosis, forms of HIV-related neuropathy, and Lyme disease present in this fashion. Leprosy, a special case in this group, is discussed further on.

**Diabetic Neuropathy** About 15 percent of patients with diabetes mellitus have both symptoms and signs of neuropathy, but nearly 50 percent have either neuropathic symptoms or nerve conduction abnormalities. Neuropathy is most common in diabetics more than 50 years of age; it is uncommon in those under 30 years of age and rare in childhood. Dyck and colleagues (1993) studied 380 diabetics—27 percent with type 1 (insulin-dependent) diabetes and 73 percent with type 2 (non-insulin-dependent); symatomatic polyneuropathy was found in 15 percent of the first group and 13 percent of the second. The percentages were far higher when the patients were examined electrophysiologically.

Several clinical syndromes have been delineated: (1) acute diabetic ophthalmoplegia that affects the third and less often the sixth nerve; (2) acute mononeuropathy of the limbs or trunk including a painful thoracolumbar radiculopathy; (3) a rapidly evolving, painful, asymmetric, predominantly motor multiple neuropathy affecting the upper lumbar roots and the proximal leg musculature and usually undergoing remission ("diabetic amyotrophy"); (4) a more symmetrical, proximal motor weakness and wasting, often with pain and with variable sensory loss that pursues a subacute or chronic course; (5) a distal, symmetrical, primarily sensory polyneuropathy affecting feet and legs more than hands in a chronically progressive manner (the commonest of the diabetic neuropathies); and (6) an autonomic neuropathy involving bowel, bladder, and circulatory reflexes; and (7) a painful thoracoabdominal radiculopathy. These forms of neuropathy often coexist or overlap, particularly the autonomic and distal symmetrical types and the subacute proximal neuropathies (items 3 and 4 in the above classification). The first five types of neuropathy listed above, and possibly the seventh type as well, are thought to be due to infarction of nerves related to a diabetic microcirculatory defect; in other words, they are all special types of so-called mononeuropathy multiplex. The remaining types are also associated with small blood vessel disease but also with a poorly understood metabolic abnormality.

**Acute Diabetic Mononeuropathies** Diabetic ophthalmoplegia is a not uncommon occurrence, usually in a patient with well-established diabetes. It presents as an isolated, painful third nerve palsy with sparing of pupillary function. In the first autopsyed patient reported by Dreyfus et al., there was an ischemic lesion in the center of the retro-orbital portion of the third nerve. Subsequently, a similar case was described by Asbury et al. Less often, the sixth nerve is involved. The disorder is distinct from other isolated affection of cranial nerves. Clinically all the major peripheral nerves have been described in diabetics, but the ones most commonly involved are the femoral, sciatic, and peroneal nerves in about that order of frequency. Rarely, a nerve in the upper extremity is affected. As mentioned, the acute mononeuropathies, cranial and peripheral, are presumably due to infarction of the nerve, and it is in the third nerve that this pathologic basis has been most convincingly established. Recovery is the rule but may take many months.

**Multiple Mononeuropathies and Radiculopathies** A unilateral or asymmetrical polyneuropathy tends to occur in older patients with relatively mild or symmetrical, and usually mild in degree.

**Distral Polyneuropathy** The distal, symmetrical, primarily sensory form is the most common type of diabetic neuropathy. Although it is a chronic process, sometimes...
unnoticed by the patient, we include here for the sake of presenting the diabetic neuropathies as a unified topic. When the polyneuropathy becomes symptomatic, the main complaints are persistent and often distressing numbness and tingling, usually confined to the feet and lower legs and worse at night. The ankle jerks are absent, and sometimes the patellar reflexes as well. As a rule the sensory signs are confined to the distal parts of the lower extremities, but in severe cases the hands may be involved and the sensory loss may spread to the anterior aspect of the lower abdomen, giving rise to confusion in diagnosis. Said et al. Trophic changes in the toes, such as lesions of the nail bed, are frequently observed on the feet. Other forms of diabetic derangement and injuries. Muscle weakness is usually mild, but in some patients a distal sensory neuropathy is combined with a proximal weakness and wasting of the types described above. Treatment of the acral pain may be a major problem and is discussed further on.

In another group of patients the clinical picture may be dominated by loss of deep sensation, ataxia, and atony of the bladder, with only slight weakness of the limbs, in which case it resembles tabes dorsalis (hence the term diabetic pseudotabes). The similarity is even closer if lancinating pains in the legs, unreceptive pupils, and neuropathic arthropathy are present.

**Autoimmune Neuropathy**

Symptoms of autonomic involvement include pupillary and lacrimal dysfunction, impairment of sweating and vascular reflexes, nocturnal diarrhea, atony of the gastrointestinal tract and bladder, sexual impotence, and postural hypotension. The basis of this type of involvement is not well understood. Duchen and associates, who studied the sympathetic ganglia in diabetics with autonomic symptoms, described vacuoles and granular deposits in neurons and fibers if any neuronal degeneration; there was also a loss of myelinated nerve fibers in the vagus and splanchnic nerves and loss of neurons in the intermediolateral columns of the spinal cord.

In all forms of diabetic neuropathy, the CSF protein may be elevated from 50 to 150 mg/dL and sometimes even higher.

**Pathology and Pathophysiology**

Thomas and Tomlinson have reviewed the neuropathology of diabetic polyneuropathy. Loss of myelinated nerve fibers is the most prominent finding in the distal symmetrical type of polyneuropathy. In addition, segmental demyelination and remyelination of remaining axons are apparent in teased nerve fiber preparations. The latter findings are probably too severe and widespread in some cases to be simply a reflection of axonal degeneration. Occasionally, repeated demyelination and remyelination leads to onion-bulb formations of Schwann cells and fibroblasts, as it does in the relapsing inflammatory neuropathies. Unmyelinated fibers are also reduced in number in some specimens. Similar lesions are found in the posterior roots and posterior columns of the spinal cord and in the rami communicantes and sympathetic ganglia. Under the electron microscope, the basement membranes of intraneuronal capillaries are seen to be thickened and duplicated.

Many uncertainties persist about the pathogenesis of the diabetic neuropathies. Both the cranial (diabetic ophthalmoplegia) and peripheral mononeuropathies as well as the painful, asymmetrical, predominantly proximal neuropathy of sudden onset are thought to be ischemic in origin, secondary to disease of the vasa nervorum; obstruction is sometimes illustrated as a Babcock clamp. Rarely were found in the nerve trunks. In other forms of the disease, a neurotrophic neuropathy, a metabolic basis, as yet undefined, has long been favored, but the observations of Dyck and of Johnson and their associates suggest that these and other forms of diabetic neuropathy might have the same vascular basis. These authors described multiple foci of fiber loss throughout the length of the peripheral nerves, with pronounced predilection for the proximal segments and distinct from those in the distal segments. This pattern of change differs from that observed in diffuse metabolic disease of Schwann cells and in dying-back neuropathy and suggests an ischemic etiology. Fagerberg noted that the fascicular capillaries and epineurial arterioles have thickened and hyalinated basement membranes, similar to the microvascular changes seen in the retina and other organs. Occlusion of vessels and frank infarction of nerve was not observed, so that a vascular pathogenesis remains somewhat unsettled. Inflammatory changes in diabetic nerves have not been impressive; in general, biochemical factors have been more important in this context. Thus, by the work of Dyck and of Said et al. The neuropathy is more limited by symptoms of their vascular claudication than the neuropathic ones. Restoration of circulation to the limbs by surgical or other means, including gene therapy, has resulted in some improvement of the regional neuropathy. The literature on this subject is to be found in the writings of Chalk et al and Eames and Lange listed in the References.

A poorly understood but presumably localized ischemic neuropathy occurs in the region of arteriovenous shunts that have been placed for the purpose of dialysis. Complaints of transient diffuse tingling of the hand are not uncommon soon after placement of the shunt, but only a few patients develop persistent forearm weakness and numbness and burning in the fingers, reflecting variable degrees of ulnar, radial, and median nerve and muscle ischemia. The role of an underlying uremic neuropathy in facilitating this neuropathy is uncertain. In another group of patients the clinical picture is dominated by loss of deep sensation, ataxia, and atony of the bladder, with only slight weakness of the limbs, in which case it resembles tabes dorsalis (hence the term diabetic pseudotabes). The similarity is even closer if lancinating pains in the legs, unreceptive pupils, and neuropathic arthropathy are present.

Bendixen and colleagues have described a progressive, symmetrical polyneuropathy due to systemic cholesterol embolism. An inflammatory and necrotizing arteritis occurs, beginning both in the small and large vessels and leads to atrophy of the autonomic nervous system. In experimental studies of peripheral nerve ischemia, lesions of nerve are produced only by combined occlusion of the aorta and many limb vessels because of the profusely ramifying neural vascularule. In our own experience comprising 12 patients with one critically ischemic leg, the neuropathy was characterized by a pronounced distal predominance—sensory loss in the feet (worse than the symptoms might suggest) and mild weakness of the toes, and the ankle reflex was lost or depressed (Weinberg et al). Although paresthesias, numbness, and deep aching pain were characteristic, the patients were no more limited by symptoms of their vascular claudication than the neuropathic ones. Restoration of circulation to the limbs by surgical or other means, including gene therapy, has resulted in some improvement of the regional neuropathy. The literature on this subject is to be found in the writings of Chalk et al and Eames and Lange listed in the References.

**Angiopathic (Arteritic) Neuropathies**

A number of focal and multifocal asymmetrical neuropathies are known to be caused by arteritis of small and medium-sized vessels. Approximately one-third of all cases of mononeuropathy multiplex can be traced to a systemic vasculitis of the vasa nervorum. Included in this category are polyarteritis nodosa, the Churg-Strauss syndrome (allergic bronchial asthma and eosinophilia), rheumatoid arthritis, lupus erythematosus, systemic sclerosis, cryoglobulinemia, Wegener granulomatosis, and an idiopathic variety. This subject has been thoroughly reviewed by Chalk et al: Dyck, Benstead et al, Said, and Kennedy. Polyarteritis nodosa is the most common of the multiple mononeuropathies that complicate Lyme disease and AIDS. In Said's series of 200 cases of vasculitis affecting the peripheral nerves, 36 percent were due to polyarteritis nodosa, 21 percent to rheumatoid arthritis, and 4 percent to other connective tissue diseases; in 35 percent there were no signs of vasculitis beyond the peripheral nerves.

**Polyarteritis Nodosa with Neuropathy**

Perhaps 75 percent of cases of polyarteritis nodosa show involvement of the small nutrient arteries of peripheral nerves (autopsy figures), but a symptomatic form of neuropathy develops in only about half this number. Involvement of the peripheral nerves may be the principal clue to the diagnosis of the underlying disease when, up to that time, the main components of the clinical picture—abdominal pain, hematuria, fever, eosinophilia, hypertension,
The neuropathy associated with polyarteritis nodosa may be diffuse and more or less symmetrical in distribution as a result of the cumulation of many small nerve infarctions, i.e., simulating a polymyeloneuropathy. In these cases, careful clinical and electrophysiologic examinations disclose elements of mononeuritis that have been essentially generalized progressively. For example, an asymmetrical foot or wrist drop, or a disproportionate affection of one nerve in a limb, such as ulnar palsy with relative sparing of function of the adjacent median nerve. More often it takes the form, throughout its course, of a mononeuropathy multiplex, i.e., a random infarction of two or more individual nerves. The onset in this latter form is usually abrupt, with symptoms of pain or numbness in the distribution of an affected nerve, followed in hours or days by motor or sensory loss in the distribution of that nerve, and then by involvement, in a saltatory fashion, of other peripheral nerves. Both spinal and cranial nerves may be affected, as in two cases described by Rechthand et al. The CSF is usually normal because the roots are not involved. Muscle biopsy, taken near the motor point so as to include nerve twigs, shows perivascular inflammation, necrosis and cellular infiltration of arterial vessel walls, and vascular occlusion, changes that are needed to corroborate the clinical impression when systemic manifestations of the disease are not evident. On the basis of the smaller size of affected vessels and the absence of perineurial cytoplasmic autolymphocytes (p-ANCA), Llorente et al have differentiated a “microscopic polyarteritis”—an entity with which we have had limited experience. Rapidly progressive glomerulonephritis and lung hemorrhage are the main features, neuropathy occurring less frequently than in typical polyarteritis.

Mononeuropathy multiplex due to polyarteritis calls for treatment with corticosteroids and cyclophosphamide. We have used intravenous methylprednisolone, 1.5 mg/kg, for several days, followed by oral treatment, and cyclophosphamide, 1 g/m² once a month for several months, but other equivalent regimens have been suggested. Azathioprine is a reasonable alternative if cyclophosphamide is not tolerated. Treatment must be continued for at least several months. In intractable cases and in those with systemic involvement, treatment with methotrexate may be indicated. Spontaneous remission and therapeutic arrest are known, but many cases have a fatal outcome. The palsy and sensory loss of the mononeuropathies generally persist even when the systemic disease is brought under control.

**Churg-Strauss and Hypereosinophilic Syndrome** These systemic illnesses involve multiple individual peripheral nerves, much as in polyarteritis, but they are characterized by an excess of circulating and tissue eosinophils and a tendency to involve the lungs and skin, in contrast to the renal and bowel infarctions in polyarteritis nodosa. They segregate into two varieties with a considerable degree of pathologic and clinical overlap: the Churg-Strauss necrotizing vasculitis with asthma and vasculitic skin lesions, and a more benign asthma-eosinophilia syndrome that is less aggressive and has a greater tendency for the eosinophils to infiltrate other tissues. A medication (zafirlukast) that is used in Europe to treat asthma is said to have precipitated several cases of Churg-Strauss disease.

The Churg-Strauss type has many similarities; indeed, the original paper by Churg and Strauss in 1951 was meant in part to distinguish the two diseases on the basis of “allergic granulomas” and eosinophilic infiltrates that involved many organs. The diffuse subcutaneous nodules created by these granulomas and vasculitic skin lesions, a marked eosinophilia of peripheral blood, and the occurrence of late-life asthma are the characteristic features of the Churg-Strauss syndrome, which begins within the skin as a nodule such as Wegener granulomatosis, lupos erythematosus, rheumatoid disease, lymphoma, and endocarditis, but the eosinophilic infiltration is less pronounced than that of the Churg-Strauss syndrome. We have seen other types of cutaneous disease, the most impressive being a massive leukocytoclastic vasculitis of the skin (necrotic polymorphonuclear cells surrounding venules)—large hemorrhagic lesions involving the skin usually only with an association with Wegener-Strauss syndrome. Usually, in the patient with Churg-Strauss syndrome, there is a progression from rhinitis or asthma, which may have been present for years, to eosinophilia and organ infiltration, particularly a pneumonia. The neuropathy, which then develops in approximately three-quarters of the patients, most often appears in the context of fever and weight loss and takes the form of an acute, painful mononeuritis multiplex. The granular cytoplasmic pattern of antineutrophil cytoplasmatic autoantibody (c-ANCA) of the same type that occurs in Wegener granulomatosis is usually found (see below). The substrate for the neuropathy, a vasculitis involving the vasa nervorum, can be detected in sural nerve biopsy, the special feature possibly being a more intense eosinophilic infiltration than is usually seen in polyarteritis.

The idiopathic eosinophilic syndrome comprises a heterogeneous group of disorders, the common fea-tures of which are a persistent and extreme degree of eosinophilia and eosinophilic infiltration of many organ systems. Neuropathy occurs in half of the cases, taking the form of a painful sensorimotor process with axonal damage or of a mononeuritis multiplex (see Moore et al). The pathologic appearance is one of infiltration of the nerves by eosinophils rather than a vasculitis. The clinical effects are attributable to the infiltration itself or to a postulated tissue-damaging efect of the eosinophil cell.

Both the Churg-Strauss and the idiopathic hypereosinophilic syndrome are best treated with high doses of corticosteroids, after which the peripheral eosinophilia as well as tissue damage should abate. Further immunosuppressive agents in the form of azathioprine, chlorambucil, or cyclophosphamide have been used intermittently in fulminant or refractory cases, which includes most of the cases that we have seen.

**Wegener Granulomatosis (Necrotizing Granulomatous Vasculitis)** This disorder has given rise to two neuropathic syndromes—one a symmetrical or asymmetrical polyneuropathy indistinguishable from the other angiopathic neuropathies described above, the other involving the lower cranial nerves directly as they exit the skull and pass through the retropharyngeal nerves. The finding of c-ANCA is relatively specific for Wegener granulomatosis and Churg-Strauss disease, as mentioned above (Specks et al) and helps to differentiate these diseases from carcinoma, chordoma, sarcoidosis, and zoster. This vasculitis and its effect on the lower cranial nerves is discussed further on page 1462.

**Essential Mixed Cryoglobulinemia** This process has been associated with a vasculitic mononeuritis multiplex as well as a more generalized polyneuropathy. In many cases, glomerulonephritis, arthritis, and purpura are conjoined, reflecting the systemic nature of the vasculopathy, but the mononeuritis may occur in isolation. The evolution in the cases has been slower than in the typical vasculitic neuropathies, sometimes weeks or longer elapsing between attacks of mononeuritis. The neuropathic disorder has become quiescent for long periods, during which time considerable improvement may occur. There is no evidence relating the mode of onset or severity of the neuropathy to the presence of cryoprecipitable proteins in the serum or to the concentration of cryoprecipitable proteins in the serum; the latter can be detected by cooling the serum and demonstrating a precipitation of IgG and IgM proteins that redissolve upon warming to 37°C. This requires that the blood sample be carefully transported to the laboratory in a warm water bath. García-Bragado and colleagues have suggested that the neuropathy is stabilized by corticosteroids and cyclophosphamide experience, plasma exchange, or plasmapheresis. We also have occasional cases of polyarteritis nodosa in which a measurement of serum cryoglobulins has not been systematically tested. The relationship of some cases to hepatitis C infection is mentioned below, and other aspects of the condition are discussed under “Neuropathies Associated with Paraproteinemia,” further on.

**Rheumatoid Arthritis** Some 1 to 5 percent of patients with rheumatoid arthritis have involvement of one or more nerves at some time in the course of their disease. Apart from pressure neuropathies due to thickened tendons and destructive joint changes, there is a form of rheumatoid arthritis that results in acute ischemic necrosis and demyelination of single or multiple nerves. The arthritis is of small-vessel fibrinoid type and immune globulins are demonstrable in the walls of the vessel. Many of the affected patients have had serositis for many years and are strongly seropositive. In addition to the neuropathy, such patients often have rheumatoid nodules, skin vasculitis, weight loss, fever, a high titer of rheumatoid factor, and low serum complement.

There are also rare forms of chronic progressive polyneuropathy that complicate rheumatoid arthritis; they are described further on, under the chronic polyneuropathy associated with the connective tissue diseases.

**Lupus Erythematosus** Approximately 10 percent of patients with lupus will exhibit symptoms and signs of peripheral nerve involvement. Usually the neuropathy appears in the established and more advanced stages of the disease, but rarely it has been the initial presentation. In several of our cases the polyneuropathy has taken the form of a symmetrically progressing, mononeuritis multiplex or polyneuritis, beginning in the feet and legs and extending to the arms, evolving over a period of several days or weeks and at times simulating GBS. In a few, weakness and areflexia were more prominent than the sensory loss; the latter involved mainly vibratory and position senses. A more common syndrome in our experience has been a progressive or relapsing disease that could not be distinguished clinically from chronic inflammatory demyelinating polyneuropathy discussed further on. Multiple mononeuritis multiplex have also been described, as has involvement of the autonomic nervous system. An elevation of CSF protein in some cases suggests root involvement. Sural nerve biopsies regularly show vascular changes consisting of endothelial thickening and mononuclear inflammatory infiltration in and around the small vessels. In the nerves, axonal degeneration is the most common change, but a chronic demyelinating pathology has also been described (Reichhand et al). Vascular injury from deposition of immune complexes is the likely mechanism.

**Isolated (Nonsystemic) Vasculitic Neuropathy** In contrast to the aforementioned disorders, which characteristically involve several tissues and organs in addition to the peripheral nerves, a necrotizing vasculitis may affect the peripheral nerves exclusively. In our hospitals a case of this type appears about yearly, i.e., as often as the systemic vasculitides appear as a cause of neuropathy. This disease takes the form of a multiple mononeuropathy and, less often, of a subacute symmetrical or asymmetric paresis. ANCA is found in a minority of cases. The clinical features of the vasculitic neuropathy and generally does not require treatment with cyclophosphamide (Dyck et al, 1987). Steroids in high doses often prevent progression of the disease. The main difficulty in diagnosis arises when the EMG performed early in the course of illness shows conduction block that simulates a demyelinating polyneuropathy.
Other Vasculitic Neuropathies

In the past, the administration of pooled serum for the treatment of infections often led to brachial neuritis (page 1430) and less often to an immune mononeuritis multiplex, presumably from deposition of antibody-antigen complexes in the walls of the vasa nervorum. A similar "serum sickness" may occur after viral infections that have caused arthritis, rash, and fever. The neuropathy that emerges with hepatic C infection may also be of this type, perhaps mediated by a frequently associated cryptoglobulinemia. Interferon, which has been effective in treating the hepatitis, may also ameliorate the neuropathy, but greater success has been reported with cyclophosphamide. Pooled immunoglobulin for the treatment of diverse neuromuscular diseases has not, to our knowledge, led to a serum-sickness neuropathy, but one of our patients with Chung-Strauss disease developed a fulminating vasculitic skin eruption when treated in this way.

The increasing appearance of vasculitic neuropathy with HIV infection, including the type that is independent of CMV infection, has already been mentioned; these cases tend to improve spontaneously or with corticosteroids. It has been stated that the CMV virus should be suspected if the number of CD4 cells in the blood is below 200/mm³ in a patient with AIDS; in about half of these cases the CSF shows a polymorphonuclear predominance. Also, from time to time a patient with a lymphoproliferative disorder such as Hodgkin disease will develop mononeuritis multiplex that is found by biopsy to be due to vasculitis.

The role of vasculitis in obscure axonal polyneuropathies in elderly patients is controversial. We have not found, as suggested by Chia and colleagues, an unexpected vasculitis in the nerve biopsies of such patients. The majority of our cases with severe neuropathy that is not explained by a known systemic disease (diabetes, cancer, or a paraproteinemia, etc.) or an overt toxic exposure remain unexplained after nerve biopsy.

Sarcoidosis Sarcoidosis is a rare cause of subacute or chronic polyneuropathy or polyradiculopathy of asymmetrical type (Zuniga et al). It may be associated with lesions in muscles (polymyositis) or with signs of central nervous system (CNS) involvement (stalk of the piliary with diabetes insipidus, cerebellum with ataxia, and a myelopathy).

Involvement of a single nerve with sarcoid most often takes the form of a facial palsy; in other cases, multiple cranial nerves are affected successively (see page 1454). Weakness and reflex and sensory loss in the distribution of one or more spinal nerves or roots may be added. The occurrence of large, irregular zones of sensory loss over the trunk is said to distinguish the neuropathy of sarcoidosis from other forms of mononeuropathy multiplex. This type of sensory loss, particularly when accompanied by pain, should also suggest a diagnosis of diabetic radiculopathy (see above).

Lyme Disease Neuropathy develops in 10 to 15 percent of patients with this disease, and it takes several forms. Cranial nerve involvement is well known: uni- or bilateral facial palsy is by far the most frequent (page 1453), but other cranial nerves can be affected as well. Almost any of the somatic roots may be affected, most often the cervical or lumbar ones. An aseptic meningitis, essentially a meningoradiculitis, and an associated pleocytosis are particularly characteristic (although the same occurs in HIV and CMV neuritis). Some of the CSF cells may have immature features that suggest a lymphomatous meningitis. The radicular pain may simulate that of cervical or lumbar disc disease. The triad of cranial nerve palsy, radiculitis, and aseptic meningitis is highly characteristic of Lyme disease and develops early in its disseminated phase, i.e., from 1 to 3 weeks following the tick bite or the appearance of the typical rash.

As to polyneuropathies, the clinical situation is more complex, since several patterns have been recognized: (1) a syndrome of multiple mononeuropathies (involvement of a single major nerve in the limbs, resulting in an isolated foot or wrist drop, is distinctly rare); (2) a lumbar or brachial plexopathy (also rare); (3) a predominantly sensory polyneuropathy in which paresthesias and loss of superficial sensation in the feet and legs are coupled with loss of ankle jerks; and (4) an axonal polyneuropathy (Haipilerin and Logiqian). The last form is mainly sensory as well and is sometimes accompanied by a mild encephalopathy.

Electrophysiologic testing indicates that the various peripheral nerve syndromes frequently overlap. All of them occur as late complications of Lyme disease, several months or even years after the initial infection (if untreated). The late neuropathic syndromes respond less favorably to treatment than the acute syndrome.

There are virtually no adequate pathologic studies of the peripheral nerves, since the disease is not fatal. No one has demonstrated the infective agent in the nerves, although this has been suggested as the mechanism of the lesions, and the pathophysiology of the peripheral neuropathy remains obscure. With treatment (see below) the neuropathic symptoms gradually recede.

An intensely painful lumbosacral polyneuropathy has long been known in Europe as the Bannwarth syndrome (also Garin-Bujadoux syndrome) and is probably due to a serum-sickness type of reaction to the virus. The radicular pain may simulate that of cervical or lumbar disc disease. The triad of cranial nerve palsies, radiculitis, and aseptic meningitis is highly characteristic of Lyme disease and develops early in its disseminated phase, i.e., from 1 to 3 weeks following the tick bite or the appearance of the typical rash.

Sjögren-Sicca Syndrome This is a chronic, slowly progressive autoimmune disease characterized by lymphocytic infiltration of the exocrine glands and resulting in keratoconjunctivitis sicca and xerostomia (dry eyes and mouth). The latter features may be combined with rheumatoid arthritis and seronegative spondyloarthropathy or with a wide range of other abnormalities, notably lymphoma, vasculitis, renal tubular defects, and most often by several types of polyneuropathy (see review by Kaplan et al.). Grant et al. collected 54 patients with sicca complex and peripheral neuropathy and found that the neuropathy had been the presenting problem in 87 percent. The sicca symptoms were usually mild and often were reported only upon specific inquiry. A symmetrical sensory polyneuropathy or ganglionopathy was the most common type. Sensorimotor polyneuropathy, polyradiculoneuropathy, autonomic neuropathy, or mononeuropathy (most often of the trigeminal nerve, as described by Kaltrieder and Tatal) are less common types. We have observed yet another neuropathic syndrome, taking the form of an asymmetrical sensory loss, mostly of position sense and involving the upper limbs predominantly, in association with tonic paresis and trigeminal anesthesia.

Nerve biopsies in some cases have revealed a necrotizing vasculitis, inflammatory cell infiltrates, and focal nerve fiber destruction. Usually, the CSF protein is normal and there is no cellular reaction.

The sensory polyneuropathy of the Sjögren syndrome—more an inflammatory ganglionitis or sensory neuropathy (see Griffin et al.)—is of particular interest to neurologists, since most cases will first be seen by them. More than 90 percent of the patients are women. The main clinical features are a widespread sensory loss that may include the trunk and a profoundly diminished kinesthetic sense, giving rise to a characteristic sensory limb and gait ataxia. Loss of pain and temperature sensation is variable. Tender reflexes are abolished. In time, many of these patients develop autonomic abnormalities such as bowel atony, urinary retention, loss of sweating, and pupillary changes. The sensorimotor polyneuropathic syndrome begins with paresthesias of the feet and is usually mild in degree.

The evaluation of all these cases, but particularly those with ganglionitis, should include a Schirmer or Rose Bengal test (page 562) to demonstrate the absence of tear production. If this test is positive, it may be followed by a biopsy of the lip to demonstrate inflammatory changes in the small salivary glands. Many patients will have serologic abnormalities such as antinuclear antibodies (anti-Ro, also termed SS-A, and anti-La, or SS-B) or increased monoclonal immunoglobulins, particularly of the IgM subclass. The frequency of Sjögren-specific antibodies varies greatly between series; they may be useful as screening tests, but the lip biopsy is a far more sensitive diagnostic procedure. The sedimentation rate is often elevated. As already mentioned, the main differential diagnostic entity is paraneoplastic sensory neuropathy-ganglionitis.

Meitgern and also Leger and his colleagues have stressed the point that a proportion of unexplained polyneuropathies in middle and late life are caused by Sjögren syndrome. The latter authors found typical Sjögren abnormalities in the lip biopsies of 7 of 32 patients with chronic axonal polyneuropathy that could not otherwise be clearly identified. Our own studies have corroborated this finding of inflammatory disruption of the minor salivary glands in obscure neuropathies in women and some men. But this has not been the experience in our clinic, where lip biopsies are routinely performed in patients with sensory neuropathies and rarely show the features of Sjögren disease.

Treatment of the sicca complex and the neuropathic manifestations is symptomatic. Corticosteroids, cyclophosphamide, and chlorambucil have been used when the
neuropathy is severe and are indicated when the vasculitis involves renal and pulmonary structures. The recent review of the neurologic manifestations of Sjögren syndrome by Lalitte is recommended.

Idiopathic and Other Sensory Ganglionopathies (Chronic Axonic Neuropathy) In addition to the paucisensory syndrome described above and those that evolve more rapidly as paraneparexic, postinfectious, or toxic processes (page 1388), there is an idiopathic condition characterized by severe global sensory loss and ataxia. We have encountered several patients with a nondescript distal sensory neuropathy and pronounced ataxia resembling the cases described by Dalakas. The numbness and sensory loss progresses over months and spread to proximal parts of the arms and legs and then to the trunk (either in an escutcheon pattern or as a sensory level). The face and top of the skull were finally involved. Despite severe ataxia and areflexia, muscular power remained normal. Pain was not a problem. When questioned, patients became completely disoriented by the ataxia, unable to walk or even feed themselves. Autonomic failure was another feature in a few of the cases, and one became deaf. Extensive examinations for an occult cancer, paraproteinemia, Sjögren disease, Refsum disease, autoimmune diseases and all potential causes of an axitic neuropathy, proved to be negative, but it is, of course, possible that some patients had as yet undiscovered tumors.

The motor nerve conduction studies have been normal or slightly affected and the sensory potentials were eventually lost over time (but they may be normal when first tested early in the illness). A puzzling feature in two patients has been an unexpected preservation of many sensory nerve potentials even after a year of illness. In these cases the process is apparently situated in the dorsal roots or the centrally directed sensory axons rather than in the dorsal ganglia. In a few instances there has been a signal change in the posterior columns of the spinal cord. The spinal fluid has generally shown a moderately elevated protein concentration.

Pathologic examination of the sensory ganglia has exposed an inflammatory process identical to that of Sjögren disease in a few cases. Our attempts at treatment using plasma exchanges, IVIG, corticosteroids, and immunosuppressive agents have been unsuccessful.

Migrant Sensory Neuritis (of Wartenberg) The defining feature of this syndrome is a searing and pulling sensation that involves a small cutaneous area of a limb and is evoked by extending or stretching the limb, as occurs when reaching for an object with the extended arm and open hand, kneeling, or pointing the foot. The pain is momentary but leaves in its wake a patch of numbness. Cutaneous sensory nerves must be involved during such a maneuver. Often these are proximal to the most terminal sensory distribution of the nerve, encompassing, for example, a patch on the lateral edge of the hand and the proximal fifth finger or a larger region over the patella (the sites of affection in three of our patients). Recovery of the numbness takes several weeks but may persist if the symptoms are induced repeatedly. Except for patches of cutaneous anaesthesia, the examination is normal. Selected sensory nerves may show abnormalities in conduction. Matthews and Esiri have listed the many areas that may be affected in a single patient and have described an increase in the endoneurial connective tissue in a biopsied sural nerve. The illness comes in attacks over many years, without symptoms between attacks, sometimes suggesting a diagnosis of multiple sclerosis.

Sensory Perineuritis Under this title, Asbury and colleagues, in 1972, described a patchy, painful, partially remitting affection of distal cutaneous sensory nerves. The pathologic picture was one of inflammatory scarring restricted to the perineurium, with compression of the contained nerve fibers. In 1979, with the Wartenberg syndrome (above), the reflexes and motor function are unaffected and distal nerves as well as the medial and lateral branches of the superficial peroneal nerve are the ones most often involved. Matthews and Squier have described a trigeminal and occipital distribution, and one of the patients of Asbury et al also had scalp lesions. A Tinel sign can be elicited by tapping the skin overlying the involved cutaneous nerves and is indicative of partial nerve damage. The differential diagnosis is from all forms of painful sensory neuropathy. The diagnosis can only be established by biopsy of a very distal cutaneous branch of a sensory nerve. A special group of patients with "burning feet" may have a small-fiber neuropathy that affects intradermal nerve fibers (see further on).

Since the original report by Asbury, the pathologic changes that characterize perineuritis have been described in a number of polyneuropathies, including diabetes and cryoglobulinemia, and in patients with nutritional diseases and malignancy (Sorenson et al). Moreover, the patients displayed a diversity of clinical patterns of neuropathy, mainly mononeuritis multiplex and demyelinating neuropathy. These findings indicate that perineuritis is possibly a nonspecific change. However, a proportion of the idiopathic cases seem to respond to corticosteroids.

Celiac-Sprue Disease Among the multitude of odd neurologic manifestations of this disease (see pages 1228 and 1198) the best known are a cerebellar ataxia and myoclonus. In addition, Hadjivasiliou and colleagues have reported nine patients with a range of neuromuscular disorders in all of whom the neurologic symptoms antedated the diagnosis of the bowel disorder. A nondescriptor sensorimotor neuropathy was the most frequent complication, but one patient was said to have a mononeuritis multiplex. Antigluten antibodies and histologic examination of a duodenal biopsy confirmed the diagnosis, and the authors suggested that a search be made for these antibodies in patients with polyneuropathies of obscure origin. It is not clear how many of their cases could be attributed to nutritional deficiency. Numerous other systemic diseases have reportedly been conjoined with peripheral neuropathy, among them, temporal arteritis. In most of these anecdotal reports it is impossible to interpret the pathogenesis of the nerve disorder.

Syndrome of Polyradiculopathy with or without Meningeal Disease Patients with disease of multiple spinal nerve roots present with a distinctive constellation of findings, quite different from those of polyneuropathy or multiple mononeuropathies. Muscle weakness due to polyradiculopathy is characteristically asymmetrical and variably distributed in proximal and distal parts of the limbs, reflecting the fact that the involved muscles have a common root innervation (for example, the combination of hamstring and gastrocnemius, or of iliopsoas, quadriceps, and obturators). However, muscles with similar innervation are not necessarily affected to the same degree because of the disproportionate contribution of a given root to each muscle. Sensory loss tends also to be similarly patchy and to involve the proximal segments of limbs as often as the distal ones; as a rule, the sensory findings are less prominent than the weakness. In keeping with the spotty affection of nerve roots, certain tendon reflexes may be spared; a normal ankle jerk accompanies a plantar flexion response (or a lumbar radiculopathy). Pain with diseases of the nerve roots is common but not invariable and takes the form of sharp jabs projected into the region innervated by the involved root. As with mononeuritis multiplex, the cumulative effect of multiple root lesions can simulate a polyneuropathy; the tendency for polyradiculopathy to involve proximal muscles is the most helpful distinguishing feature.

An elevated CSF protein and a pleocytosis usually accompany neoplastic or inflammatory meningeal diseases that implicate the nerve roots. Often what appears to be a polyneuropathy on clinical grounds turns out to have an electrophysiologic pattern of root disease at many spinal levels. McGonagle and colleagues estimate that polyradiculopathies account for 5 percent of all cases referred to their laboratory. Careful EMG testing is the most useful ancillary examination and the pattern of muscle denervation can be ascertained by this test. Foremost among the EMG findings is the preservation of sensory nerve potentials in nerves that supply weak and denervated muscles. This demonstrates that the lesion is located proximal to the dorsal root ganglion and spares the peripheral sensory axons. The proximal location of the lesion can be corroborated by finding evidence of denervation in the paraspinal, gluteal, or hamstring muscles, which are innervated by nerves that arise proximal to their respective plexuses.

Some of the diseases that affect nerve roots solely or predominantly have already been discussed. They can be grouped into three broad categories: diseases of the spinal column that compress roots, infiltrative diseases of the meninges that secondarily involve the roots as they course through the subarachnoid space, and primary neuropathies, usually inflammatory, infectious, or diabetic, that have a predilection for the radicular portion of the nerves.

Among the acute and subacute meningeal radiculopathies, neoplastic infiltration (carcinomatous and lymphomatous) is the most common. Others are Lyme disease, sarcoidosis, herpes genitallis, arachnoiditis and the AIDS-related cauda equina neuritis caused by CMV or independently by EBV. In the past, meningeal syphilis was a common but not invariable process of scarring and compression of the contained nerve fibers. With the Wartenberg syndrome (above), the reflexes and motor function are unaffected and distal nerves as well as the medial and lateral branches of the superficial peroneal nerve are the ones most often involved. Matthews and Squier have described a trigeminal and occipital distribution, and one of the patients of Asbury et al also had scalp lesions. A Tinel sign can be elicited by tapping the skin overlying the involved cutaneous nerves and is indicative of partial nerve damage. The differential diagnosis is from all forms of painful sensory neuropathy. The diagnosis can only be established by biopsy of a very distal cutaneous branch of a sensory nerve. A special group of patients with "burning feet" may have a small-fiber neuropathy that affects intradermal nerve fibers (see further on).

Numerous other systemic diseases have reportedly been conjoined with peripheral neuropathy, among them, temporal arteritis. In most of these anecdotal reports it is impossible to interpret the pathogenesis of the nerve disorder.

SYNDROME OF CHRONIC SENSORY-MOTOR POLYNEUROPATHY

In these syndromes, impairment of sensation, weakness, and muscular atrophy progress over a period of many months or years. Within this overall category, two
groups are readily distinguished. In the first and less chronic of the two groups ("early chronic"), the neuropathy develops over a period of many months or a year or two. Comprising this group are the acquired paraneoplastic (which may also appear subacutely), chronic demyelinating, certain metabolic, and the immune-mediated polyneuropathies. Leptomeningeal is the one infectious member of this group and also the one exception to the rule that all chronic neuropathies are more or less symmetrical in distribution. The polyneuropathies that make up the second group are far more chronic than the first, evolving over many years ("late chronic"). Constituting this second group are mainly the heredodegenerative diseases of the peripheral nervous system.

**Acquired ("Early") Forms of Chronic Polyneuropathy**

**Neuropathies Associated with Paraproteinemias** The occurrence of a chronic sensorimotor polyneuropathy in association with an abnormality of immunoglobulin is being recognized with increasing frequency. The excess protein, also called paraprotein, which gives rise to polyneuropathy, may be an isolated abnormality or a by-product of a plasma cell malignancy, notably multiple myeloma, plasmacytoma, or Waldenström macroglobulinemia or one of the special forms of neuropathy associated with acquired amyloidosis. The latter group is discussed further on with the genetic forms of amyloidosis. Several lines of evidence suggest that a pathogenetically active antibody against components of myelin or axon is present in at least some of these cases.

**Monoclonal Gammapathy of Undetermined Significance (MGUS, Benign Monoclonal Gammapathy)** In recent years, a category of polyneuropathy with isolated monoclonal gammopathies has been recognized to be of multiple myeloma and solitary plasmacytoma (see reviews of Kyle and Dyck and of Thomas and Willison). This non-neoplastic group is far more common than the malignant one and in our own experience, the monoclonal proteins underlie the largest group of otherwise unexplained neuropathies in older adults. Forssman and colleagues first described a patient with a benign IgM paraproteinemia and a neuropathy, an association that was treated as coincidental until Kahn established a compelling statistical association between them.

These polyneuropathies occur in patients with a monoclonal protein in the blood of less than 3 g/100 mL (usually less than 1.8 g/100 mL), in whom there is no evidence of multiple myeloma or other malignant disease. It should be emphasized that routine serum protein electrophoresis fails to detect the majority of these paraproteins; immunoelectrophoresis (SPEP) or the more sophisticated immunofixation (IEP) testing is required. The bone marrow shows a normal or only mildly increased proportion of plasma cells, which are the osseous source of the paraprotein, and the plasma cells are not "atypical," as they are in myeloma. Insofar as myeloma becomes manifest in fewer than one-third of patients many years after the gammopathy has been recognized, the condition is now termed monoclonal gammapathy of undetermined significance (MGUS), although the older term, "benign monoclonal gammapathy," is less cumbersome.

Some 6 percent of patients referred to the Mayo Clinic with peripheral neuropathy of unknown cause and as many as 20 percent in our experience and in other series have proved to have a monoclonal paraproteinemia of this type. Despite the fact that IgG is the most frequent paraprotein, the polyneuropathy is associated more often with the IgM class. Combining three large series of patients with neuropathy and monoclonal paraproteinemias (62 patients of Yeung et al, 65 patients of Gorson et al, 22 patients of Simovic et al), there were 11 cases of IgG subclass or IgM, 5 of light chain and 12 of IgA type paraproteins. Most have had a kappa light chain component. In our experience and that of others, the IgM group has tended to have more sensory findings and a demyelinating type of EMG abnormality compared with the IgG group. However, with the exception of the anti-MAG syndrome (see below), we have not found the degree of clinical difference and features to treatment that has been reported by others (Simovic et al).

An identical but infrequent condition is found in which the only light chain component of an immunoglobulin is produced by the plasma cells and the paraprotein is found exclusively in the urine (similar to the Bence-Jones protein of myeloma). A proportion of all these patients will develop myeloma or Waldenström disease within 10 years, but in the large majority of our patients there has been no transformation to a malignancy.

The neuropathy of monoclonal gammapathy affects mainly males in the sixth and seventh decades of life. The onset is insidious, with numbness and paresthesias of the feet and then of the hands, followed by a symmetrical weakness and wasting of these parts. In some patients sensory signs predominate and the tendon reflexes are preserved or only diminished in the early part of the illness. The neuropathy is usually slowly progressive, rarely remitting and relapsing. The Raynaud phenomenon is observed in some, even in the absence of a cryoprotein. The CSF typically shows an elevation of the protein concentration in the range of 50 to 100 mg/dL, not due to passive diffusion of the paraprotein into the CSF.

The majority of reported cases of monoclonal gammapathy have a demyelinating or mixed axonal-demyelinating pattern by EMG, but we found 16 patients with predominantly axonal features in a series of 36 consecutive cases during a 5-year period. With the exception of less severe sensory loss and reduced but preserved tendon reflexes in some of the axonal cases, the axonal and demyelinating groups could not be distinguished on clinical grounds or by their response to therapy (Gorson et al). Sural nerve biopsies have shown an extensive loss of myelinated fibers of all sizes; unmyelinated fibers are mostly spared; hypertrophic changes are present in about half the cases (Smith et al). The latter authors found the monoclonal IgM antibody bound to the surviving myelin sheaths, and Latov and coworkers have shown that the serum IgM fraction displays antemyelin activity.

Although more than a dozen specific antibodies against myelin have been identified in these neuropathies, the most important ones, present in 50 to 75 percent of patients with IgM-associated neuropathies, are those that react with a myelin-associated glycoprotein (MAG) or with related glycolipid or sulfatide components of myelin, referred to as SGPg and SPLPG. An association has been reported between the latter antibodies and infection with CMV. Deep sensory loss with gait imbalance and ataxia are common in patients with IgM group with anti-MAG activity, but weakness tends to appear late in the illness. Other, mainly IgM antineuronal antibodies have a more tentative connection to polyneuropathy. Polyclonal IgM antibodies against the GM1, antigen of myelin are linked with multifocal motor conduction block, described under "Chronic Inflammatory Demyelinating Polyradiculoneuropathy (CIDP)," below. It is reasonable to assume that IgM monoclonal gammapathies are also capable of causing chronic neuropathies, but the evidence is less compelling; it has been suggested that in many reported instances this association is coincidental. Certainly IgG gammapathies are frequent in older individuals; when treated similarly to the IgM group, they seem to respond as well or better.

In most cases of uncomplicated monoclonal gammapathy, plasma exchange provides transient improvement for several weeks to months, somewhat more so in patients with IgG and IgA types of neuropathy than in those with the IgM type (Dyck et al, 1991). The treatment regimen is the same as for GBS, a total volume of approximately 250 mL/kg being exchanged in each of four to six treatments.

In patients found to have serum activity against specific components of myelin (MAG), plasma exchange alone has effected transient improvement in 40 percent but sustained periods of improvement in only 10 percent of our patients. This discouraging outcome is particularly true for slowly progressive cases of severe ataxia with marked distal sensory loss. In some patients, the response to immunosuppression with intravenous cyclophosphamide or fludarabine, or oral chlorambucil, coupled with plasma exchanges has been somewhat better. Improvement with high doses of infused immunoglobulin (IVIG) has not been effective according to some reports, but half of our cases with typical paraproteinemia and 20 percent of those with anti-MAG neuropathy have improved for at least a brief time. In almost all instances the plasma exchanges and immunosuppressive treatment must be repeated at intervals of one to several months as determined by the clinical course. This group of neuropathies does not appear to respond to corticosteroids.

**Osteosclerotic Myeloma (POEMS Syndrome) and Multiple Myeloma** The neuropathy of multiple myeloma has already been mentioned, under "Paraneoplastic Neuropathy." Polyclonal neuropathies complicates 13 to 14 percent of cases of multiple myeloma and has a disproportionately high association with the osteosclerotic form. An abnormal and excessive gamma globulin (with mainly the kappa light chain component in multiple myeloma and lambda in the osteosclerotic type) is found in the serum of 80 percent of patients with myelomatous neuropathy.

In many patients with osteosclerotic myeloma, the sensorimotor polyneuropathy—which tends to be of moderate severity—is associated with organomegaly, endocrinopathy, elevated M protein, and skin changes (mainly hypertrichosis and skin thickening) making up the acronym POEMS (also referred to as the Castellani syndrome in Japan, where the disease is more prevalent). Unlike in these patients is not due to increased IgM, which is different from that of patients in whom the systemic features are lacking. Also, in many cases, there is the lymphomatis of Castellane disease, as discussed earlier. A characteristic feature of the osteosclerotic related polyneuropathy is a greatly elevated CSF protein. The diagnosis can be suspected from the presence of a paraprotein in the blood, often polyclonal or biclonal rather than monoclonal, and possessing a lambda light chain component. The diagnosis requires the demonstration of the osteosclerotic myeloma by a radiographic survey of the long bones, pelvis, spine, and skull (a bone scan may miss the sclerotic lesions) and a bone marrow examination, which shows a moderate elevation in the proportion of well-differentiated plasma cells. In most of our cases there have been several bone lesions concentrated in the ribs and spine; the skull and long bones may harbor such lesions as well, or the lesions may be single. The neuropathy that complicates a solitary plasmacytoma may improve markedly following irradiation of the bone lesion; multiple lesions are treated with chemotherapy (melphalan and prednisone) and some improvement or stabilization in the neuropathy can be expected. Treatment with plasma exchange yields uncertain results.
Waldenstrom Macroglobulinemia

Macroglobulinemia was the term applied by Waldenstrom to a systemic condition occurring mainly in elderly persons and characterized by fatigue, weakness, and a bleeding diathesis. Immunoelectrophoretic examination of the blood discloses a marked increase in the IgM plasma fraction. A significant proportion of patients with hyperproteinemia have a hyperviscosity state manifest by a diffuse slowing of retinal and cerebral circulation (Bing-Neel syndrome)—giving rise to episodic confusion, coma, and sometimes strokes—in addition to peripheral neuropathy. The latter may evolve subacutely but is more often chronic in nature, and either asymmetrical in a multiple nerve trunk pattern (particularly at the onset of the neuropathy) or in a symmetrical and distal sensorimotor pattern. Our few cases have been of the latter type, very slowly progressive, and limited to the feet and legs, with mild sensory ataxia and loss of knee and ankle jerks. The CSF protein is usually elevated and the globulin fraction increased. In a case recorded by Rowland et al., the polyneuropathy was purely motor and simulated motor neuron disease; other cases of this type, albeit rare, have been brought to our attention.

Cryoglobulinemia

As mentioned previously in the section on vasculitic neuropathies, cryoglobulinemia is characterized by a serum protein that precipitates on cooling. The cryoglobulins are usually IgG or IgM. Cryoglobulinemia may occur without any apparent associated condition (essential cryoglobulinemia) but as frequently it accompanies a wide variety of disorders such as myeloma, lymphoma, connective tissue disease, chronic infection, and, particularly, hepatitis C. Peripheral neuropathy occurs in a small proportion of both types of cases. Occasionally the neuropathy evolves over a period of a few days and remits rapidly. More often it takes the form of a distal symmetrical sensorimotor loss, which develops insidiously in association with the Raynaud phenomenon and purpural eruptions of the skin. Initially, the neuropathic symptoms consist only of pain and paresthesias that may be precipitated by exposure to cold. Later, weakness and wasting develop, more in the legs than in the arms and more or less in the distribution of the vascular changes. Less often, there is a mononeuropathy multiplex, with severe denervation in the territory of the involved nerve(s). Garcia-Bragado et al. In a few of our cases, the two neuropathic syndromes have been combined.

Any of the paraproteinemias may be associated with amyloid polyneuropathy. This subject is accorded a separate section, below.

The pathology of the neuropathies associated with macroglobulinemia and cryoglobulinemia has been incompletely studied, and the mechanisms by which these disorders cause neuropathy are quite uncertain. One presumes that some component of the paraprotein acts as an antineural antibody or that deposition of the protein is toxic. In our most thoroughly autopsied case, there was widespread distal axonal degeneration of nondescript type without amyloid deposition or inflammatory cells; yet in other reported cases, amyloid has been found. Immune deposits of IgM had impregnated the inner layers of the perineurium in the case reported by Ognerboer de Visser and colleagues. Dalakas and Engel have made similar observations. Possibly the neuropathy of cryoglobulinemia is due to the intravascular deposition of cryoglobulins, causing a vasculitic ischemia, as alluded to earlier (Chad et al.).

In the macroglobulineic neuropathies, the use of prednisone, the alkylating agent chlorambucil, cyclophosphamide, or plasma exchange has at times led to improvement in the systemic and neuropathic symptoms, although recovery has been incomplete.

Primary (Nonfamilial, AL) Amyloid Neuropathy

There are sporadic instances, far more common than familial ones, in which a peripheral neuropathy is associated with amyloid deposition in the heart, kidneys, and gastrointestinal tract (called primary systemic amyloidosis to distinguish it from the inherited varieties). In most cases, the neuropathy is secondary to malignant sources of oncotic protein, with the prototype being myeloma. In a large series of Kyle and Bayrd, 26 percent of patients with primary amyloidosis had a single pea cell dyscrasia. In 90 percent of cases of primary amyloidosis, there is a monoclonal protein (rarely polyclonal) in the blood; macrophage enzymes cleave the larger immunoglobulin molecules to form light chains that make up the actual amyloid deposits in tissue, or the plasma cells produce light chains directly ("light-chain disease"). Lambda light chain predominates in the idiopathic variety and kappa light chain in myeloma. In a few cases the light chain is found only in the urine (Bence Jones protein). In primary amyloidosis there is no evidence of preceding or coexisting disease (except the association with paraproteinemias or multiple myeloma), in distinction to secondary amyloidosis, which is associated with chronic infection or other chronic disease outside the nervous system. As a rule, secondary amyloidosis is not associated with neuropathy. Familial amyloidosis, a third variety, is at times associated with neuropathy (see page 1423).

Primary amyloidosis is a main disease of older men, the median age at the time of diagnosis being 65 years. In our clinical material, the majority of the patients with AL have had peripheral neuropathy, but in other series fewer than one-third were affected in this way (Kyle and Dyck). The neuropathic symptoms and signs are similar to amyloid polyneuropathy, with sensory involvement preceding the motor, and the progression is considerably more rapid. The initial symptoms are sensory—numbness, paresthesias, and, often acral pain—and the signs are characteristic of involvement of small-diameter sensory fibers (loss of pain and thermal sensation). Weakness follows, initially limited to the feet but becoming more extensive as the disease progresses and affecting also the hands and arms. Loss of large fiber—mediated sensation may appear. Twenty-five percent of patients have a carpal tunnel syndrome from infiltration of the flexor retinaculum.

Autonomic involvement can be severe and becomes evident early in the course of the illness; several of our patients presented with disturbances of gastrointestinal motility, especially episodic diarrhea, or with orthostatic symptoms and also with impotence and bladder disturbances. The pupils may react slowly, and there may be a reduction in sweating. An infiltrative amyloid myopathy occurs as a rare complication of the disease; it presents as an enlargement and induration of many muscles, particularly those of the tongue (macroGLOSSIA), pharynx, and larynx. Progression of the illness is relatively rapid, the mean survival being 12 to 24 months. A more indolent neuropathy that evolves over years is not likely to be due to amyloid, though we have seen a few such cases. Death is usually due to the renal, cardiac, or gastrointestinal effects of amyloid deposits, the manifestations of which are already evident in at least half of the patients who present with neuropathy. A neuropathic syndrome is particularly characteristic.

Analysis of the serum and urine, searching for an abnormal paraprotein (found in most of our patients), followed by a microscopic examination of abdominal fat pad, gingival, or rectal biopsy for amyloid, are the most useful screening tests. If a sensory neuropathy or evidence of organ infiltration is evident, biopsy of the sural nerve or an abdominal fat pad should be performed. If high diagnostic criteria are satisfied and the kidney in a nephrotic syndrome, biopsies are mandatory. In several of our patients with a clinical syndrome typical of amyloid neuropathy, amyloid was not found in the sural nerve; only after sequential biopsy of numerous sites (fat pad, kidney, liver) was the diagnosis established. If the sural nerve is severely depopulated of nerve fibers, the amount of congophilic staining and the characteristic birefringence may be meager and yield a spuriously negative result. It is also critical to assure the accuracy of congophilic staining by comparison with positive and negative control tissue from the same laboratory. The CSF has a normal or moderately elevated protein concentration.

The prognosis is dismal and attempts at immunomodulation, immunosuppression (which may help the renal disease), or removal of amyloid by plasma exchange have been made without effect. The most recent approach has been stem cell replacement (harvested from the patient) after bone marrow suppression with high doses of melphalan. Several such patients have survived for several years with marked improvement in the neuropathy. The pain may be treated with transcutaneous fentanyl patches or with oral narcotic medications, and orthostasis responds to the use of leg stockings and mineralocorticoids.

The differential diagnosis of acquired amyloid neuropathy includes the more slowly evolving familial types (see further on), the myelomatous varieties, toxic and nutritional small-fiber neuropathies, and an idiopathic small-fiber sensory neuropathy, which we have encountered more frequently than amyloidosis.

Chronic Inflammatory Demyelinating Polyradiculoneuropathy (CIDP)

This form of polyneuropathy was separated from acute inflammatory polyradiculopathy, or GBS, by Austini in 1958 on the basis of a chronic relapsing course, enlargement of nerves, and responsiveness to steroids. Undoubtedly there are clinical similarities between these disorders. Both are widespread polyradiculoneuropathies, usually with cytoalbuminologic dissociation of the CSF; both exhibit nerve conduction abnormalities with the characteristics of a demyelinating neuropathy (reduced conduction velocity and partial or complete block in motor nerves). Pathologically, both show evidence of a perivascular inflammatory change. But there are also important differences, the most evident of which are their modes of evolution and prognosis. As a rule, CIDP begins insidiously and evolves slowly, either in a steady progressive or stepwise manner, attaining its maximum severity after several months or even years or longer. From the beginning it may be asymmetrical. In only a small proportion of patients (16 percent in the series of McCombe et al, and the same proportion in our own series) does the disease evolve at a tempo that mimics GBS. Thereafter it runs a persistent relapsing or fluctuating course, or it may simply worsen slowly and progressively.

In contrast to acute GBS, many cases of CIDP respond favorably to the administration of prednisone. Antecedent infections can be identified far less regularly in patients with CIDP than in those with GBS (see further on), and in this respect, CIDP may be somewhat analogous to the Guillain-Barré syndrome. CIDP may be more frequently associated with diarrhea or other chronic disease outside the nervous system. As a rule, secondary amyloidosis is not associated with neuropathy. Familial amyloidosis, a third variety, is at times associated with neuropathy (see page 1423).

The EMG findings of demyelination in CIDP essentially define the illness—multifocal conduction block as described in Chap. 45, prolonged distal latencies (distal block), nerve conduction slowing to less than 80 percent of normal in several nerves, loss of late responses, and dispersion of the compound muscle action potentials;
one or more of these changes have been present in more than three-quarters of our patients (Gorson et al.). In the early stages of the disease these changes must be carefully sought by testing multiple nerves at several sites along the course of each nerve. After several months, these findings are often associated with some degree of axonal change (30 percent of our cases), but the fundamental process continues to be one of multiple foci of demyelination. Even more salient findings in such patients are the absence of denervation changes despite weakness and reduced amplitude of the motor action potential, and weakness of a muscle that can be made to contract by stimulating the nerve distally, indicative of a demyelinating conduction block at a proximal site.

Several large series of CIDP have been reported. Dyck and colleagues (1975) studied 53 patients in whom the neuropathy progressed for more than 6 months. The clinical course was monophasic and slowly progressive in about one-third of their patients, stepwise and progressive in another third, and relapsing in the remaining third. The disease, either remittent or irreversible, or both, usually occurs in the first 3 months preceding the onset of CIDP were no more frequent than in the population at large. Weakness of the limbs, particularly of the proximal leg muscles, or numbness, paresthesias, and dysesthesias of the hands and feet were the initial symptoms. In 45 of the 53 patients, the signs were those of a mixed sensorimotor polyneuropathy with weakness of the shoulder, upper arm, and thigh muscles in addition to motor and sensory loss of the legs. In 5 patients the monophasic course, and 1 patient relapsed, with sensory symptoms prior to motor. Cranial nerve abnormalities were distinctly unusual. Enlarged, firm nerves were found in 6 patients; thus CIDP has to be distinguished from other chronic and recurrent polyneuropathies, particularly the hereditary ones.

In the series of McCombe et al., comprising 92 patients, two major subgroups were recognized—relapsing (corresponding to the relapsing and stepwise progressive groups of Dyck et al.) and nonrelapsing (corresponding to Dyck’s monophasic and gradually progressive groups). In our series of more than 100 patients, we have been impressed with unusual patterns of clinical presentation in one-third of patients. Numbness and weakness of the hands before the feet are similarly atypical. Some patients had a polyneuropathy confined to the hands (Gorson et al.). A sensory ataxic form, a pure motor form, and mononeuropathies superimposed on a mild generalized polyneuropathy each accounted for approximately 7 percent of the cases. A small proportion, fewer than 10 percent, began as acute GBS but continued to progress or relapsed in the following months.

Other comprehensive accounts have been given by Barohn, Comblath, Dyck, and Hughes and their associates. All these authors place the demyelinating polyneuropathies that progress for over 8 to 12 weeks within the CIDP category. Also recognized is the frequency (up to one-quarter of the patients in some series, far less often in our experience) with which systemic conditions such as paraproteinemia, lymphoma, an undifferentiated reactive adenopathy, and lupus accompany the neuropathy. These associations create problems in nosology that can be reconciled by labeling a given case as “CIDP with paraproteinemia” or whatever the underlying disease may be, thus separating it from the idiopathic-inflammatory variety.

Several polyneuropathies that share many of the features of CIDP have been given separate names because of some unique clinical or electrophysiologic attribute. They include the axonal polyneuropathies, in which the conduction block is a prominent feature of CIDP; if its main feature is a motor conduction across the same site in a limited number of nerves. Multifocal motor neuropathy, on the other hand, shows multiple focal sites of block of motor conduction alone, without any change in sensory conduction. The distinction between these two entities has been obscured by the finding of mild but consistent demyelination in sensory nerve biopsies from patients with multifocal motor neuropathy (Gors et al.). Both of these syndromes may begin with a partial mononeuropathy, an uncharactertistic finding in most cases of CIDP. While these conditions are best considered for the moment as types of CIDP, there is a high concordance of multifocal motor neuropathy with a particular antibody, anti-GM1, against a ganglioside component of peripheral myelin (Pestronk et al.). For this reason, some view this illness as belonging to the class of paraproteinemic neuropathies (see above and Simmons et al.).

The CSF protein is elevated in 80 percent of patients with CIDP, typically in the range of 75 to 200 mg/dL. In a few instances there is papilledema and a pseudotumor syndrome, corresponding to extremely high levels of CSF protein (usually >1000 mg/dL). Elevation of the CSF gamma globulin and a mild lymphocytic pleocytosis are said to occur in some 10 percent of patients (more consistently in those who are HIV-seropositive), a considerably higher percentage than in our series.

In biopsy material (sural nerve), a few of the patients are found to have interstitial and perivascular infiltrates of inflammatory cells, although one expects that most would show these changes if sufficient nerves could be sampled. As in GBS, the demyelination appears to be effected by T cells and macrophages within the endoneurium but also in the perineurium. Myelinated fibers are lost to a varying degree, and many of the remaining ones are seen to be undergoing degeneration or showing demyelinating or demyelinating-remyelinating changes. The few complete autopsy studies have shown only minimal or patchy inflammation and a considerable degree of axonal damage. The presence of endoneurial and subperineurial edema has been emphasized by Prineas and McLeod and by Pollard.

The status of a predominantly axonal polyneuropathy that simulates CIDP and responds to the same immunomodulating treatments is unclear (Uncini et al; Gorson et al; and Ropper). The present authors have the impression that it is an immune mediated neuropathy in the spectrum of CIDP.

Treatment

Several trials have shown benefit from the intravenous infusion of high doses of gamma globulin (2 g/kg in divided infusions over 4 or 5 days), and we can verify this. More than half of our patients have responded to this treatment, albeit for only several weeks to months, after which the infusions must be repeated. However, efforts to spare patients the side effects of indefinite prednisone administration make this mode of therapy a reasonable alternative. Some patients have been treated with repeated infusions for many weeks without ill effects. IVIG is also effective in the treatment of multifocal motor neuropathy, but sustained improvement with the addition of prednisone remains controversial, such as oral cyclophosphamide. Patients who require treatment at such short intervals as to be impractical have sometimes benefited from the addition of small doses of prednisone. The main drawbacks of IVIG are its expense and the several hours required for its infusion; rare instances of nphrotic syndrome, aseptic meningitis (both now infrequent), serum sickness, thrombotic arterial occlusion, and hypotension have been reported, particularly if the infusion is too rapid.

Close to half of these patients also respond well to plasma exchange. In a prospective double-blind trial, Dyck and colleagues found that plasma exchange, administered twice weekly for 3 weeks, had a beneficial effect on both the neurologic disability and nerve conduction. The response to plasma exchange in our patients has been comparable to that obtained with IVIG and with steroids, some patients responding to only one type of treatment. However, the beneficial effects in many patients begin to wane in subacute to 14 days. In some cases responses longer, as reported by Dyck and by Nath et al. For this reason we prefer to try plasma exchange or immune globulin before committing a patient to long-term treatment with prednisone. When the response is clear, three or four brief series of plasma exchange or infusions of immune globulin often suffice, again supplemented by small doses of prednisone when frequent treatments become impractical. When these measures prove unsatisfactory, we have added cyclophosphamide or cyclosporine, but we have been unable to draw any firm conclusions as to their effectiveness.

Corticosteroids were formerly the mainstay of therapy, but most patients become dependent on the medication and the general approach has shifted to utilizing these medications as a third resort, or as an adjunct to one of the above-mentioned treatments. A usual regimen begins with 80 mg of prednisone that is tapered over months to the lowest effective dose. We have not had much success with daily doses of less than 25 mg. A number of patients will not respond to corticosteroids within 1 or 2 months but will do so if treatment is continued. The drug produces a tremor or may exaggerate the one caused by the neuopathy. Should a sustained trial of prednisone therapy prove unsuccessful, a course of azathioprine (for at least 3 months), 3 mg/kg in a single daily dose, has been recommended (Dalakas and Engel), but a controlled trial has failed to show benefit from this combination and we have had little success with it.

Some patients who have failed to benefit from the aforementioned treatments have improved in response to the administration of a-interferon (Gorson et al.). We have noted the following features of this immunomodulation and continued good health of a few patients after a severe bacterial infection (Ropper).

It has been stated that patients with discrete relapses have a better prognosis than those with a progressive course. In McCombe’s series, 73 percent were said to have made a good recovery, but the long-term outcome in this disease has generally been poor in our experience, involving decades of disability and dependence on treatment. In a small number of patients, fewer than 10 percent, the disease burns out after many years and treatment can be withdrawn.

Uremic Polyneuropathy

Uremic polyneuropathy is probably the most common complication of chronic renal failure. Robson estimated that it complicates end-stage renal failure in two-thirds of patients about to begin dialysis therapy. Bolton’s figures are much the same, 70 percent of patients being dialyzed regularly having uremic polyneuropathy, and in 30 percent the neuropathy was moderate or severe degree. As the original description by Ashby, Vidor, and Adams, the neuropathy takes the form of a painless, progressive, symmetrical sensorimotor paralysis of the legs and then of the arms. In some patients, the neuropathy begins with burning dysesthesias of the feet or sensations of creeping, crawling, and itching of the legs and thighs, which tend to be worse at night and are relieved by movement (“restless legs” syndrome, page 412). Renal failure accompanied by diabetes may give rise to a particularly severe neuropathy.

The combination of muscle weakness and atrophy, areflexia, sensory loss, and the graded distribution of the neurologic deficit in the limbs leaves little doubt about...
the neuropathic nature of the disorder. Usually the neuropathy evolves slowly over many months, at times in subacute fashion. Rare instances of a more acute sensorimotor polyneuropathy have been reported as well, occurring mainly in diabetics receiving peritoneal dialysis (see page 1388; Asbury et al; Ropper). Also, a uremic polymyositis with hypophosphatemia has been described (Layzer). The neuropathy has been observed with all types of chronic kidney disease. More important to the development of neuropathy than the nature of the renal lesion is the duration and severity of the renal failure and symptomatic uremia (not merely azotemia).

With long-term hemodialysis, the symptoms and signs of polyneuropathy stabilize, but they improve in relatively few patients. In fact, rapid hemodialysis may occasionally worsen the polyneuropathy temporarily. Peritoneal dialysis appears to be more successful than hemodialysis in improving the neuropathy but this has not been studied systematically. Complete recovery, occurring over a period of 6 to 12 months, usually follows successful renal transplantation, for the reason given below.

The pathologic findings are those of a nonspecific axonal degeneration. In rapidly progressive cases, there is a tendency for the large fibers to be affected; this is evident particularly on electrophysiologic testing. The changes are most intense in the distal segments of the nerves, with the expected chromatolysis of their cell bodies.

The cause of uremic polyneuropathy is unknown. The “middle molecule” theory is the most plausible. The end stage of renal failure is associated with the accumulation of toxic substances in the range of 300 to 2000 mol wt. Furthermore, the concentration of these substances, which include methylguanidine and myoinositol, has been shown to correlate with the degree of neurotoxicity (Funck-Brentano et al). These toxins (and the clinical signs of neuropathy) are not greatly reduced by chronic hemodialysis. On the other hand, the transplanted kidney effectively eliminates substances of wide-ranging molecular weights, which would account for the invariable improvement of neuropathy after transplantation.

Alcoholic–Nutritional and Subacute Diabetic Neuropathy In all patients with alcoholic-nutritional polyneuropathy who for some reason remain untreated, the weakness and atrophy of the legs, and to a lesser extent the arms, may reach an extreme degree. Thus this disease, though subacute in its evolution, becomes a frequent cause of chronic polyneuropathy. Certain cases of diabetic neuropathy behave similarly.

Leprous Polyneuritis This is the classic example of an infectious neuritis, being due to the direct invasion of nerves by the acid-fast Mycobacterium leprae. The disease is endemic in India and Central Africa, but there are many lesser endemic foci, including parts of South America and of Florida, Texas, and Louisiana that border on the Gulf of Mexico.

The initial lesion in leprosy is an innocuous-appearing skin macule or papule, which is often hypopigmented and lacking in sensation and is caused by the invasion of cutaneous nerves by M. leprae. The disease may progress no further than this stage, which is spoken of as indeterminate leprosy, or it may evolve in several ways, depending mainly upon the resistance of the host. The bacilli may be locally invasive, producing a circumscribed epithelioid granuloma that implicates cutaneous and subcutaneous nerves and results in a characteristic patch of superficial sensory loss (tuberculoid leprosy). The subcutaneous sensory nerves may be palpably enlarged. If a large nerve in the vicinity of the granuloma is invaded (the ulnar, median, peroneal, posterior auricular, and facial nerves are most frequently affected in this way), a sensorimotor deficit in the distribution of that nerve is added to the patch of cutaneous anesthesia.

Lack of resistance permits the proliferation and hematogenous spread of bacilli and the diffuse infiltration of skin, ciliary bodies, testes, lymph nodes, and nerves (lepromatous leprosy). Widespread invasion of the cutaneous nerves produces a symmetrical pattern of pain and temperature loss, involving the pinnae of the ears as well as the dorsal surfaces of hands, forearms, and feet and anterolateral aspects of the legs—a distribution that is apparently determined by the relative coolness of these parts of the body. Eventually the anesthesia spreads to involve most of the cutaneous surface. Extensive sensory loss is followed by loss of motor function owing to invasion of muscular nerves where they lie closest to the skin (the ulnar nerve is the most vulnerable). There is a loss of sweating in areas of sensory loss, but otherwise the autonomic nervous system is unaffected. In distinction to other polyneuropathies, tendon reflexes are usually preserved in leprosy despite widespread sensory loss. Probably this depends upon sparing of the muscular and larger sensory nerves. Because of widespread anesthesia, injuries may pass unrecognized, with resultant infections, trophic changes, and loss of tissue. Variations in host immunity result in patterns of disease having both tuberculoid and lepromatous characteristics (dimorphous leprosy).

All forms of leprosy require long-term treatment with sulfones (dapsone being the most commonly used), rifampin, and clofazidine. The skin lesions of lepromatous leprosy are responsive to thalidomide, which itself may cause a sensory neuropathy (page 1286; Barnhill and McDougall).

Polyneuropathy with Hypothyroidism Although characteristic disturbances of skeletal muscle are known to complicate hypothyroidism (see Chap. 51), the demonstration of a polyneuropathy has been infrequent. However, a number of elderly myxedematous patients complain of weakness and numbness of the feet, legs, and, to a lesser extent, hands, for which no other explanation can be found. Loss of reflexes, diminution in vibratory, joint-position, and touch-pressure sensations, and weakness in the distal parts of the limbs are the usual findings. The neuropathic manifestations are seldom severe. Nerve conduction velocities are significantly diminished, and the protein content of the CSF is usually increased, to more than 10 mg/dl in some patients; possibly this is a reflection of the increased protein content of the serum. The subjective improvement and complete or near-complete reversibility of neuropathic signs following treatment with thyroid hormones provides convincing evidence of a hypothalamic etiology. In biopsies of nerve, an edematous protein infiltration of the endoneurium and perineurium, a kind of metachromatic mucoid material, has been seen. Dyck and Lambert noted segmental demyelination in teased fiber preparations. In electron-microscopic sections, a slight increase in glycogen, acid mucopolysaccharides, and aggregates of glycogen and cytoplasmic laminar bodies in Schwann cells have been observed by others.

Polyneuropathy of sensorimotor type has also been observed in association with chronic lymphocytic thyroiditis and alopecia (Hart et al).

Chronic Benign Sensory Polyneuropathy of the Elderly The authors have observed numerous cases of a benign, relatively nonprogressive sensory polyneuropathy in elderly patients. Tingling paresthesias of feet and lower legs, sensory loss, and absent ankle reflexes are the usual findings. The hands may be mildly affected but leg weakness and imbalance are absent or trivial. Laboratory studies may be normal or reveal minimally altered sensory conduction, but the evaluation has usually not been extensive, and therefore it is difficult to say if Sjögren syndrome or another underlying disease is responsible.

The most common variant of this form of chronic sensory polyneuropathy is one that affects mainly elderly women, who complain of slowly progressive (over years) burning and weakness of the feet, ascending to the ankles or midcalves. There are few findings on examination; often only a mild loss of pinprick and thermal sensation, and ankle reflexes that may or may not be reduced. There is little or no progression over the years.

Electrophysiologic tests are likewise normal or virtually so, a few showing diminished sural nerve potentials and minor changes of motor amplitudes. When these changes cannot be ascribed to diabetes, malnutrition, or medications, a substantial group of patients is left in need of symptomatic relief. Some have been helped by gabapentin or by antidepressants (amitryptiline, desipramine, or sertraline) and capsaicin cream applied nightly to the soles and toes. Surprisingly, a few of the more severe cases have apparently responded to gamma globulin infusions, but these observations require corroboration (Funck-Brentano et al). These toxins (and the clinical signs of neuropathy) are not greatly reduced by chronic hemodialysis. On the other hand, the transplanted kidney effectively eliminates substances of wide-ranging molecular weights, which would account for the invariable improvement of neuropathy after transplantation.

GENETIC ("LATE") FORMS OF CHRONIC POLYNEUROPATHY

In this category of chronic polyneuropathy, the disease evolves gradually over a period of many years. The neuropathic disease may be remarkably restricted, as in familial analgesia with foot ulcers, or extensive, as in chronic amyloidosis and familial peroneal muscular atrophy. The time of onset of these very chronic neuropathies is often uncertain, although the hereditary familial types are obviously present from early life. In infants, the condition may be mistaken for muscular dystrophy or infantile muscular atrophy until sensory testing becomes possible. In the developing child, whose musculature naturally increases in power and volume, it may be difficult to decide whether the disease is progressive. Atlaxa of the limbs may be pronounced at a stage when sensory loss exceeds paresis. As characteristic as the chronicity is a symmetry of neurologic findings and EMG abnormalities (except one variety that causes a susceptibility to compression neuropathies).

Pes cavus and, in extreme forms, talipes equinus are strong indicators of the early onset of inherited polyneuropathy. In the later stages of these neuropathies, trophic changes of skin and bone in distal parts of the limbs indicate involvement of small (pain) fibers, and the presence of deformed and degenerated joints (Charcot joint)
indicates a loss of large proprioceptive fibers. The mutilating effects are the result of repeated injury to analgesic parts and to a lack of autonomic vascular reflexes. The atrophy of muscle and trophic changes in the skin are more marked than in the acute and subacute forms of polyneuropathy; for this reason, the more chronic syndrome must be differentiated from the other forms of severe muscular atrophy, i.e., motor system disease, the distal type of muscular dystrophy, and syringomyelia.

The CSF protein content may remain mildly or moderately elevated over a period of years. Most of the inherited neuropathies are axonal in nature when studied by EMG with the notable exception of the commonest variety, Charcot-Marie-Tooth disease type 1. Another distinctive feature of hereditary neuropathy is the uniformity of the electrophysiologic changes, e.g., the same degree of slowing of nerve conduction velocity in all the nerves of the lower limbs, a feature that distinguishes this group from all acquired neuropathies.

There has been much difficulty in classifying the chronic familial polyneuropathies. The time-honored clinical classification divides them into two broad groups, each with several subgroups: (1) a mixed sensorimotor group, the prototype of which is Charcot-Marie-Tooth disease, and (2) a predominantly sensory type, often with autonomic involvement and trophy lesions. Recent genetic findings have not greatly simplified the matter of classification but have permitted the creation of a nosology that more or less parallels the clinical one. The proposed classifications in Table 46-1 and Table 46-2 represent an attempt to conciliate the clinical and genetic data.

### Table 46-2 Classification of the main inherited neuropathies

#### Inherited Polyneuropathies of Predominantly Sensory Type

Common to the several diseases comprised by this group are insensitivity to pain, lancinating pains, and ulcers of the feet and hands, leading to osteomyelitis, osteitis, stress fractures, and recurrent episodes of cellulitis. Since similar symptoms and signs occur in syringomyelia, leprosy, and tabes dorsalis, there is considerable uncertainty in older writings on this subject as to whether the reported cases were examples of one of these diseases or of hereditary neuropathy. According to Dyck, it was Leplat in 1846 who first described plantar ulcers (mal perforant du pied), followed by Neltan in 1852. Morvan in 1883 reported his observations of adult patients who had developed suppuration of the pulps of insensitive fingers (whitlows). It is now generally agreed that Morvan's cases were examples of syringomyelia, whereas the family described by Neltan was probably an example of the recessive form of childhood sensory polyneuropathy, since familial syringomyelia in children is practically unknown. We agree with Dyck that most such cases are examples of sensory polyneuropathy.

#### Mutilating Hereditary (Dominant) Sensory Polyneuropathy in Adults

The characteristic features of this group of polyneuropathies are an autosomal dominant mode of inheritance and onset of symptoms in the second decade or later. Characteristically there is involvement mainly of the feet, with callouses of the soles and, later, episodes of blistering, ulceration, and lymphangitis followed by osteomyelitis and osteolysis, shooting pains, distal sensory loss with greater affection of pain and thermal sensation than of touch and pressure, loss of sweating, diminution or absence of tendon reflexes, and only slight loss of muscle power.

The plantar ulcer overlying the head of a metatarsal bone is the most dreaded complication, since it may develop into an osteomyelitis. Infection of the pulp of the fingers and paronychias are uncommon. Some patients have a mild pes cavus and weakness of the peroneal and pretilial muscles; with foot drop and steppage gait. Lancinating pains may occur in the legs, thighs, and shoulders, and, exceptionally, the pain may last for days or longer and be as disabling as that of tabes dorsalis; however, in the majority of patients there is no pain whatsoever. Neural deafness was present in one of Denny-Brown's patients. In the latter case, which was studied postmortem, there was a loss of small nerve cells in the lumbar and sacral dorsal root ganglia; the dorsal roots were thin, and the fibers in the posterior columns of the spinal cord and peripheral nerves were diminished in number. Neuralated and unmyelinated fibers were both affected. Both axonal degeneration and segmental demyelination have been demonstrated in teased nerve preparations. Sensory nerve conduction may be absent or is uniformly slow in every nerve tested.

#### Recessive Mutilating Sensory Polyneuropathy of Childhood

Here the pattern of inheritance is autosomal recessive. Onset is in infancy and early childhood and walking is delayed; there is pes cavus deformity and the first movements are atactic. Ulcerations of the toes and fingers are absent, but muscular power is well preserved. All sensory modalities are impaired (touch-pressure somewhat more than pain-temperature), mainly in the distal parts of the limbs but also over the trunk. In addition, there are reports of several sibships in which multiple members had a sensory neuropathy manifest by a generalized insensitivity to pain of the type described below. The lesions and electrophysiologic findings are similar to those in the dominantly inherited sensory neuropathy.

In both types of hereditary sensory neuropathy, measures must be taken to prevent stress fractures, acral mutilation, and infection. This is more difficult in the small child who does not understand the problem.

#### Congenital Insensitivity to Pain

In congenital insensitivity to pain, a syndrome in which the patient throughout his life is unreactive to the pain of injury, there is no loss of the ability to distinguish pinprick and other noxious stimuli from nonnoxious ones. Furthermore, the nervous system of such individuals seems to be normal. There is, however, another variety characterized by universal analgesia (Swanson and colleagues). This latter type is inherited as an autosomal recessive trait and at least one form involves the gene for a nerve growth factor receptor located on chromosome 1q immediately adjacent to the site of the mutation for Charcot-Marie-Tooth disease type 1B. During childhood, one of the patients of Swanson et al had high fever when the environmental temperature was raised, and the other possibly had orthostatic hypotension. One of the patients died in his 12th year and was found to have an absence of small neurons in the dorsal root ganglia, an absence of Lissauer's tracts, and a decrease in size of the descending spinal tracts of the trigeminal nerves. Sweat glands were present in the skin but were not innervated.

#### Other Forms of Inherited Sensory Neuropathy

Included here are the neuropathy of Friedreich ataxia, which is discussed in Chap. 39; the Riley-Day syndrome, which is discussed further on in this chapter; and the neuropathies in which there are recognized metabolic abnormalities, including familial amyloidosis. Also, we have seen unclassifiable examples of an almost pure sensory or sensorimotor type. Some years ago a young man and woman with universal anesthesia affecting head, neck, trunk, and limbs came to our attention (Adams et al); all forms of sensation were absent. The patients were areflexic but retained nearly full motor power; the movements were atactic. Anomalous functions were impaired but not abolished. In a sural nerve biopsy, nearly all fibers—large and small, myelinated and unmyelinated—had disappeared. Surprisingly, there were no trophic changes of any kind. Another of our families with ulcers and loss of digits had a symmetrical sensory and motor polyneuropathy of the extremities with areflexia. The inheritance was of autosomal dominant type, with onset in adolescence. Donaghy and others have described a unique variant of the recessively inherited form of sensory neuropathy in which there was an associated neurotrophic keratitis and a selective loss of small myelinated fibers in sural nerve biopsies. We continue to observe variant and unclassifiable cases such as these every year.

### Inherited Polyneuropathies of Mixed Sensorimotor-Autonomic Types

**Peroneal Muscular Atrophy** [Charcot-Marie-Tooth Disease, or CMT Types 1 and 2; Hereditary Motor-Sensory Neuropathy, or HMSN Types I and II (Dyck);](#)
The hallmark of this class of neuropathies (Table 46-2) is genetic transmission, complete symmetry, slow progression, and axon-myelin fiber loss (Dyck). These are among the most common forms of inherited peripheral neuropathy and indeed among the most common of all inherited neurologic diseases. The frequency of the disease cannot be stated with precision because of its clinical heterogeneity, but overall the usually quoted prevalence is 1 in 2500 of the population, the most frequent subtype occurring in 1 in 4000. More than 15 subtypes have been described but only a few occur with any regularity.

Because the disease was described in 1866 almost simultaneously by Tooth in England and by Charcot and Marie in France, all their names were attached to it, even though similar cases had been recorded earlier by Eulenberg (1856), Friedreich (1873), Ormerod (1884), and Osler (1880). Because of secondary changes in the spinal cord and the occasional association of this disease with Friedreich ataxia, early observers considered it to be a hereditary myelopathy and did not class it with the other forms of pure peroneal muscular atrophy, which support a neuropathic explanation. The two important advances in our understanding of this disease, since the original descriptions, have been the separation of the main subtypes on the basis of their electrophysiologic (EMG) features, and the assignment of the loci of certain genotypes to regions that code for components of peripheral nerve myelin.

**Genetic Transmission** The pathologic pattern of inheritance of Charcot-Marie-Tooth disease is most often autosomal dominant, with almost complete penetrance (the frequency of clinical expression of a genotype); less often it is autosomal recessive and rarely X-linked dominant or X-linked recessive (Table 46-2). Some cases arise as de novo mutations (Hoogenrijk et al). Most kinships with autosomal dominant inheritance have been linked to a gene locus on chromosome 17p (the demyelinating type referred to below); however, other kinships are linked to chromosome 1 (the axonal type), and still others are linked to neither, implying additional and as yet undiscovered loci. Kindreds that are connected to chromosomes 1 or 17 cannot be distinguished from one another on clinical grounds.

Seven subtypes of CMT type 1 can be derived from duplication of the gene for peripheral myelin protein (PMP-22 on chromosome 17). Other studies of the PMP-22 and MPZ (another myelin protein) gene expression in CMT1 and CMT2 cases (Dejerine-Sottas disease) have yielded different results because mutations on different loci, including on chromosome 1, lead to different presentations, as noted in Table 46-2. The disease termed hereditary liability to pressure palsies also displays an aberration on chromosome 17, but in the form of a deletion rather than a duplication of the gene for PMP 22. This disease is discussed further on, under "Brachial Plexus Neuropathies." Yet another X-linked variant derives from a mutation of the gene for connexin, another component of myelin.

Undoubtedly further studies of genes and gene products will continue to advance our understanding of the inherited neuropathies, but for the present, clinicians are still best served by the descriptive clinical classification outlined in Table 46-1, acknowledging, of course, the heterogeneity of this class of disorders.

**Clinical and Electrophysiologic Features** Dyck and Schurr have subdivided CMT disease into two types: hereditary motor sensory neuropathy (HMSN) I and II (or CMT1 and 2). This subdivision was made on the basis of conduction velocity in the median or ulnar nerve—slow (mean conduction velocity less than 38 m/s) in type I and normal or near normal in type 2. Electrophysiographers therefore refer to these respectively as the demyelinating and axonal type CMT disease. Although muscle action potentials and sensory potentials are found in both types, there are findings of denervation in type 1 there is severe slowing of nerve conduction, but the type of conduction block that characterizes the acquired demyelinating neuropathies is not found. In distinction to acquired diseases, the EMG findings, particularly the pronounced slowing of conduction in CMT1, are uniform throughout the peripheral nervous system.

The classic form of CMT has its onset during late childhood or adolescence, although neurologists are increasingly aware that some cases, particularly type 2, may not attract attention until middle life. Difficulty running, frequent weakness and sprains of the ankles, or stumbling and slapping of the feet are noted by the parents of younger children. Older patients have difficulty dating the onset of symptoms. With milder forms, they may not even be aware of having a neuropathic illness. In some cases the striking and widespread changes on EMG only come to light when this test is performed for the diagnosis of an unrelated problem or a patient becomes aware of his neuropathy when a child proves to have the disease. Type 1 cases have a peak appearance during the first decade. Peak onset of type 2 is in the second decade and even later in many cases; an onset in middle adult life is not unknown. Both motor and sensory signs are said to be more severe in the first type (Harding and Thomas).

Essentially, the chronic degeneration of peripheral nerves and roots results in distal muscle atrophy, beginning in the feet and legs and later involving the hands. The extensor hallucis and digitorum longus, the peronei, and the intrinsic muscles of the feet are affected early and produce pes cavus and ‑pie en griffe (high arches and hallux valgus). Atrophy of the long flexors of the fingers and forearms is late. After these muscles have been lost, the remaining intrinsic muscles still have a normal relationship to the bone until the muscles atrophy, at which point they can be observed as cordlike structures through the skin. The extensor hallucis longus and the extensor digitorum brevis muscles remain in this way even when all other muscles are completely atrophied. Talipes equinovarus postures with claw feet and later claw hands are common. All modalities of sensation are impaired in a distal distribution, and the tendon reflexes are absent. Miotic, unreactive pupils, nystagmus, and kypohoscoliosis have been observed in some cases. The trunk and other cranial nerves are spared. The ulnar, median, radial, posterior, and peroneal nerves stand out like tendons and are easily followed with the gently roving finger. The enlarged nerves are not tender.

Clinical and electrophysiologic findings in CMT type 1 are a pattern of slow conduction in the median or ulnar nerve, and slow conduction block. In contrast, in acquired demyelinating neuropathies, conduction block is often associated with conduction velocity that is within the normal range. The clinical and electrophysiologic features of CMT type 2 are similar to those of type 1, but motor and sensory symptoms are less severe and there is more evidence of axonopathy. The terminal branches of the nerves are often spared.

The walking difficulty, which is the main disability, is due to a combination of sensory axatia and weakness. Foot drop and instability of the ankles are additional handicaps. The feet and legs may ache after use and cramps may be troublesome, but otherwise pain is exceptional; the feet are often cold, swollen, and blue, secondary to inactivity of the muscles of the feet and legs and their dependent position. There is usually no disturbance of autonomic function. Fixed pupils, optic atrophy, nystagmus and endocrinopathies, epilepsy, and spina bifida, which have been reported occasionally in association with peroneal muscular atrophy, probably represent degenerative changes in the spinal cord and the occasional association of this disease with Friedreich ataxia, early observers considered it to be a hereditary myelopathy and did not class it with the other forms of pure peroneal muscular atrophy, which support a neuropathic explanation. The two important advances in our understanding of this disease, since the original descriptions, have been the separation of the main subtypes on the basis of their electrophysiologic (EMG) features, and the assignment of the loci of certain genotypes to regions that code for components of peripheral nerve myelin.

Historically, CMT disease has been subdivided into two types: peroneal muscular atrophy and Charcot-Marie-Tooth disease (CMT). The peroneal muscular atrophy type is characterized by weakness and atrophy of the muscles of the feet and lower legs, which may lead to a claw foot deformity and equinovarus posture. The Charcot-Marie-Tooth disease type is characterized by a slower progression and a more widespread involvement of peripheral nerves, leading to weakness and atrophy of the hands and feet, as well as sensory symptoms.

**Pathologic Findings** Degenerative changes in the nerves result in depletion of the population of large sensory and motor fibers, leaving only the condensed endoneurial connective tissue. As far as one can tell, axons and myelin sheaths are both affected, the distal parts of the nerve more than the proximal. In type 1, the nerves may be enlarged, with "onion-bulb" formations of Schwann cells and fibroblasts, as in Dejerine-Sottas disease (type III HMSN in the Dyck classification). This change can often be seen in sural nerve biopsy. Anterior horn cells are slightly diminished in number and some are chromatolyzed. Dorsal root ganglion cells suffer a similar fate. The disease involves sensory posterior root fibers with degeneration of the posterior columns of Goll more than of Burdach. The autonomic nervous system remains relatively intact. The muscles contain large fields of atrophic fibers (group atrophy). Some of the larger fibers have a target appearance and may show degenerative changes. This muscle lesion is of the denervative type. Claims of a coincidental myelopathy and degeneration of spinocerebellar and corticospinal tracts probably indicate that the associated disease was really Friedreich ataxia or some other combination of chronic myelopathy and neuropathy.

**Treatment** No specific treatment is known. Stabilizing the ankles by arthrodeses is indicated if foot drop is severe and the disease has reached the point where it may evolve over decades.

**Differential Diagnosis** involves the distal dystrophies (page 1050), late forms of familial motor system disease, Friedreich ataxia (page 1145), Roussy-Lévy syndrome (see below) and other familial polyneuropathies, and, in adults, CIDP and the paraproteinemic neuropathies, discussed earlier.
confined to wheelchairs at an early age. Treatment is purely symptomatic.

It is important to emphasize that the occurrence of hypertrophic neuropathy is not confined to this particular inherited disease. If one groups all patients in whom the nerves are diffusely enlarged (incorrectly called “hypertrophic,” since it is mainly the epineural and perineural connective tissue that enlarges), several different diseases, both genetic and acquired, are included. The identifying histologic lesion in these cases is the “onion bulb,” which consists of a whorl of overlapping, intertwined, attenuated Schwann cell processes that encircle naked or finely myelinated axons. Enlarged nerves have been described in some cases of recurrent demyelinating polyneuropathy, familial amyloidosis, Refsum disease (HMSN type IV of Dyck), peroneal muscular atrophy type I, and other diseases. As was first noted by Thompson, any pathologic process that causes recurrent segmental demyelination and subsequent repair may result in this effect. In some patients with a history of early childhood polyneuropathy, the nerves are not yet palpably enlarged, but the characteristic Schwann cell abnormalities can be seen in a biopsy of a cutaneous nerve.

Hereditary Areflexic Dystasia (Roussy-Lévy Syndrome) In 1926 Roussy and Lévy reported seven cases of a dominantly inherited malady that had not previously been described. Its close relation to Friedreich ataxia and the amyotrophy of Charcot-Marie-Tooth disease was recognized. For many years thereafter the existence of this entity was disputed and only recently, on the basis of molecular genetic testing, have these relationships been clarified.

The condition in question is a sensory ataxia (dystasia) with pes cavus and areflexia, affecting mainly the lower legs and progressing later to involve the hands. Some degree of sensory loss, mainly of vibratory and position sense, has been described in all cases. Areflexy of the muscles of the legs and postural tremor become prominent eventually. None of the patients has had evidence of cerebellar ataxia. Kyphoscoliosis is described in several. Although the feet may be cold or slightly discolored, no autonomic defects are documented. The nerves are not palpably enlarged. Electrodiagnostic abnormalities similar to those of Friedreich ataxia have been noted in some families. The onset in many patients is during infancy, possibly dating from birth, and the course is benign; all descendants of the original Roussy-Lévy family were still able to walk during their seventh decade of life.

On clinical and pathologic grounds, Dyck et al placed the Roussy-Lévy kinships within the demyelinating type of Charcot-Marie-Tooth disease (CMT1). The mode of inheritance of the two syndromes, benign course, pattern of neurologic signs, slow nerve conduction, and biopsy features (demyelination of nerve fibers with onion bulb formation) are much the same. This view has been reinforced by the recent genetic findings of Planté-Bordeneuve et al. In affected members of the original Roussy-Lévy family, these investigators identified a point mutation in the domain of the myelin protein gene Po, on chromosome 17 p 11.2, the same gene that is implicated in CMT and Déjerine-Sottas disease.

Chronic Polyneuropathy with Hereditary Spastic Paraplegia From time to time we have observed children and young adults with unmistakable progressive spastic paraplegia superimposed on which was a sensorimotor polyneuropathy of extremely chronic evolution. Sural nerve biopsy in two of our cases disclosed a typical “hypertrophic” polyneuropathy. In another case only loss of nerve fibers was found. Cavanagh and colleagues and Harding and Thomas have reported similar patients. Our patients were severely disabled, being barely able to stand on their atrophic legs. The disease is slowly progressive. The patients described by Cavanagh and coworkers had mainly sensory deficits and were not disabled.

While few in number, some cases of chronic polyneuropathy are combined with optic atrophy, with or without deafness or retinitis pigmentosa, and Dyck has classified these in separate groups. Jaradeh and Dyck have also described a hereditary motor-sensory polyneuropathy with the later development of a parkinsonian or a choreo-dystonic syndrome that responded to L-dopa. Most cases of this type have had an autosomal recessive inheritance.

Inherited Polyneuropathies with a Recognized Metabolic Disorder

Refsum Disease (Herediopathia Atactica Polyneuritiformis; HMSN IV of Dyck) This rare disorder is inherited as an autosomal recessive trait and has its onset in late childhood, adolescence, or early adult life. Diagnosis is based on a combination of clinical manifestations—retinitis pigmentosa, cerebellar ataxia, and chronic polyneuropathy—coupled with an increase in blood phytanic acid. Cardiomyopathy and neurogenic deafness are present in most patients, and pupillary abnormalities, cataracts, and ichthyoid skin changes (particularly on the shins) are added features in some. Anosmia and night blindness with constriction of the visual fields may precede the neuropathy by many years; usually the latter develops gradually, sometimes rapidly. The polyneuropathy is sensorimotor, distal, and symmetrical in distribution, affecting the legs more than the arms. All forms of sensation are reduced and tendon reflexes are lost. The CSF protein is increased, sometimes markedly.

Although the nerves may not be palpably enlarged, “hypertrophic” changes with onion-bulb formation are inevitable pathologic features. The metabolic defect is in the utilization of dietary phytol; a failure of oxidation of phytanic acid—a tetramethylated 16-carbon fatty acid—results in its accumulation. The relation between the increased phytanic acid and the polyneuropathy is uncertain. Clinical diagnosis is confirmed by the finding of increased phytanic acid in the blood; the normal level is less than 0.3 mg/dL, but in patients with this disease it constitutes 5 to 30 percent of the total fatty acids of the serum lipids. Diets low in phytol may be beneficial, but this is difficult to judge, for after an acute attack there is sometimes a natural remission. The effects of plasma exchange have also been difficult to interpret. Some patients there is a very slow and gradual progression of the disease, and in others a more rapid progression with death from cardiac complications. Diagnosis is confirmed by measuring serum and urinary phytanic acid.

Ataxia, Retinitis Pigmentosa, and Peripheral Neuropathy without Increase in Phytanic Acid (NARP) Like Tuck and McLeod, we have observed several cases over a period of years in which the clinical picture was almost identical to that of Refsum disease, but changes in phytanic acid could not be detected. A mild ichthyosis, sensorineural deafness, ataxia of mixed ataxic-cerebellar type, areflexia, and retinitis pigmentosa were the main findings. None of our cases had a personal or family history of Refsum disease. Sural nerve biopsy in one case revealed an increase in nerve fiber diameters; biochemical abnormalities in the blood were not detected. There was a mitochondrial disorder in most of the recently studied cases. This, so-called NARP syndrome, was described in detail on page 1043. The onset of the disease has been in adolescence with slow progression.

Abetalipoproteinemia (Bassen-Kornzweig Syndrome) This rare autosomal recessive disorder has been described in Chap. 37 (page 1021) with the inherited metabolic disorders of the nervous system. It is mentioned here because the brunt of the neurologic disorder falls upon the peripheral nerves; acanthocytosis is an identifying feature. The first neurologic finding is diminution of peripheral nerves and subsequent repair and remyelination. Diagnosis is confirmed by the finding of acanthocytes, low serum cholesterol, and b (low-density)-lipoproteins. What is known about the pathogenesis and treatment is discussed in Chap. 37. A deficiency of vitamin E, due to malabsorption, may be an important factor, and large doses of the vitamin should be tried as therapy.

A closely related disease, also with familial hypobetalipoproteinemia, has been described by van Buchem and coworkers. It too is associated with a malabsorption syndrome, an ill-defined weakness, ataxia, dysaesthesia of the legs, and Babinski signs. There is no sensory loss.

Tangier Disease This is an exceedingly rare familial disorder, named for the island off the Virginia coast, where the first-described cases resided. It is inherited as an autosomal recessive trait. The genetic abnormality is situated in the gene for the so-called ATP-cassette transporter protein. It is marked by a deficiency of high-density lipoprotein, low cholesterol, diminution of phospholipids, and high triglyceride concentrations in the serum. Perhaps because of these abnormalities, the patients are disposed to early and severe atherosclerosis. The presence of enlarged, yellow-orange (cholesterol-laden) tonsils is said to be a frequent manifestation.

About half of the reported cases have had neurologic symptoms, taking the form of an asymmetrical sensorimotor neuropathy that fluctuates in severity. The polyneuropathy may come in attacks—that is to say, it is recurrent. In the two sisters reported by Engle and coworkers, the onset of symptoms was in childhood and in infancy, respectively. The sensory loss is predominant for pain and temperature and extends over the entire body; at times it is limited to the face and upper extremities, simulating syringomyelia (pseudosyringomyelia). Tactile and proprioceptive sensory modalities tend to be preserved.

The muscular weakness, if present, affects either the lower or upper extremities or both, particularly the hand muscles, which may undergo atrophy and show...
denervation potentials by EMG. In one of our patients, only a facial diplegia was present, and the pain and temperature loss was restricted to the head, neck, and arms. Nerve conduction is slowed. Tendon reflexes are often lost or diminished. Transient pnosis and diplopia have been reported.

Fat-laden macrophages are present in the bone marrow and elsewhere. No complete pathologic studies are available. There is no known treatment. Dietary measures may help, particularly in preventing atherosclerosis, but whether they influence the neuropathy is uncertain.

**Fabry Disease (Anderson-Fabry Disease)** The genetic and metabolic aspects of this sex-linked disorder have already been considered with the inherited metabolic diseases (page 1037). Here we offer some additonal remarks about the painful neuropathic component.

The pain, which is usually the initial symptom in childhood and adolescence, often has a burning quality or occurs in brief lancinating jabs, mostly in the fingers and toes, and may be accompanied by parasthesias of the palms and soles. Changes in environmental temperature and exercise may induce pain. These abnormalities are due to the accumulation of glycolipids (ceramide trihexoside) in peripheral nerves, both perineurally and intraneurally, as well as in cells of the spinal ganglia and the anterior and intermediolateral horns of the spinal cord. Ohnishi and Dyck have demonstrated a preferential loss of small myelinated and unmyelinated fibers and small neurons of dorsal root ganglia. Involvement of the latter cells and the associated degenerative changes in the afferent fibers are thought to be the likely cause of the painful sensory phenomena (Kahn).

Later in the illness there is progressive impairment of renal function and cerebral and myocardial infarction. But the most characteristic feature is an eruption of dark red macules and papules, up to 2 mm in diameter, over the trunk and limbs, most closely clustered over the thighs and lower trunk and around the umbilicus (angiokeratoma corium disopsiform).

Phenylalanine, carboxamiphen, or gabapentin and amitriptyline may be helpful in alleviating the pain and dysesthesias, but there is no specific therapy for the disease.

**Polyneuropathy of Acromegaly and Gigantism** Nerve entrapment, particularly of the median nerve, is a well-known feature of acromegaly. Pickert and colleagues identified a carpal tunnel syndrome in 58 percent of acromegalics. Also recognized as a complication of acromegaly, but not due to multiple nerve entrapments, is a polyneuropathy characterized by paresthesias, loss of tendon reflexes in the legs, and atrophy of slight degree in the distal leg muscles. Sometimes there are enlarged nerves. In the case reported by Stewart, the enlargement was the result of hypertrophic changes in the endoneurial and perineurial tissues, similar to those that occur in other so-called hypertrophic neuropathies of inflammatory or heredofamilial origin. In cases of extreme gigantism, a more severe polyneuropathy has been reported, to the point of causing Charcot joints (Rheumatic). We have also observed a severe motor neuropathy in a patient with Pyle disease, a metaphyseal dysplasia that resembles acromegaly.

**Metachromatic Leukodystrophy** (See also Chap. 37.) In this disease the congenital absence of the degradative enzyme sulfatase leads to massive accumulation of sulfatide throughout the central and peripheral nervous systems and to a lesser extent in other organs. The abnormally is transmitted as an autosomal recessive trait. Progressive cerebral deterioration is the most obvious clinical feature, but hyporeflexia, muscular atrophy, and diminished nerve conduction velocity reflect the presence of a neuropathy. Early in the course of the illness, the weakness, hypotonia, and areflexia may suggest Werding-Hoffmann disease; in older children there may be parasthesias and demonstrable sensory loss. Bilateral weakness has been reported. Sensory and motor conduction velocities are slowed. Metachromatically staining granules accumulate in the cytoplasm of Schwann cells in all peripheral nerves as well as in the cerebral white matter. There is also a loss of myelinated fibers. The measurement of arylsulfatase A activity in peripheral leukocytes or urine and sural biopsy may be used to establish the diagnosis, even early in the course of the illness.

**Familial Dysautonomia (Riley-Day Disease; See also Chap. 28.)** This disorder, inherited as an autosomal recessive trait, affects Jewish children predominantly.

The condition is manifest at birth (poor sucking, failure to thrive, unexplained fever, episodes of pneumonia). Hyporeflexia and impairment or loss of pain and temperature sensation, with relative preservation of pressure and tactile sense, are the main neuropathic manifestations. Motor fibers are probably involved as well, but only to a slight degree; this is shown less by weakness than by reduced motor conduction velocity in peripheral nerves. At a later age the neuropathy continues to be overshadowed by other manifestations of the disease, notably the repeated infections and abnormalities of the autonomic nervous system—lack of tears, corneal ulceration, fixed pupils, biolchioritis of the skin, defective temperature control, cold hands and feet, excessive sweating, lability of blood pressure, postural hypotension, difficulty in swallowing, esophageal and intestinal distalation, emotional instability, recurrent vomiting, and stunted growth. The tongue shows an absence of fungiform papillae.

Nerve biopsy reveals a diminution of small myelinated and unmyelinated fibers, which explains the impairment of pain and temperature sensation. In autopsy material, sympathetic and parasympathetic ganglion cells and, to a lesser extent, nerve cells in the sensory ganglia are diminished in number. Patients excrete increased amounts of homovanillic acid and decreased amounts of vanillylmandelic acid and methoxyhydroxyphenylglycol. Weinshilboum and Axelrod demonstrated a significant decrease in serum dopamine b-hydroxylase, the enzyme that converts dopamine to norepinephrine, and this is now the standard diagnostic test. There is no treatment for the disease except to provide symptomatic relief of gastrointestinal symptoms and fainting.

Other examples of congenital polyneuropathy with absence of autonomic function, probably different from the Riley-Day dysautonomia, have been reported. Some of these, in our experience, develop transient episodes of reflex sympathetic dystrophy. A congenital failure of development of neural elements derived from the neural crest is postulated.

Ataxia telangiectasia and Chrdhiak-Higashi disease are other genetic diseases with a recognized metabolic abnormality that may cause a polyneuropathy. They are described in Chap. 37, with the hereditary metabolic disorders.

**Inherited (FA) Amyloid Neuropathies Amyloid is a descriptive term for any of the proteins that may be deposited in filamentous beta-pleated sheets; it can be derived from a number of sources. Peripheral neuropathy is a common and often the most prominent manifestation of amyloidosis. The polyneuropathies are of two main types—those associated with familial amyloidosis (referred to as FA) and the other associated with primary (nonfamilial) systemic deposition of amyloid (termed AL), which is derived from a circulating monoclonal protein. The second type has been discussed earlier under "Paraproteinemic Neuropathies." The most noticeable difference between these two types is the absence of the paraprotein in the inherited forms. As noted on page 1409, the amyloidosis that is secondary to chronic suppurative or inflammatory disease, referred to as AA or secondary amyloidosis, does not affect the nerves.

The familial amyloid polyneuropathies comprise several distinct clinical groups. The pattern of inheritance in all types is autosomal dominant; males and females are affected with equal frequency. However, a descriptive classification based on the ethnic origin of affected families is still in use clinically, it is now possible to categorize these diseases according to their genetic errors and the corresponding chemical structure of the abnormal protein that is deposited in the tissue as amyloid. The most common familial amyloid neuropathies, described below as the Portuguese (Andrade) and Indiana-Swiss types, the amyloid is derived from an abnormal serum protein transthyretin (formerly called prealbumin). Several different amino acid substitutions have been identified in each group. In the originally described Andrade type, methionine replaces valine at amino acid 30; this has therefore been referred to as transthyretin amyloidosis. In the third or Iowa-van Allen type, the amyloid consists of human apolipoprotein C-III, in which there is single erroneous amino acid substitution. In the fourth, or Finnish, type, which includes cranial neuropathies and corneal lattaceous dystrophy, the amyloid fibrils are derived from the protein gelsolin. The latter is normally an actin-binding protein, but it is also an important constituent of basement membranes, which may explain the deposition of amyloid in the cornea and skin. The recent cloning of many more of the amyloid protein genes has made possible not only the detection of the transthyretin gene abnormality but should also make available diagnostic DNA tests for the other types of familial amyloidosis in the near future.

Liver transplantation has recently proved curative of one of the familial amyloid polyneuropathies but obviously has no role in the acquired forms.

Characteristic of the amyloid polyneuropathies is the involvement of small-diameter sensory and autonomic nerves.

The following are the recognized types of familial amyloid neuropathy.

1. **The Portuguese (Andrade) type** Andrade, in 1939, first recognized that a chronic familial illness known as "foot disease" among the inhabitants of Oporto, Portugal, was a special type of amyloid neuropathy. He was not the first to have seen amyloid in degenerating nerve but deserves credit for identifying the disease as one of the heredofamilial polyneuropathies. By 1989 he had studied 148 sibships, comprising 623 individuals, among whom there were 249 with polyneuropathy. Descendants of this family have been traced to Africa, France, and Brazil. Other foci of the disease have been reported in Japan (Ikeda et al.), the United States (Kantarjian and DeJong), Germany (Delank et al.), Poland, Greece, Sweden, and northwest Ireland (Staunton and others). As far as one can tell,
these are separate, unrelated probands in different ethnic groups.

The age of onset of this form of familial amyloid polyneuropathy is between 25 and 35 years. The disease progresses slowly and terminates fatally in 10 to 15 or more years. The initial symptoms are usually numbness, paresthesias, and, sometimes pain in the feet and lower legs. Weakness is minimal, and the tendon reflexes, although diminished, may be retained early in the course of the disease. Pain and thermal sense are reduced more than tactile, vibratory, and proprioceptive functions. (pseudosyringomyelia). Autonomic involvement is another important characteristic—loss of pupillary light reflexes and miosis, anhidrosis, vasomotor paralysis with orthostatic hypotension, alternating diastole and constrictia, and impotence. These autonomic changes tend to be more extensive than the sensory ones. Difficulty in walking also develops and has its basis in a combination of faulty position sense and mild muscle weakness. Later, tendon reflexes are abolished and the legs become thin. The nerves are not enlarged. Cranial nerve involvement (facial weakness and numbness, loss of taste) is a late manifestation and occurs in only a few cases.

Cases vary somewhat. Cardiac enlargement and irregularities in cardiac rhythm due to bundle branch or atrioventricular (AV) block occur early in some and late in others. A few patients have had severe amyloid heart disease from the onset. Weight loss may be pronounced, owing to anorexia and disordered bowel function and the later development of a malabsorption syndrome, and the liver may become enlarged. Vitreous opacities (veils, specks, and strands) may progress to blindness, but this has been rare; in a few, there has been an impairment of hearing. Involvement of the CNS—manifest as behavioral abnormalities, cerebellar ataxia, and bilateral corticospinal signs—has been reported. Albinuria, a nephrotic syndrome, and uremia terminate life in a few of the patients. The CSF may be normal or the protein content may be increased (50 to 200 mg/dL); the blood is normal except for anemia caused by amyloidosis of the bone marrow.

2. Familial amyloidosis with carpal tunnel syndrome (Swiss type) Falls and coworkers in 1955 and later Rukavina and associates described a large group of patients of Swiss stock living in Indiana who developed, in their fourth and fifth decades, a characteristic syndrome of acroparesthesias due to deposition of amyloid in the connective tissues in and deep to the carpal ligaments. Similar kindreds, of German descent, were recognized in Maryland. There was sensory loss and atrophic muscle weakness in the distribution of the median nerves, which were compressed. Section of the carpal ligaments relieved the symptoms. In some of the patients, other nerves of the arms were said to have become involved later. Vitreous deposits have been observed frequently in this form of the disease.

3. Familial amyloid neuropathy—Iowa type In 1969, van Allen described an Iowa kindred with onset, in their 30s, of a fairly severe sensorimotor neuropathy, involving the legs and then the arms. There was amyloid deposition in the testes, adrenal glands, and kidneys (the usual cause of death) as well as a high incidence of peptic ulcer disease.

4. Cranial neuropathy with corneal dystrophy This unusual form of amyloid neuropathy was first described in three Finnish families by Mereljova—hence “Finnish type.” Subsequently, it was reported from several different parts of the world in families of other than those of Finnish heritage.

The disease usually begins in the third decade, with corneal dystrophy. Vitreous opacities are not observed, and visual acuity is little affected. Peripheral neuropathy may not become evident until the fifth decade, at which time the lower limbs, particularly the upper branches, become affected. The nerves of the limbs are involved even later and to a much lesser extent than in other amyloid neuropathies. At postmortem examination, deposits of amyloid are found in virtually every organ, but mainly in the kidneys and blood vessels and in the perineurium of affected nerves.

Pathologic Findings In familial amyloid polyneuropathy, amyloid deposits are demonstrable in the blood vessels, the interstitial (endoepithelial) tissues of the peripheral somatic and autonomic nerves, and in the spinal and autonomic ganglia and roots. There is a loss of nerve fibers, the unmyelinated and small myelinated fibers being more depleted than the large myelinated ones. The anterior horn and sympathetic ganglion cells are swollen and chromatolyzed due to involvement of their axons, and the posterior columns of the spinal cord degenerate.

The pathogenesis of the fiber loss in the type, as acquired, is not fully understood. On the basis of their findings in a sporadic case of amyloid neuropathy with diabetes mellitus, Kernohan and Woltman suggested that amyloid deposits in the walls of the small arteries and arterioles interfere with the circulation in the nerves and that amyloid neuropathy is essentially an ischemic neuropathy. In other cases, however, the vascular changes are relatively slight and the degeneration of the nerve fibers appears to be related to their compression and distortion by the endoneurial deposits of amyloid. Amyloid is also seen in the tongue, gums, heart, gastrointestinal tract, kidneys, and many other organs, where it may possibly act as a tissue toxin.

Neuropathies Associated with AIDS These patients are prone to several types of neuropathy, including a predominantly sensory type that may be painful, a lumbosacral polyradiculopathy, cranial and limb mononeuropathies, CIDP, GBS, and, rarely, a vasculitic mononeuritis multiplex—none of which differs from the idiopathic or conventional varieties of these neuropathies, except that there is often a pleocytosis. Unique to the AIDS patient are the CMV cauda equina neuritis and an acute or subacute painful infiltrative lymphocytic neuropathy—a component of the diffuse infiltrative lymphocytosis (DILS) with CD8 cells (Meulinger et al.). Polyneuropathy may also be induced by antiviral agents that are used in the treatment of HIV infection, as discussed in Chap. 33.

Problems in Diagnosis of the Chronic Polyneuropathies This is the group that has given the present authors the most difficulty. The cause of most of the acute and many of the subacute and relapsing forms can usually be established by the clinical and laboratory methods presently available in large centers. It is the early and late chronic cases that continue to baffle the neurologist and general physician, despite the respectable advances that have been made in the field of genetics.

Diagnosis of Early Chronic Polyneuropathies A sensorimotor paralysis, which evolves over several weeks (subacutely) or more slowly, over many months or a year or two, and involves legs more than arms and distal parts more than proximal should, in an adult, always lead to a search for diabetes, occult neoplasia (carcinoma, lymphoma, multiple myeloma, or plasmacytoma), HIV infection, paraproteinemia (including amyloid neuropathy), and CIDP. In exceptional cases, a neoplastic process remains hidden for as long as 2 or 3 years after the onset of neuropathy. In our experience, an environmental toxin, endocrine disorder (except for diabetes), or nutritional cause is seldom identified, despite the frequent attribution of obscure polyneuropathies to such causes. Nonetheless, history of exposure to industrial or hobbyist toxins, sociopathy or psychopathy that would lead to toxin ingestion, or foreign travel should be sought and testing should include heavy metals in obscure hobbies. Nutritional cause is seldom identified, despite the frequent attribution of obscure polyneuropathies to such causes. Nonetheless, history of exposure to industrial or hobbyist toxins, sociopathy or psychopathy that would lead to toxin ingestion, or foreign travel should be sought and testing should include heavy metals in obscure hobbies.

In the purely or predominantly sensory polyneuropathies—some painful, some not, some with marked ataxia—an association with occult carcinoma, an IgM paraproteinemia, amyloidosis, or Sjögren syndrome are the primary considerations. Rarely, milder neuropathy may be seen with biliary cirrhosis. When the symptoms are confined to the feet and legs, a sporadic example of hereditary sensory neuropathy must be considered if the condition is of very long standing. Intoxications with pyridoxine or metals account for a few chronic sensory neuropathies. Despite all these considerations, we still regularly encounter patients in whom the cause is not identified. Unusual causes of nutritional deficiency, such as celiac-sprue disease and other malabsorption syndromes (Whipple disease, Crohn disease, chronic hepatic disease, intestinal bypass surgery), have usually been obvious enough when present, so that the experienced clinician rarely overlooks them. Vitamin B12 deficiency should be sought in any case of large-fiber neuropathy. A difficult type of case is that of an older person with a mild, nonprogressive sensorimotor polyneuropathy in whom there is evidence of mild hypothyroidism, marginally low vitamin B12 and folate acid levels in the blood, a somewhat unbalanced diet, perhaps an excessive alcohol intake, and an abnormal glucose tolerance curve. It is easy to imagine but hard to prove that any one of these factors is relevant.

In our experience, the subacute and chronically evolving demyelinating neuropathies that are suspected clinically and then confirmed by slowed conduction velocity, conduction block, and relatively normal needle EMG studies generally turn out to be variants of CIDP. Some others are associated with a paraproteinemia. Often the electrophysiologic tests point to a combined axonal and demyelinating process, the latter reflected in prolonged distal latencies, conduction slowing or block, and loss of late responses. Marked weakness and reduced muscle action potential amplitudes in the face of minimal denervation, even if present in only a few nerves, also indicate at least a component of focal demyelination. Most of the mixed axonal-demyelinating cases in which one eventually arrives at a diagnosis will also be related to an immune (paraproteinemic) or inflammatory (CIDP) process: for the moment, it is useful to place these in the demyelinating category since many will respond the same measures as are used in the treatment of purely demyelinating CIDP.

Laboratory tests that are useful in the investigation of this group of neuropathies are listed in Table 46-3.
Guarantors of Brain are particularly useful and are listed in the references. Peripheral nerves should be consulted. In the examination of individual nerves, the illustrated manual of Devinsky and Feldmann and the one published by the

For the anatomic plan of the brachial (and lumbosacral) plexus and their relations to blood vessels and bony structures, one of the more detailed monographs on the Brachial plexus neuritis

In assessing the type and degree of plexus injury, electrophysiologic testing is of particular importance. Early after a traumatic injury or other acute disease of the plexus, the only electrophysiologic abnormality may be an absence of late responses (F wave). After 7 to 10 days or longer, as the process of wallerian degeneration

Brachial plexus neuropathies, usually unilateral, comprise an interesting group of neurologic disorders. Some may develop without apparent cause and manifest themselves by sensorimotor derangements ascribable to one or more of the cords of the plexus. Others result from trauma in which the arm is hyperabducted or the shoulder violently separated from the neck. Difficult births are an important source of such traction injuries. Rarely, the brachial plexus or other peripheral nerves may

The distinguishing feature of this group of neuropathies is that either one or several individual peripheral nerves are involved by a disease process. The diagnosis rests on the finding of motor, reflex, or sensory changes confined to the territory of a single nerve; of several individual nerves affected in a random manner (mononeuritis or mononeuropathy multiplex); or of a plexus of nerves or part of a plexus (plexopathy). Certain neuropathies of this type—traceable to polyarteritis nodosa and other vasculitides, leprosy, sarcoid, or diabetes—have already been discussed and are the main causes of diseases in this category. In addition to the signs of mononeuritis multiplex, pain, sometimes local erythema over the infarction, and irregularly elevated CSF protein with pleocytosis are the main features (e.g., Lyme disease; see Chap. 32). A subacute or chronic inflammatory neuropathy and the immune neuropathy caused by antibodies to GM 1 should also be considered.

The reader should refer to Table 48-1 (page 1468), which lists the roots, nerves, and muscles that are involved in particular movements.

Brachial Plexus Neuropathies

Brachial plexus neuropathies, usually unilateral, comprise an interesting group of neurologic disorders. Some may develop without apparent cause and manifest themselves by sensorimotor derangements ascribable to one or more of the cords of the plexus. Others result from trauma in which the arm is hyperabducted or the shoulder violently separated from the neck. Difficult births are an important source of such traction injuries. Rarely, the brachial plexus or other peripheral nerves may be damaged at the time of an electrical injury, either from lightning or from a household or industrial source. There may be impairment of function of the brachial plexus or portions thereof developing many months or years after radiation therapy. Direct compression of parts of the plexus by adjacent skeletal anomalies (cervical rib, fascial bands, narrowed thoracic outlet) or infiltration by breast or apical lung tumors represents another category of brachial plexus injury. A subcutaneous or intramuscular injection of vaccine or foreign serum may be followed by a brachial plexopathy, usually partial.

Brachial plexus neuritis of obscure origin, also called neuralgic amyotrophy or Parsonage-Turner syndrome, stands as a special clinical entity, often difficult to distinguish from other types of brachial pain. Some of these cases, surprisingly, are familial: others occur in small outbreaks. There are plexus lesions of presumed toxic nature, such as those following heroin injection. Granulomatous diseases such as sarcoid and secondary inflammatory processes related to lymphoma may implicate the plexus.

In summary, most brachial plexus disorders are due to trauma, infiltration by tumor, compression, obscure infections (possibly viral), and the delayed effects of radiotherapy (page 1431).

In assessing the type and degree of plexus injury, electrophysiologic testing is of particular importance. Early after a traumatic injury or other acute disease of the plexus, the only electrophysiologic abnormality may be an absence of late responses (F wave). After 7 to 10 days or longer, as the process of wallerian degeneration proceeds, sensory potentials are lost and the amplitudes of compound muscle action potentials are variably reduced, in proportion to the severity of axonal loss. Fibrillation potentials, indicative of denervation, then begin to appear in the corresponding muscles. Even later, usually after several weeks, signs of reinervation can be detected. In all of these features may be evident when the patient is first studied. The pattern of degenerated nerves allows a distinction to be made between a plexopathy, radiculopathy, and mononeuritis multiplex based on the known patterns of innervation. If denervation changes are found in the paraspinal muscles, the source of weakness and pain is in the intraspinal roots. This localization is corroborated by finding preserved sensory potentials in nerves that are unaffected by lesions central to the ganglion. MRI may expose infiltrative lesions of the plexus (it is normal in so-called plexitis or neuralgic amyotrophy), but small nodular lesions may escape detection, and one then refers to the clinical data if these suggest an infiltrative or compressive lesion.

For the anatomic plan of the brachial (and lumbosacral) plexus and their relations to blood vessels and bony structures, one of the more detailed monographs on the peripheral nerves should be consulted. In the examination of individual nerves, the illustrated manual of Devinsky and Feldmann and the one published by the Guarantors of Brain are particularly useful and are listed in the references.
For quick orientation, it is enough to remember that the brachial plexus is formed from the anterior and posterior divisions of cervical roots 5, 6, 7, and 8 and the first thoracic nerve roots (see Fig. 46-4). The fifth and sixth cervical roots merge into the upper trunk, the seventh root forms the middle trunk, and the eighth cervical and first thoracic roots form the lower trunk. Each trunk divides into an anterior and posterior division. The posterior divisions of each trunk unite to form the posterior cord of the plexus. The anterior divisions of the upper and middle trunks unite to form the lateral cord. The anterior division of the lower trunk forms the medial cord. Two important nerves emerge from the upper trunk (dorsal scapular nerve to the rhomboid and levator scapulae muscles, and long thoracic nerve to the anterior serratus). The posterior cord gives rise mainly to the radial nerve. The medial cord gives rise to the ulnar nerve, medial cutaneous nerve to the forearm, and medial cutaneous nerve to the upper arm. This cord lies in close relation to the subclavian artery and apex of the lung and is the part of the plexus most susceptible to traction injuries and to compression by tumors that invade the costoclavicular space. The median nerve is formed by the union of parts of the medial and lateral cords.

Lesions of the Whole Plexus

The entire arm is paralyzed and hangs uselessly at the side; the sensory loss is complete below a line extending from the shoulder diagonally downward and medially to the middle third of the upper arm. Biceps, triceps, radial periosteal, and finger reflexes are abolished. The usual cause is vehicular trauma.

Upper Brachial Plexus Paralysis

This is due to injury to the fifth and sixth cervical nerves and roots, the most common causes of which are forceful separation of the head and shoulder during difficult delivery, pressure on the supravascular region during anesthesia, injections of foreign serum or vaccines, and idiopathic brachial plexitis (see below). The muscles affected are the biceps, deltoid, supinator longus, supraspinatus and infraspinatus, and rhomboids. The arm hangs at the side, movements of the hand and forearm are unaffected. The prognosis for spontaneous recovery is generally good, though this may be incomplete; injuries of the upper brachial plexus and spinal roots incurred at birth (Erb-Duchenne palsies) may persist throughout life.

Lower Brachial Plexus Paralysis

This is usually the result of traction on the abducted arm in a fall or during an operation on the axilla, infiltration or compression by tumors arising from the apex of the lung (superior sulcus or Pancoast syndrome), or compression by cervical ribs or bands. Injury may occur during birth, particularly with breech deliveries (Dijerine-Klumpke paralysis). There is weakness and wasting of the small muscles of the hand and a characteristic claw-hand deformity. Sensory loss is limited to the ulnar border of the hand and the inner forearm; if the first thoracic motor root is involved, there may be an associated paralysis of the cervical sympathetic nerves with a Horner syndrome. Invasion of the lower plexus by tumors is usually painful; postradiation lesions are more likely to cause paresthesias without pain (Lederman and Wilbourn).

Infractoclavicular Lesions Involving Cords of the Brachial Plexus

A lesion of the lateral cord causes weakness of the muscles supplied by the musculocutaneous nerve and the lateral root of the median nerve; it manifests itself mainly as a weakness of flexion and pronation of the forearm. The intrinsic muscles of the hand innervated by the medial root of the median nerve are spared. A lesion of the medial cord of the plexus causes weakness of muscles supplied by the medial root of the median nerve and the ulnar nerve. The effect is that of a combined median and ulnar nerve palsy. A lesion of the posterior cord results in weakness of the deltoid muscle, extensors of the elbow, wrist, and fingers, and sensory loss on the outer surface of the upper arm.

One group of infractoclavicular injuries, often iatrogenic, results from damage to the subclavian or axillary vessels and the formation of pseudoaneurysms or hematomas. Small puncture wounds—as might occur with catheterization of the subclavian vein, anesthetic block of the brachial plexus, or transaxillary arteriography—are likely to produce this type of injury. Compression of the plexus evolves subacutely, up to 3 weeks at times, although once started, the deterioration may be rapid. Prompt recognition of the condition and early decompression are essential. Other frequent causes of injury to the cords are dislocation of the head of the humerus, direct axillary trauma (stab wounds), pressure of a cervical rib or band, and supraclavicular compression during anesthesia. All cords of the plexus may be injured, or they may be affected in various combinations.

Costoclavicular (Thoracic Outlet) Syndrome

This is discussed in Chap. 11 (page 227).

Brachial Plexus Neuropathy (Neuralgic Amyotrophy, Brachial Neuritis or Plexitis, Parsonage-Turner Syndrome)

This illness, of obscure nature, may develop abruptly in an otherwise healthy individual; it may also complicate an infection, an injection of vaccine or antibiotic, childbirth, surgical procedures of any type, or the use of heroin. Magee and De Jong in 1960 and Tsairis and coworkers in 1972 reported large series of cases and amplified a well-known clinical picture that the authors have observed repeatedly. Our patients have nearly all been adults ranging from 20 to 65 years of age. Males are slightly more susceptible (2.4:1). Beginning as an ache in and around the shoulder, at the root of the neck or base of the skull, and suspected at first of being only a “wry neck,” the pain rapidly becomes more severe. It is made worse by movements that involve the muscles in the region, and the patient searches for a comfortable position. After a period of 3 to 10 days there is a rapid development of muscular weakness and sensory and reflex improvement. With the development of weakness and soon afterwards of atrophy, the pain tends to subside. In a few cases, the neurologic disorder occurs with little or no antecedent pain. Possibly, in some, the pain is not followed by demonstrable weakness.

Unlike restricted radicular lesions, which almost never cause complete paralysis of a muscle, certain muscles involved in brachial neuritis—such as the serratus anterior, deltoid, biceps, or triceps—may be totally or almost totally paralyzed. Rarely are all the muscles of the arm involved (4 of 99 cases of Tsairis et al). Recovery of paralysis and restoration of sensation are usually complete in a matter of 6 to 12 weeks but sometimes not for a year or longer. In 5 to 10 percent of cases, there is residual weakness and wasting of the affected muscles, and a similar number have had a recurrence on the same or the opposite side.

Motor nerve conduction becomes impaired in 7 to 10 days. The lesions are presumably of axonal type, and signs of denervation follow. A small proportion of cases are bilateral, usually sequentially, rather than simultaneously, and recurrences have been reported. Most of the neurologic deficits in our cases have been localized around the shoulder and upper arm; rarely the hand has been affected predominantly. Either the biceps or triceps reflex may be abolished. In a few of our cases there has been an additional median, radial, or posterior interosseous nerve palsy that can be isolated by EMG to a site distal to the plexus (see below).

The term neuralgic amyotrophy was applied to this symptom complex by Parsonage and Turner, who wrote extensively on the subject. Their term for the condition is not entirely inappropriate, since the clinical and EMG findings suggest a lesion of the peripheral nerves of the shoulder girdle and upper arm rather than the cords of the plexus. Actually, the exact site of the pathologic changes has not been established. Such patients usually have no fever, leukocytosis, or increased sedimentation rate. Occasionally there is a mild pleocytosis (10 to 50 white blood cells per cubic millimeter) and slightly increased protein in the CSF.

There are probably highly restricted forms of the same disorder that affects only one or two nerves of the brachial plexus. The most common of these is an isolated palsy of the serratus anterior (long thoracic nerve). The suprascapular, axillary, posterior interosseus, and phrenic nerves are other common solitary sites of affection. In the case of a unilateral phrenic nerve paralysis, there is mild dyspnea on exertion and one hemidiaphragm is found to be elevated on the chest film. When the process is not progressive and no mediastinal lesion can be detected, the phrenic palsey can be assumed to fall into this idiopathic category.

Duchowey and colleagues have described a patient in whom a typical brachial neuritis occurred as part of a febrile illness that proved to be due to CMV infection, and...
the same has been observed in patients with AIDS. A few outbreaks have been recorded and prompted the suggestion that the Coxsackie virus is the cause. The therapeutic use of interleukin-2 and interferon has apparently precipitated a few cases. Formerly, when animal antisera were in common use, this entity was rather frequent, but now it is rare. About 3 to 10 days after the administration of horse tetanus antitoxin, for example, there occurred the acute onset of severe pain in the shoulder and upper arm on one side, sometimes on both sides. The pain coincided with or followed, within a day or two, the development of other systemic manifestations of serum sickness. Several days after the onset of pain, with brachial neuritis of idiopathic type, weakness about the shoulder was noted, usually in the distribution of the upper (lateral) trunk of the brachial plexus. Or there would be only an isolated mononeuropathy (most often of the axillary, suprascapular, musculocutaneous, or long thoracic nerve). Plexitis following vaccines is similar. It has been seen after injection of tetanus toxoid, typhoid-paratyphoid vaccine, and triple vaccine (pertussis, diphtheria, and tetanus).

Plexitis also occurs as an uncommon idiopathic complication of the postpartum state (Lederman and Wilbourn). Some of these instances are repetitive or bilateral and some are familial, but otherwise the plexitis has no distinguishing features from the idiopathic type of brachial neuritis.

One must differentiate brachial plexitis from the following conditions: (1) spondylosis or ruptured disc with root involvement, particularly the C5 and C6 roots, in which paralysis is rarely as severe as it is in plexitis; (2) brachialgia from bursitis or “rotator cuff syndrome”; (3) polymyalgia rheumatica; (4) entrapment neuropathies, particularly of the subscapular or dorsal scapular nerve; (5) carcinomatous plexopathy; (6) radiation plexopathy; and, rarely, (7) saccor and other granulomatous infiltrations. The special case of plexopathy in patients with a genetic proclivity to pressure palsies is discussed below.

Pathologic data are sparse, but Suarez and coworkers have reported collections of intense mononuclear inflammation in fascicles of the plexus obtained by biopsy. Lymphocytes could be found endoneurally and perivascularly in the epineurium. The disease has not been reproduced in the experimental animal. Therapy is purely symptomatic. In some, the condition is embarking on a course of steroids and, in a few cases, other immunosuppressive methods have been used. The outcome in some of these patients is favorable, and in other instances, no cause may be apparent. The anatomic diagnosis depends on recognition of paralysis of abduction of the arm (in testing for a triple vaccine, the outstretched arm is pushed forward against resistance. This nerve is often involved as part of a brachial plexus neuropathy of either the sporadic or inherited type. It may be affected during infectious illnesses and may be injured in gymnasts or as a result of local pressure, from carrying heavy objects on the shoulder (“meat-packer’s neuropathy”). An entrapment syndrome has also been reported; it is characterized by pain and weakness on external rotation of the shoulder joint with atrophy of the infraspinatus muscle (see also Lederman and Wilbourn). Rarely, radiation may give rise, many years later, to a malignant tumor of nerve or the surrounding connective tissue. Myokymic discharges and fasciculations are particularly suggestive of radiation damage.

Heredofamilial Plexopathy and Pressure Palsies Rarely, an acute recurrent brachial neuropathy occurs in families. The pattern of inheritance is autosomal dominant, and the attacks occur most commonly in the second and third decades of life. The authors have observed this syndrome in three generations of a family, some members having had three to five attacks at ages ranging from 3 to 45 years. Lower cranial nerve involvement and mononeuropathies in other limbs were combined in some instances (see Table 48-1). Again, the clinical course is benign. We have also seen the concomitance of one of brachial plexitis in an adult brother and sister who shared the same household but had no family history of a similar problem. A shared susceptibility to viral or environmental agents was suspected.

Brachial Neuropathy following Radiation Therapy This is usually a complication of irradiation of the axilla for carcinoma of the breast. Stoll and Andrews studied a group of 117 such patients who were treated with high-voltage, small-field therapy and had received either 6300 or 5775 cGy in divided doses. Of those receiving the larger dose, 73 percent developed weakness and sensory loss in the hand and fingers between 4 and 30 months after treatment, most of them after 12 months. In one autopsied case, the brachial plexus was enmeshed in dense fibrous tissue; distal to this zone, both myelin and axons had disappeared (secondary to wallerian degeneration), presumably as a result of entrapment of nerves in fibrous tissue; possibly a vascular factor was also operative.

Kori and coworkers, who analyzed the brachial plexus lesions in 100 patients with cancer, also found that doses exceeding 6000 cGy were associated with radiation damage. Usually the upper plexus was involved and was associated with a painless lymphedema. In patients who received lower doses, the development of brachial plexus symptoms is delayed, and the nerve palsies may be bilateral (see also Lederman and Wilbourn). Rarely, radiation may give rise, many years later, to a malignant tumor of nerve or the surrounding connective tissue. Myokymic discharges and fasciculations are particularly suggestive of radiation damage.

Heredofamilial Plexopathy and Pressure Palsies (See Chap. 33).

Brachial Mononeuropathies (See Table 48-1)

Long Thoracic Nerve (of Bell) This nerve is derived from the fifth, sixth, and seventh cervical nerves and supplies the serratus anterior muscle, which fixes the lateral scapula to the chest wall. Paralysis of this muscle results in an inability to raise the arm over the head and winging of the medial border of the scapula when the outstretched arm is pushed forward against resistance. The nerve is injured most commonly by carrying heavy weights on the shoulder or by strapping the shoulder down. As stated above, the neuropathy sometimes followed immunization. At times it may be the only affected nerve in a brachial plexus neuropathy of either the inherited or idiopathic variety (Phillips). Suprascapular Nerve This nerve is derived from the fifth (mainly) and sixth cervical nerves and supplies the supraspinatus and infraspinatus muscles. Lesions may be recognized by the presence of atrophy of these muscles and weakness of the first 15 degrees of abduction (supraspinatus) and of external rotation of the arm at the shoulder joint (infraspinatus). The latter is tested by having the patient flex the forearm and then, pinning the elbow to the side, asking him to swing the forearm backward against resistance. This nerve is often involved as part of a brachial plexus neuropathy of either the sporadic or inherited type. It may be affected during infectious illnesses and may be injured in carrying heavy objects on the shoulder (“meat-packer’s neuropathy”). An entrapment syndrome has also been reported; it is characterized by pain and weakness on external rotation of the shoulder joint with atrophy of the infraspinatus muscle (Table 46-1). Decompression of the nerve where it enters the spinoglenoid notch relieves the condition.

Axillary Nerve This nerve arises from the posterior cord of the brachial plexus (mainly from the C5 root, with a smaller contribution from C6) and supplies the teres minor and deltoid muscles. It may be involved in dislocations of the shoulder joint, fractures of the neck of the humerus, serum- and vaccine-induced neuropathies, and brachial neuritis; in other instances, no cause may be apparent. The anatomic diagnosis depends on recognition of paralysis of abduction of the arm (in testing this function, the angle between the side of the chest and the arm must be greater than 15 degrees and less than 90 degrees), wasting of the deltoid muscle, and slight impairment of sensation over the outer aspect of the shoulder.

Musculocutaneous Nerve The origin of this nerve is from the fifth and sixth cervical roots. It is a branch of the lateral cord of the brachial plexus and innervates the biceps brachii, brachialis, and coracobrachialis muscles. Lesions may be recognized by weakness in flexion of the supinated forearm. Sensation may be impaired along the radial and volar aspects of the forearm (lateral cutaneous nerve). Isolated lesions of this nerve are usually the result of fracture of the humerus.

Radial Nerve This nerve is derived from the sixth to eighth (mainly the seventh) cervical roots and is the distal extension of the posterior cord of the brachial plexus. It innervates the triceps, brachioradialis, and supinator muscles and continues below the elbow as the posterior interosseous nerve, which innervates the extensor muscles of the wrist and fingers, and the abductor of the thumb, and the extensors of the fingers at both joints. A complete radial nerve lesion results in paralysis of extension of the elbow, flexion of the elbow with the forearm midway between pronation and supination (due to paralysis of the brachioradialis muscle), supination of the forearm, extension of the wrist and fingers, and extension and abduction of the thumb in the plane of the palm. If the lesion is confined to the posterior interosseous nerve, only the extensors of the wrist and fingers are affected. Sensation is impaired over the posterior aspects of the forearm and over a small area on...
The radial nerve may be compressed in the axilla (“crutch palsy”) but more frequently at a lower point, where the nerve winds around the humerus (Table 46-4); pressure palsies incurred during an alcoholic stupor and fractures of the humerus commonly injure the nerve at the latter site. It is susceptible to lead intoxication and is frequently involved as part of a neuralgic amyotrophy.

<tbody>
<tr>
<td>Median Nerve</td>
<td>This nerve originates from the fifth cervical to the first thoracic roots but mainly from the sixth cervical root and is formed by the union of the medial and lateral cords of the brachial plexus. It innervates the pronators of the forearm, long finger flexors, and abductor and opponens muscles of the thumb and is a sensory nerve to the palmar aspect of the hand. Complete interruption of the median nerve results in inability to pronate the forearm or flex the hand in a radial direction, paralysis of flexion of the index finger and terminal phalanges of the thumb, weakness of flexion of the remaining fingers, weakness of opposition and abduction of the thumb in the plane at a right angle to the palm (abductor and flexor pollicis brevis), and sensory impairment over the radial two-thirds of the palm and dorsum of the distal phalanges of the index and third fingers. The nerve may be injured in the axilla by dislocation of the shoulder and in any part of its course by stab, gunshot, or other types of wounds. Incomplete lesions of the median nerve between the axilla and wrist may result in causalgia (see further on).</td>
</tr>
<tr>
<td>Carpal Tunnel Syndrome</td>
<td>Compression of the nerve at the wrist (carpal tunnel syndrome) is the most common disorder affecting the median nerve and the most frequent nerve entrapment syndrome. This is usually due to excessive use of the hands and occupational exposure to repeated trauma. Infiltration of the transverse carpal ligament with amyloid (as occurs in multiple myeloma) or thickening of connective tissue in rheumatoid arthritis, acromegaly, mucopolysaccharidosis, and hypothyroidism are less commonly identified causes. It is not uncommon for the condition to make its appearance during pregnancy. In elderly individuals, the cause of the carpal tunnel syndrome is often not apparent.</td>
</tr>
<tr>
<td>Dysestheasias and pain in the fingers, referred to for many years as “acroparesthesiae” and attributed to cervical ribs, came to be recognized as a syndrome of median nerve compression only in the early 1950s. According to Kremer and colleagues, it was McArdle, in 1949, who first suggested that the cause of this syndrome was a compression of the median nerve at the wrist and that the symptoms would be relieved by division of the flexor retinaculum forming the ventral wall of the carpal tunnel. The paresthesias are characteristically worse during the night. As pointed out in Chap. 11, the pain in carpal tunnel syndrome often radiates into the forearm and even into the region of the biops and rarely to the shoulder. The syndrome is essentially a sensory one; the loss or impairment of superficial sensation affects the thumb, index, and middle fingers (especially the index finger) and may or may not split the ring finger (splitting does not occur with a plexus or root lesion). Weakness and atrophy of the abductor pollicis brevis and other median-innervated muscles occur in only the most advanced cases of compression. Electrophysiologic testing confirms the diagnosis and explains cases in which operation has failed (see also the review by Stevens).</td>
<td></td>
</tr>
<tr>
<td>Surgical division of the carpal ligament with decompression of the nerve is curative. Splinting of the wrist, to avoid flexion, almost always relieves the discomfort but denies the patient the full use of the hand. It is a useful temporizing measure, however, as it is the injection of hydrocortisone into the carpal tunnel.</td>
<td></td>
</tr>
<tr>
<td>Another site of compression of the median nerve is at the elbow, where the nerve passes between the two heads of the pronator teres, or just above that point behind the bicipital aponeurosis. It gives rise to the pronator syndrome, in which forceful pronation of the forearm produces an aching pain (Table 46-4). There is weakness of the abductor pollicis brevis and opponens muscles and numbness of the first three digits and palm.</td>
<td></td>
</tr>
<tr>
<td>Ulnar Nerve</td>
<td>This nerve is derived from the eighth cervical and first thoracic roots. It innervates the ulnar flexor of the wrist, the ulnar half of the deep finger flexors, the adductors and abductors of the fingers, the adductor of the thumb, the third and fourth lumbricals, and muscles of the hypothenar eminence. Complete ulnar paralysis is manifest by a characteristic claw-hand deformity; wasting of the small hand muscles results in hyperextension of the fingers at the metacarpophalangeal joints and flexion at the interphalangeal joints. The flexion deformity is most pronounced in the fourth and fifth fingers, since the lumbrical muscles of the second and third fingers, supplied by the median nerve, counteract the deformity. Sensory loss occurs over the fifth finger, the ulnar aspect of the fourth finger, and the ulnar border of the palm.</td>
</tr>
<tr>
<td>The ulnar nerve is vulnerable to pressure in the axilla from the use of crutches, but it is most commonly injured at the elbow by fracture or dislocation involving the joint. Delayed (“tardive”) ulnar palsy may occur many years after an injury to the elbow that had resulted in a cubitus valgus deformity of the joint. Because of the deformity, the nerve is stretched in its groove over the ulnar condyle, and its superficial location renders it vulnerable to compression. A shallow ulnar groove, quite apart from abnormalities of the elbow joint, may expose the nerve to compressive injury. Anterior transposition of the ulnar nerve is a simple and effective form of treatment for these types of ulnar palsy. Compression of the nerve may occur just distal to the medial epicondyle, where it runs beneath the aponeurosis of the flexor carpi ulnaris (cubital tunnel). Flexion at the elbow causes a narrowing of the tunnel and constriction of the nerve. This type of ulnar palsy is treated by incising the aponeurotic arch between the olecranon and medial epicondyle. Yet another site of ulnar nerve compression is in the ulnar tunnel, at the wrist. Prolonged pressure on the ulnar part of the palm may result in damage to the deep palmar branch of the ulnar nerve, causing weakness of small hand muscles but no sensory loss. This site is most often implicated in patients who hold tools or implements tightly in the hand for long periods (we have seen it in machinists and cake decorators). The lesion is localizable by nerve conduction studies.</td>
<td></td>
</tr>
<tr>
<td>A characteristic syndrome of burning pain and associated symptoms (causalgia) may follow incomplete lesions of the ulnar nerve (or other major nerves of the limbs) and is described further on.</td>
<td></td>
</tr>
<tr>
<td>Lumbosacral Plexus and Crural Neuropathies</td>
<td>The twelfth thoracic, first to fifth lumbar, and first, second, and third sacral spinal nerve roots compose the lumbosacral plexuses and innervate the muscles of the lower extremities (see Fig. 46-5). The following are the common plexus and crural nerve palsies.</td>

Lumbosacral Plexus Lesions

Excluding it as does from the upper lumbar area to the lower sacrum and passing near several lower abdominal and pelvic organs, the lumbosacral plexus contains a number of special innervation and diseases, most of them secondary. The cause of invasion may be difficult to ascertain because the primary disease is often not within reach of the palpating fingers, either from the abdominal side or through the anus and vagina; even refined radiologic techniques may not reveal it. Diagnosis involves exclusion of spinal root (cauda equina) lesions by EMG, examination of CSF, CT myelography, and MRI. The clinical findings help to focus studies on the appropriate part of the lumbosacral plexus.

The main effects of upper lumbosacral plexus lesions are weakness of flexion and adduction of the thigh and extension of the leg, with sensory loss over the anterior thigh and leg; these effects must be distinguished from the symptoms and signs of femoral neuropathy (see below). Lower plexus lesions weaken the posterior thigh, leg, and foot muscles and abolish sensation over the first and second sacral segments (sometimes the lower sacral segments also). Lesions of the entire plexus, which occasionally occur, cause a weakness of or paralysis of all leg muscles, with atrophy, areflexia, anesthesia from the toes to the perianal region and autonomic loss with warm, dry skin. Usually there is edema of the leg as well.

The types of lesions that involve the lumbosacral plexus are usually not those affecting the brachial plexus. Trauma is a rarity except with massive pelvic, spinal, and abdominal injuries because the plexus is so well protected. Occasionally a pelvic fracture will damage the sciatic nerve as it issues from the plexus. In contrast, some part of the plexus may be damaged during surgical procedures on abdominal and pelvic organs, often for reasons that may not be entirely clear. For example, hysterectomy has on a number of occasions led to neurologic consultation in our hospitals because of numbness and weakness of the anterior thigh. Either the cords of the upper part of the plexus or the femoral nerve was compressed by retraction against the psoas muscle or, in vaginal hysterectomy (when thighs are flexed, abducted, and externally rotated), the femoral nerve was compressed against the inguinal ligament. A similar type of injury may be associated with childbirth. Lumbar sympathectomy has also been associated with upper plexus lesions, of which the most disabling sequelae are burning pain and hypersensitivity of the anterior thigh. Appendectomy, pelvic explorations, and hernial repair may injure branches of the upper plexus (ilioguinal, iliohypogastric, and genitofemoral nerves), with severe pain and slight sensory loss in the distribution of one of these nerves. The pain may last for months or a year or more.

The lumbosacral plexus may be compressed by an aortic atherosclerotic aneurysm. Usually there is pain that radiates to the hip, the anterior thigh, and occasionally the flank. Slight weakness in hip flexion and altered sensation over the anterior thigh are found on examination. Plexus involvement with tumors is commonplace and at times presents special difficulties in diagnosis. Carcinoma of either the cervix or prostate may seed itself along the perineural lymphatics and cause pain in the groin, thigh, knee, or back without much in the way of sensory, motor, or reflex loss. The pain is more often unilateral than bilateral. The CSF and spinal canal (by MRI) are normal. Testicular, uterine, ovarian, and colonic tumors or retroperitoneal lymphomas, by extending along the pararenal gutter, implicate various parts of the lumbosacral plexus. Instances of endometriosis that involve the plexus have also been reported. The neurologic symptoms are projected at a distance in the leg and may or may not be confined to the territory of one nerve. Pelvic and rectal examinations may be negative, and CT scanning and MRI may be necessary to show such lesions. If all these examinations are negative, exploratory laparotomy may have to be undertaken.

In cancer patients, it is sometimes difficult to distinguish the effects of radiation on the lumbosacral plexus from those of metastatic tumor, as is the case in relation to the brachial plexus. Thomas and colleagues found that the earliest symptom in metastatic lumbosacral plexopathy was pain, whereas in radiation plexopathy it was weakness. Plexopathy from metastatic tumor was usually unilateral and detectable by CT scanning; radiation plexopathy was usually bilateral and not evident in CT scans. Fasciculations and myokymia were more likely to be seen in patients with radiation plexopathy, which seemingly occurs more frequently in patients with diabetic neuropathy.

Reference has already been made to femoral nerve injury during parturition, but other puerperal complications are also observed. Back pain in the latter part of pregnancy is common, but there are rare instances in which the patient complains of severe pain in the back of one or both thighs during labor and after delivery has numbness and weakness of the leg muscles, with diminished ankle jerks. *Parturitional lumbosacral plexus injuries* occur with a frequency of 1 per 2000 deliveries. This type of plexus injury is usually unilateral and is manifest by pain in the thigh and leg and symptoms and signs of involvement of the superior gluteal and sciatic nerves (Feasby et al). The attribution of these symptoms to pressure of the fetal head on the sacral plexus(es) is conjectural. A limited plexopathy, occurring after difficult vaginal delivery, mainly impairs sensation in the perineum and sphincteric function (Israel et al). The perineal muscles may show signs of denervation. Protrusion of an intervertebral disc may also occur during delivery.

A neuralgic amyotrophy or lumbosacral plexitis, analogous to the brachial variety, is observed from time to time. Bradley and coworkers have recorded such cases. After causing widespread unilateral or bilateral sensory, motor, and reflex changes in a leg, lumbosacral plexitis may leave the patient with dysesthesias as troublesome as those that follow herpes zoster (which may also occur at this level). Some patients have had an exploration of the cauda equina (for ruptured disc), even though loss of sweating and warmth of the feet should have indicated interruption of autonomic fibers by lesions in peripheral nerves. (Lesions that are confined to nerve roots spare autonomic functions.) The sedimentation rate may be elevated. Immunosuppressant drugs were beneficial in 4 of 6 cases (Bradley et al). Sarcoidosis is another cause and may be responsive to corticosteroids. Diabetic amyotrophy, due to involvement of the lumbar plexus(es), has a vascular origin (page 1397), and there are probably also nondiabetic vascular lesions that give rise to lumbar and upper leg pain and weakness in proximal muscles. The plexus lesions of polyarteritis nodosa, unilateral or bilateral, are also vascular. Polyarteritis nodosa multiplex, the manifestation of mononeuropathy multiplex in diabetics is augmented by an associated occlusive vascular disease of the lower extremities. Diabetic mononeuropathy multiplex is discussed in an earlier part of this chapter and protruded intervertebral disc syndromes are described in Chap. 11.

**Figure 46-5** Diagram of the lumbar plexus (left) and the sacral plexus (right). The lumbosacral trunk is the liaison between the lumbar and the sacral plexuses. (From Haymaker and Woodhall by permission.)

*Lumbosacral Plexus Lesions*

Enters the thigh beneath Poupart’s ligament, lateral to the femoral artery. Branches arising within the pelvis supply the iliacus and psoas muscles. Just below the innervation of the internal and external rotators. The adductors have the added function of flexing the hip. The nerve may be injured by the fetal head or forceps during the course of a difficult labor or compressed by an obturator hemia. Rarely, it is affected in diabetes, polyarteritis nodosa, and osteitis pubis and by retroperitoneal spread of carcinoma of the cervix, uterus, and other tumors (Rogers et al).

**Femoral Nerve**

This nerve is formed from the second, third, and fourth lumbar roots. Within the pelvis it passes along the lateral border of the psoas muscle and enters the thigh beneath Paupert's ligament, lateral to the femoral artery. Branches arising within the pelvis supply the iliacus and psoas muscles. Just below Paupert's ligament the nerve splits into anterior and posterior divisions. The former supplies the pectineus and sartorius muscles and carries sensation from the anteromedial surface of the thigh; the posterior division provides the motor innervation to the quadriiceps and the cutaneous innervation to the medial side of the leg from the knee to the internal malleolus.
Following injury to the femoral nerve, there is weakness of extension of the lower leg, wasting of the quadriceps muscle, and failure of fixation of the knee. The knee jerk is abolished. If the nerve is injured proximal to the origin of the branches to the iliacus and psoas muscles, there is weakness of hip flexion. The adductor of the thigh (innervated by the obturator nerve) is spared, distinguishing femoral neuropathy from an L3 radiculopathy.

The commonest cause of femoral neuropathy is diabetes. The nerve may be involved by pelvic tumors. Not uncommon is injury of the nerve during pelvic operations. Usually this is the result of improper placement of retractors, which may compress the nerve directly or indirectly by undue pressure on the psoas muscle. Bleeding into the iliacus muscle or the retroperitoneum, observed in patients receiving anticoagulants and in hemophiliacs, is a relatively common cause of isolated femoral neuropathy (Goodfellow et al). The presenting symptom of iliacus hematoma is pain in the groin spreading to the lumbar region or thigh, in response to which the patient assumes a characteristic posture of flexion and lateral rotation of the hip. A palpable mass in the iliac fossa and the signs of femoral nerve compression (quadriceps weakness and loss of knee jerk) follow in a day or two. Infarction of the nerve may occur in the course of diabetes mellitus and polyarteritis nodosa. Not infrequently acute femoral neuropathy is of indeterminate cause.

**Sciatic Nerve**

This nerve is derived from the fourth and fifth lumbar and first and second sacral roots, for which reason a ruptured disc at these levels may simulate sciatic neuropathy (sciatica). The sciatic nerve supplies motor innervation to the hamstring muscles and all the muscles below the knee through its two divisions, the tibial and peroneal nerves. (see below); the sciatic nerve conveys sensory impulses from the posterior aspect of the thigh, the posterior and lateral aspects of the leg, and the entire sole. In complete sciatic paralysis, the knee cannot be flexed and all muscles below the knee are paralyzed. Weakness of gluteal muscles and pain in the buttock and posterior thigh point to nerve involvement in the pelvis. Lesions beyond the sciatic notch spare the gluteal muscles but not the hamstrings. Partial compressive lesions are more common and tend to involve peroneal-innervated muscles more than tibial ones, giving the impression of a peroneal palsy.

As mentioned, rupture of one of the lower lumbar intervertebral discs is perhaps the commonest cause of sciatica although it does not directly involve the sciatic nerve. The associated motor and sensory findings allow localization of the root compression (L4-5 disc compressing L5 root: pain in posterolateral thigh and leg with numbness over the inner foot and weakness of dorsiflexion of the foot and toes; L5-S1 disc compressing S1 root: pain in posterior thigh and leg, numbness of lateral foot, weakness of foot dorsiflexion and loss of ankle jerk).

The sciatic nerve is commonly injured by fractures of the pelvis or femur, fracture/dislocation of the hip, gunshot wounds of the buttock and thigh, and the injection of toxic substances into the lower gluteal region. Total hip arthroplasty is another common cause. Tumors of the pelvis (sarcomas, lipomas) or gluteal region may compress the nerve. Sitting for a long period with legs flexed and abducted (lotus position) under the influence of narcotics or barbiturates or lying flat on a hard surface in a sustained stator may severely injure one or both sciatic nerves or branches thereof. The nerve may be involved by neurofibromas and infections and by ischemic necrosis in diabetes mellitus and polyarteritis nodosa. Cryptogenic forms also arise and are often more frequent than those of identifiable cause. Partial lesions of the sciatic nerve occasionally result in causalgia (see further on).

**Common Peroneal Nerve**

Just above the popliteal fossa the sciatic nerve divides into the tibial nerve (medial, or internal, popliteal nerve) and the common peroneal nerve (external, popliteal nerve). The latter passes around the head of the fibula to the anterior aspect of the leg, giving off the superficial peroneal nerve (to the anterior tibial, or deep peroneal, nerve. Branches of the latter supply the dorsiflexors of the foot and toes and carry sensory fibers from the dorsum of the foot and lateral aspect of the lower leg. There was weakness of dorsiflexion of the foot in all of the 116 cases of common peroneal neuropathy reported by Katzir and Wilbourn, and numbness of the dorsum of the foot was present in most cases. Weakness of eversion of the foot is usually demonstrable; inversion, a function of the L5 and tibial nerve, is spared. Pain is variable; it was quite severe in a few of our patients.

Pressure during an operation or sleep or from tight plaster casts, obstetric strinups, habitual and prolonged crossing of the legs while seated, and tight knee boots are the most frequent causes of injury to the common peroneal nerve. The point of compression of the nerve is where it passes over the head of the fibula. Ermation increases the incidence of these types of compressive injury. The nerve may also be affected in diabetic neuropathy and injured by fractures of the upper end of the fibula. A Baker cyst, which consists of inflamed synovium extending into the retropopliteal space, and it may be damaged by muscle swelling or small hematomas behind the knee in asthenic athletes.

**Tibial Nerve**

This, the other of the two divisions of the sciatic nerve (it divides in the popliteal fossa), supplies all of the calf muscles—i.e., the plantar flexors and invertors of the foot and toes—after which it continues as the posterior tibial nerve. This nerve passes through the tarsal tunnel, an osseofibrous channel that runs along the medial aspect of the calcaneus and is roofed by the flexor retinaculum. The tunnel also contains the tendons of the tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles and the vessels to the foot. The posterior tibial nerve terminates under the flexor retinaculum and divides into medial and lateral plantar nerves (supplying the small muscles of the foot).

Complete interruption of the tibial nerve results in a calcaneovalgus deformity of the foot, which can no longer be plantar-flexed and inverted. There is loss of sensation over the plantar aspect of the foot.

The posterior tibial nerve may be compressed in the tarsal tunnel (entrapment syndrome) by thickening of the tendon sheaths or the adjacent connective tissues or by osteoarthritic changes. Tingling pain and burning over the sole of the foot appear after standing or walking for a long time. Usually there is no motor deficit. Relief is obtained by severing the flexor retinaculum.

**Entrapment Neuropathies**

Reference is made in several places in the preceding pages to entrapment neuropathies. A nerve passing through a tight canal is trapped and subjected to constant movement or pressure, forces not applicable to nerves elsewhere. The epineurium and perineurium become greatly thickened, strangling the nerve, with the additional possibility of demyelination. Function is gradually impaired, sensory more than motor, and the symptoms fluctuate with activity and rest. The most frequently compressed nerves are the median, ulnar, peroneal, tibial, and plantar in approximately that order. It is well to keep in mind the systemic processes that enhance the additional possibility of demyelination. Function is gradually impaired, sensory more than motor, and the symptoms fluctuate with activity and rest. The most frequently compressed nerves are the median, ulnar, peroneal, tibial, and plantar in approximately that order. It is well to keep in mind the systemic processes that enhance the incidence of these types of compressive injury. The nerve may also be affected in diabetic neuropathy and injured by fractures of the upper end of the fibula. A Baker cyst, which consists of inflamed synovium extending into the retropopliteal space, and it may be damaged by muscle swelling or small hematomas behind the knee in asthenic athletes.

**Causalgia**

Causalgia and Reflex Sympathetic Dystrophy

(See also pages 148 and 230.) Causalgia was the name applied by Weir Mitchell to a rare (except in time of war) type of peripheral neuralgia consequent upon trauma, with partial interruption of the median or ulnar nerve andperhapes less often, the sciatic or peroneal nerve. It is characterized by persistent, severe pain in the hand or foot, most pronounced in the digits, palm of the hand, or sole. The pain has a burning quality and frequently radiates beyond the territory of the injured nerve. The painful parts are exquisitely sensitive to contactual stimuli, so the patient cannot bear the pressure of clothing or drafts of air; even ambient heat, cold, noise, or emotional stimuli intensify the causalgic symptoms. The affected extremity is kept protected and immobile, often wrapped in a cloth moistened with cool water. Sudomotor, vasomotor, and, later, trophic abnormalities are usual accompaniments of the pain. The skin of the affected part is moist and warm or cool and soon becomes shiny and smooth, at times scaly and discolored.

A number of theories have been proposed to explain the causalgic syndrome. For many years it was attributed to a short-circuiting of impulses, the result of an artificial connection between efferent sympathetic and somatic afferent pain fibers at the point of the nerve injury. The demonstration that the causalgic pain could be abolished by depletion of neurotransmitters at the sympathetic adrenergic endings shifted the presumed site of sympathetic-afferent interaction to the nerve terminals and suggested that the abnormal cross-excitation is chemical rather than electrical in nature. An explanation favored in recent years is that an abnormal adrenergic sensitivity develops in injured nociceptors and that circulating or locally secreted sympathetic neurotransmitters trigger the painful afferent activity. Another theory holds that a sustained period of bombardment by sensory pain impulses from one region results in the sensitization of central sensory structures. "True causalgia" of this type can be counted upon to respond favorably, if only temporarily, to procaine block of the appropriate sympathetic ganglia and, over the longer run, to regional sympathectomy. Prolonged cooling and the intravenous injection of guanethidine into the affected limb (with the venous return blocked for several minutes) may alleviate the pain for days or longer. Epidural infusions, particularly of analgesics or ketamine, infusion of bispho-phonates and spinal cord stimulators are other forms of treatment (Kemler). The roles of the central and sympathetic nervous systems in causalgic pain have been critically reviewed by Schott and by Schwartzman and McLellan.
The term causalgia is best reserved for the syndrome described above—i.e., persistent burning pain and abnormalities of sympathetic innervation consequent upon trauma to a major nerve in an extremity. Others have applied the term to a wide range of conditions that are characterized by persistent burning pain but have only an inconstant association with sudomotor, vasomotor, and trophic changes and an unpredictable response to sympathetic blockade. These latter states, which have been described under a plethora of titles (Sudeck atrophy of bone, minor causalgia, shoulder-hand syndrome, algoneurodystrophy), may follow nontraumatic lesions of the peripheral nerves or even lesions of the CNS (“minicausalgia”).

Also, we have no explanation for the so-called causalgia-dystonia syndrome (Bhatia et al) in which a fixed dystonic posture is engrafted on a site of causalgia pain. The clinical features of both the causalgic and dystonic elements of the syndrome were somewhat unusual in the cases of these investigators. The degree of injury was often trivial or nonexistent and no signs of a neuropathic lesion were evident. Remarkably, both the causalgia and dystonia spread from their initial sites to widely disparate parts of the limbs and body. The syndrome did not respond to any form of treatment, although some patients recovered spontaneously. Its origin is not explained.

Traumatic Interruption of Nerves

The management of such lesions is best delegated to specialized neurosurgeons, but several aspects involve the neurologist. Surgical advances have allowed the successful apposition of severed nerve ends. The current recommendations are that a sharp and clean division should be repaired by end-to-end suturing of the stumps within 72 h. In cases where the nerve is found on exploration to be bluntly severed with ragged ends, most surgeons recommend tacking the free ends to adjacent connective tissue planes and attempting repair in 2 to 4 weeks. The majority of injuries however, are blunt and retain some continuity of the nerve. If such continuity of the nerve across the traumatized region can be demonstrated by electrophysiologic examination, operation is not necessary. In the absence of improvement in the clinical and electrophysiologic features after several months (up to 6 months for plexus lesions) surgical repair may facilitate limited healing.

CHAPTER REFERENCES

The cranial nerves are susceptible to a number of special diseases, some of which never affect the spinal peripheral nerves. For this reason alone they deserve to be considered separately. Certain of them have already been discussed: namely, disorders of olfaction, in Chap. 12; of vision and extraocular muscles, in Chap. 13 and Chap. 14; of cochlear and vestibular function, in Chap. 15; and craniofacial pain in Chap. 10. There remain to be described the disorders of the facial (seventh) nerve and of the lower cranial nerves (IX to XII) as well as certain aspects of disordered trigeminal (fifth) nerve function. These are considered below.

The Fifth, or Trigeminal, Nerve

Anatomic Considerations

The fifth nerve (Fig. 47-1) is a mixed sensory and motor nerve. It conducts sensory impulses from the greater part of the face and head; from the mucous membranes of the nose, mouth, and paranasal sinuses; and from the cornea and conjunctiva. It also innervates the dura of the anterior and middle cranial fossae. The cell bodies of the sensory part of the nerve lie in the gasserian, or semilunar, ganglion. This, the largest sensory ganglion in humans, lies in the medial part of the middle cranial fossa at the base of the cranium. The central axons of the ganglion cells form the sensory root. These fibers, on entering the midpons, divide into short ascending and long descending branches. The former are concerned mainly with tactile and light pressure sense and synapse with second-order neurons in the principal sensory nucleus. Proprioceptive afferents from facial muscles and the masseter terminate in the mesencephalic nucleus. The fibers that mediate pain and temperature sensation do not end in these nuclei but form the long descending branches of the spinal trigeminal tract. The latter pathway, which contains both facilitatory and inhibitory fibers, together with its nucleus, extends from the junction of the pons and medulla to the uppermost segments (C2 or C3) of the spinal cord (facial pain has been relieved after medullary trigeminal tractotomy). From all parts of the principal sensory and spinal nuclei, second-order fibers cross to the opposite side and ascend to the thalamus. They come to lie in the most medial part of the spinothalamic tract and lateral part of the medial lemniscus. These systems of fibers are called the trigeminothalamic tract. In addition, the secondary trigeminal neurons project to the facial and hypoglossal nuclei bilaterally, the salivatory nuclei, the cuneate nuclei of the upper cervical segments, and other cranial nerve nuclei. The main sensory and spinal trigeminal nuclei receive fibers from the reticular formation, the thalamus, the nucleus solitarius, and the sensory cortex. The spinal nucleus is a continuation of the spinal tract of Lissauer and substantia gelatinosa; the main sensory nucleus is a continuation of the nucleus of the medial lemniscus.

Figure 47-1 Scheme of the trigeminal nuclei and some of the trigeminal reflex arcs. I, ophthalmic division; II, maxillary division; III, mandibular division. (From Carpenter MB, Sutin J: Human Neuroanatomy, 8th ed. Baltimore, Williams & Wilkins, 1982, by permission.)

The peripheral branches of the gasserian ganglion form the three sensory divisions of the nerve. The first (ophthalmic) division passes through the superior orbital fissure; the second (maxillary) division leaves the middle fossa through the foramen rotundum; and the third (mandibular), through the foramen ovale.

The motor portion of the fifth nerve, which supplies the masseter and pterygoid muscles, has its origin in the trigeminal motor nucleus in the midpons; the exiting fibers pass underneath the gasserian ganglion and become incorporated into the mandibular nerve. The masseter and pterygoid muscles are utilized in chewing and are implicated in a number of brainstem reflexes, the best known of which is the jaw jerk. Tapping the chin with the jaw muscles relaxed stimulates proprioceptive afferents that terminate in the mesencephalic nucleus of the midbrain, which sends collaterals to the motor nucleus of the fifth nerve and causes the masseters to contract. This reflex is enhanced in spastic bulbar (pseudobulbar) palsy. Another pontine reflex that utilizes afferent trigeminal sensory nerves is the blink reflex. Tapping of the brow or bridge of the nose evokes bilateral blink through activation of the orbicularis oculi muscles (facial nerve efferents). Touching the eyelids and cornea (corneal reflex) does the same.

Because of their wide anatomic distribution, complete interruption of both the motor and sensory fibers of the trigeminal nerve is rarely observed. On the other hand, partial affection of the trigeminal nerve, particularly of the sensory part, is not uncommon. The various cranial nerve and brainstem syndromes in which the fifth nerve is involved are listed in Table 47-1 and Table 47-2 and Table 31-4.

Table 47-1 Extramedullary cranial nerve syndromes (see also Table 31-4 and Table 47-3)
Gradenigo syndrome.

Figure 47-2

Erythematosus, and Sjögren disease. We have seen several patients with Sjögren disease in whom the trigeminal neuropathy and the associated antibodies or autoantibodies. The symptoms may involve the other side years later. Hughes has also reported cases of trigeminal neuropathy with scleroderma, lupus, and idiopathic. The nature of the pain, its unilateral nature, and tendency to involve the second and third divisions of the trigeminal nerve, an intensity that makes the patient grimace or wince (tic), the presence of an initiating or trigger point, the lack of demonstrable sensory or motor deficit, and its response in more than half of the cases to carbamazepine, phenytoin, and other drugs are characteristic. The diagnosis of the idiopathic form of trigeminal neuralgia and its differentiation from symptomatic forms—as well as from cluster headache, dental neuralgia, temporomandibular pain, and atypical facial pain—is usually not difficult, especially if there is a trigger point and no demonstrable evidence of sensory or motor impairment. The treatment of idiopathic trigeminal neuralgia is considered on page 196.

In rare instances trigeminal neuralgia is preceded or accompanied by hemifacial spasms, a combination that Cushing called tic douloureux. This is often indicative of a tumor (cholesteatoma), an aneurysmal dilatation of the basilar artery, or an arteriovenous malformation that compresses both the trigeminal and facial nerves. Trigeminal neuralgia and glossopharyngeal neuralgia (pain in the tonsillar region) may also be combined in these disease states, but these conditions are usually idiopathic.

Of the conditions that damage the branches of the trigeminal nerve, cranial injuries and fractures are the most common. The most superficial branches—the supratrochlear, supraorbital, and infraorbital—are the ones usually involved. The sensory loss is present from the time of the injury, and partial regeneration may be involved branches of the trigeminal nerve at their foramina of entry or exit. The mandibular division may be compressed by the roots of an impacted third molar (wisdom) tooth. We have several times observed numbness of the chin and lower lip (infiltration of the mental nerve) as the first indication of metastatic carcinoma of the breast and prostate and from multiple myeloma. Massey and colleagues have described 19 such cases (“numb-chin syndrome”). A perineural spread of tumor (cholesteatoma), an aneurysmal dilatation of the basilar artery, or an arteriovenous malformation that compresses both the trigeminal and facial nerves. Trigeminal neuralgia and glossopharyngeal neuralgia (pain in the tonsillar region) may also be combined in these disease states, but these conditions are usually idiopathic.

The trigeminal root may be compressed or invaded by intracranial meningiomas, acoustic neuromas, trigeminal neuromas (Fig. 47-2), cholesteatomas, and chordomas. Sinus tumors and metastatic disease may also implicate the nerve, causing pain and a gradually progressive sensory loss. The ophthalmic division of the fifth nerve may be involved in the wall of the cavernous sinus in combination with the third, fourth, and sixth nerves by a variety of processes, including thrombosis of the cavernous sinus. Tumors of the sphenoid bone (myeloma, metastatic carcinoma, squamous cell carcinoma, and lymphoepithelioma of the nasopharynx) may involve branches of the trigeminal nerve at their foramina of entry or exit. The mandibular division may be compressed by the roots of an impacted third molar (wisdom) tooth. We have several times observed numbness of the chin and lower lip (infiltration of the mental nerve) as the first indication of metastatic carcinoma of the breast and prostate and from multiple myeloma. Massey and colleagues have described 19 such cases (“numb-chin syndrome”). A perineural spread of tumor from squamous cell skin cancers of the face is discussed further on, under “Multiple Cranial Nerve Palsies.”

Table 47-3 Causes of extramedullary multiple cranial nerve palsies

Diseases Affecting the Fifth Nerve A variety of diseases may affect the peripheral branches of the trigeminal nerves, the gasserian (semilunar) ganglion, and the roots (sensory and motor). These have been ably described by Hughes. The most frequent, and at the same time the most elusive from the standpoint of its pathologic basis, is trigeminal neuralgia (tic douloureux), which is also discussed on page 196. This condition has been known since ancient times, having been described by Arateus in the first century A.D., by John Locke in 1677, by Nicolaus Andre in 1756, and by John Fothergill in 1776 (according to Katusic et al). The overall incidence rate for both sexes combined is 4.3 per 100,000 persons per year, but it is higher for women than for men (in a ratio of 3:2) and is much higher in the elderly. The mean age of onset is 52 to 58 years for the idiopathic form and 30 to 35 years for the symptomatic forms, the latter being caused by trauma or vascular, neoplastic, and demyelinating diseases. The nature of the pain, its unilateral nature, and tendency to involve the second and third divisions of the trigeminal nerve, an intensity that makes the patient grimace or wince (tic), the presence of an initiating or trigger point, the lack of demonstrable sensory or motor deficit, and its response in more than half of the cases to carbamazepine, phenytoin, and other drugs are characteristic. The diagnosis of the idiopathic form of trigeminal neuralgia and its differentiation from symptomatic forms—as well as from cluster headache, dental neuralgia, temporomandibular pain, and atypical facial pain—is usually not difficult, especially if there is a trigger point and no demonstrable evidence of sensory or motor impairment. The treatment of idiopathic trigeminal neuralgia is considered on page 196.

In rare instances trigeminal neuralgia is preceded or accompanied by hemifacial spasms, a combination that Cushing called tic douloureux. This is often indicative of a tumor (cholesteatoma), an aneurysmal dilatation of the basilar artery, or an arteriovenous malformation that compresses both the trigeminal and facial nerves. Trigeminal neuralgia and glossopharyngeal neuralgia (pain in the tonsillar region) may also be combined in these disease states, but these conditions are usually idiopathic.

Of the conditions that damage the branches of the trigeminal nerve, cranial injuries and fractures are the most common. The most superficial branches—the supratrochlear, supraorbital, and infraorbital—are the ones usually involved. The sensory loss is present from the time of the injury, and partial regeneration may be attended by constant pain, often demanding nerve block and sectioning. Stilbamidine and trichloroethylene are known to cause sensory loss, tingling, burning, and itching exclusively in the trigeminal sensory territory.

Of the various inflammatory and infectious diseases that affect the trigeminal nerves or ganglia, herpes zoster ranks first (page 799). Herpes simplex virus has been isolated from the ganglia in as many as 50 percent of routine autopsies, but in nearly all patients this virus is associated only with lesions of the skin and lips. Middle ear infections and osteomyelitis of the apex of the petrous bone may spread to the ganglion and root, also implicating the sixth cranial nerve (Gradenigo syndrome).

The trigeminal root may be compressed or invaded by intracranial meningiomas, acoustic neuromas, trigeminal neuromas (Fig. 47-2), cholesteatomas, and chordomas. Sinus tumors and metastatic disease may also implicate the nerve, causing pain and a gradually progressive sensory loss. The ophthalmic division of the fifth nerve may be involved in the wall of the cavernous sinus in combination with the third, fourth, and sixth nerves by a variety of processes, including thrombosis of the cavernous sinus. Tumors of the sphenoid bone (myeloma, metastatic carcinoma, squamous cell carcinoma, and lymphoepithelioma of the nasopharynx) may involve branches of the trigeminal nerve at their foramina of entry or exit. The mandibular division may be compressed by the roots of an impacted third molar (wisdom) tooth. We have several times observed numbness of the chin and lower lip (infiltration of the mental nerve) as the first indication of metastatic carcinoma of the breast and prostate and from multiple myeloma. Massey and colleagues have described 19 such cases (“numb-chin syndrome”). A perineural spread of tumor from squamous cell skin cancers of the face is discussed further on, under “Multiple Cranial Nerve Palsies.”

Figure 47-2

Trigeminal neuroma (schwannoma) that caused only minor sensory changes on the face seen on a gadolinium-enhanced MRI. The dumbbell-shaped tumor is pinched at the foramen ovale.

Loss of facial sensation can occur as part of a widespread sensory neuropathy that occurs as a remote effect of cancer or as part of Sjögren disease (pages 727 and 1403). Far more common is the association between isolated trigeminal neuropathy and immune-mediated connective tissue disease. Of 22 such cases described by Locky and colleagues, 9 had either scleroderma or mixed connective tissue disease, and a similar number had either organ- or non-organ-specific serum autoantibodies. The symptoms may involve the other side years later. Hughes has also reported cases of trigeminal neuropathy with scleroderma, lupus erythematosus, and Sjögren disease. We have seen several patients with Sjögren disease in whom the trigeminal neuropathy and the associated antibodies or...
inflammation of the minor salivary glands were evident well before the characteristic sicca syndrome or other systemic manifestations of the disease. The condition may remain troublesome for years. Pathologic data are limited but point to an inflammatory lesion of the trigeminal ganglion or sensory root.

Every neurologist from time to time encounters idiopathic instances of slowly evolving unilateral or bilateral trigeminal neuropathy in which there is a sensory impairment confined to the territory of the trigeminal nerve, sometimes associated with pain and paresthesias and disturbances of taste. Spillane and Wells stressed the importance of this isolated trigeminal neuropathy (it has been called "Spillane's trigeminal neuritis" in some texts). Four of their 16 patients had an associated paranasal sinusitis, but subsequent reports have failed to substantiate a causal relationship between sinusitis and cranial neuritis. One wonders how many of these individuals had an occult connective tissue disease. A less common form of idiopathic trigeminal sensory neuropathy has a more acute onset and a tendency to resolve completely or partially, in much the same manner as Bell's palsy, with which it is sometimes associated (Blay et al). A recurrent variety of uncertain origin has been reported in the dental literature. We have had experience with patients whose facial numbness was a component of an upper cervical disc syndrome that included numbness on the same side of the body. Cases such as these are reported in the literature.

A pure unilateral trigeminal motor neuropathy is a clinical rarity. Chia has described five patients in whom an aching pain in the cheek and unilateral weakness of mastication were the main features. Electroneurography (EMG) showed denervation changes in the ipsilateral masseter and temporalis muscles. The outcome was apparently favorable.

In most cases of trigeminal neuropathy except those due to tumor, the results of gadolinium-enhanced MRI are normal, as is the cerebrospinal fluid. The function of the nerve may be studied by the electrical recording of blink reflexes. A few laboratories have developed an evoked potential test specifically of the trigeminal nerve.

The Seventh, or Facial, Nerve

The seventh cranial nerve is mainly a motor nerve supplying all the muscles concerned with facial expression on one side. The sensory component is small (the nervus intermedius of Wrisberg); it conveys taste sensation from the anterior two-thirds of the tongue and probably cutaneous sensation from the anterior wall of the external auditory canal. The taste fibers at first traverse the lingual nerve (a branch of the mandibular) and then join the chorda tympani, which conveys taste sensation to the nucleus of the tractus solitarius. Secretomotor fibers innervate the lacrimal gland through the greater superficial petrosal and submaxillary glands through the chorda tympani (Fig. 47-3).

Several other anatomic facts are worth remembering. The motor nucleus of the seventh nerve lies ventral and lateral to the abducens nucleus, and the intrapontine fibers of the facial nerve hook around and pass ventrolaterally to the abducens nucleus before emerging from the pons, just lateral to the corticospinal tract. The facial nerve enters the internal auditory meatus with the acoustic nerve and then bends sharply forward and downward around the anterior boundary of the vestibule of the inner ear. At this angle (genualis) lies the sensory ganglion (named geniculate because of its proximity to the genu). The nerve continues its course in its own bony channel, the facial canal, within which, just distal to the geniculate ganglion, it provides a branch to the pterygopalatine ganglion, i.e., the greater superficial petrosal nerve; somewhat more distally, it gives off a small branch to the stapedius muscle and is joined by the chorda tympani. It makes its exit from the skull at the stylomastoid foramen, then passes through the parotid gland and subdivides into five branches that supply the facial muscles, the stylomastoid muscle, and the posterior belly of the digastric muscle.

A complete interruption of the facial nerve at the stylomastoid foramen paralyzes all muscles of facial expression. The corner of the mouth droops, the creases and skin folds are effaced, the forehead is unfurrowed, the palpebral fissure is widened, and the eyelids will not close. Upon attempted closure of the lids, both eyes roll upward (Bell's phenomenon), but the one on the paralyzed side remains visible. The lower lid sags also, and the punctum falls away from the conjunctiva, permitting tears to spill over the cheek. Food collects between the teeth and cheek, and saliva may dribble from the corner of the mouth. The patient complains of a heaviness or numbness and sometimes an aching pain in the face, but sensory loss can usually not be demonstrated. Taste, however, is intact because the lesion is beyond the site where the chorda tympani has separated from the main trunk of the facial nerve.

If the lesion is in the facial canal above the junction with the chorda tympani but below the geniculate ganglion, all the above symptoms occur; in addition, taste is lost over the anterior two-thirds of the tongue and possibly over the buccal mucosa and palate. Tastefullness on the affected side may recur. If the nerve to the stapedius muscle is involved, there is hyperacusis (painful sensitivity to loud sounds). With a stethoscope in the patient's ears, a tuning fork at the bell is louder on the side of the paralyzed stapedius muscle. If the geniculate ganglion or the motor root proximal to it is involved, lacrimation and salivation may be reduced. Lesions at this point may also affect the adjacent eighth nerve, causing deafness, tinnitus, or dizziness. Intrapontine lesions that paralyze the face often affect the abducens nucleus and the corticospinal and sensory tracts (Millard-Gubler syndrome; Table 47-2).

If the peripheral facial paralysis has existed for some time and return of motor function has begun but is incomplete, a kind of contracture (in reality a continuous diffuse myokymic contraction) may appear. The palpebral fissure becomes narrowed and the nasolabial fold deepens. Attempts to move one group of facial muscles result in contraction of all of them (associated movements, or synkinesias). Spasms of facial muscles may develop and persist indefinitely, being initiated by every facial movement. However, this condition, called hemifacial spasm, occurs most often in adults who have never had a facial palsy and may be related to compression of the nerve by a tortuous blood vessel on the surface of the ventral pons as discussed further on (page 1455).

Anomalous regeneration of the seventh nerve fibers, following a Bell's palsy or other injury, may result in other curious disorders. The most common is the "jaw-winking" phenomenon (also called Wartenberg's or inverse Marcus-Gunn sign), in which jaw movements, especially lateral movements (pterygoid muscle), cause an involuntary closure of the eyelid. If regenerating fibers originally connected with the orbicularis oris became connected with the orbicularis oculi, closure of the lids may cause a retraction of the corner of the mouth; or if visceromotor fibers originally innervating the salivary glands later come to innervate the lacrimal gland, anomalous tearing (crocodile tears) occurs whenever the patient salivates. A similar mechanism explains gustatory sweating of the cheek and upper lip. With the passage of time, the corner of the mouth and even the tip of the nose may become pulled to the affected side.

Bell's Palsy

The most common disease of the facial nerve is Bell's palsy (incidence rate of 23 per 100,000 annually, according to Hauser et al). This disorder affects men and women more or less equally and occurs at all ages and all times of the year. There is controversy regarding an increased incidence in women during the third trimester of pregnancy, particularly in the 2 weeks preceding delivery and in the first 2 weeks postpartum; up to a threefold increase has been cited by some authors, but others have failed to find this disproportionate number of cases. Supporting such a procivity for facial palsy are scattered reports of a recurrence with each pregnancy. Bell's palsy is probably more common in diabetics and possibly in hypertensives than in the normal population.
showing varying degrees of degeneration of nerve fibers. One case was said to show inflammatory changes, but these may have been misinterpreted (see Kernes).

Regarding causation of Bell's palsy, a viral agent has long been suspected (Baringer). Only in the past few years, however, has such a mechanism been established with a reasonable degree of certainty for the majority of cases formerly considered to be idiopathic. Burgess and colleagues identified the genome of herpes simplex virus (HSV-1) in the buccal ganglion of an elder of Bell's palsy. Moreover, they were able to detect HSV DNA by polymerase chain reaction (PCR) technique to amplify viral genomic sequences, identified HSV type I in the endolymphic fluid surrounding the seventh nerve in 11 of 14 cases of Bell's palsy; the fluid was obtained during surgical decompression of the nerve in seven cases. The same investigators have produced facial paralysis by inoculating HSV into the ears and tongues of mice; virus antigens were then found in the facial nerve and geniculate ganglion. Varicella zoster virus (VZV) was not found in the blood of patients with Bell's palsy or Ramsay Hunter syndrome (page 1472). From patients with poliovirus, inoculating HSV into the ears and tongues of mice; virus antigens were then found in the facial nerve and geniculate ganglion. Varicella zoster virus (VZV) was not found in the blood of patients with Bell's palsy or Ramsay Hunter syndrome (page 1472). From patients with poliovirus, the finding of virus DNA was altogether lacking. The finding of virus DNA was altogether lacking.

The onset of Bell's palsy is acute; about one-half of the cases attain maximum paralysis in 48 h and practically all cases within 7 days. Pain behind the ear may precede the paralysis by a day or two and in a few patients is quite intense. In a small number of people, a hypesthesia in one or more branches of the trigeminal nerve can be demonstrated. The explanation of this finding is not clear. Impairment of taste to some degree in almost all patients but rarely persists beyond the second week of paralysis. As indicated above, it means that the lesion has extended to or near the point where the chorda tympani fibers join the facial nerve. Hyperacusis or distortion of sound in the ipsilateral ear indicates paralysis of the stapedius muscle. Unlike the fifth nerve in idiopathic trigeminal neuritis, the facial nerve in Bell's palsy is often seen to display enhancement on the gadolinium-enhanced MRI. Correspondingly, there is a mild increase of lymphocytes and mononuclear cells in the CSF in a few of the cases.

Fully 80 percent of patients recover within a few weeks or in a month or two. Recovery of taste precedes recovery of motor function; if the former occurs in the first week, it is a good prognostic sign. Early recovery of some motor function in the first 5 to 7 days is the most favorable prognostic sign. Electromyography may be of value in distinguishing temporary condition defects from a pathological interruption of nerve fibers if there is evidence of denervation after 10 days, one may expect a long delay in the onset of recovery (3 months, on average). Recovery then proceeds by regeneration of nerve, a process that may take 2 years or longer and may be incomplete.

Idiopathic Bell's palsy is said to recur in 8 percent of cases (van Amstel and Devriese; Pits et al), presumably as a result of reactivation of the herpetic virus. The palsy reemerges during an infection or pregnancy or for no apparent reason. The interval between episodes is unpredictable but has been 10 years, on average. Other recurrent forms of facial paralysis occur with Lyme disease and sarcoidosis, and in a familial variety as mentioned below.

Protection of the eye during sleep, massage of the weakened muscles, and a strict diet to prevent drooping of the lower part of the face are the measures generally employed in the management of such cases. There is no evidence that surgical decompression of the facial nerve is effective, and it may be harmful. The administration of prednisone (40 to 60 mg/day) during the first week to 10 days after onset may be beneficial; it is thought to decrease the possibility of permanent paralysis. The use of corticosteroids alone to treat Bell's palsy may be familial. Biopsy of the lip may reveal a granulomatous inflammation. Causes of facial palsy are often incomplete.

Other Causes of Facial Palsy Lyme disease commonly involves the facial nerve, as indicated on pages 768 and 1403. The mechanism is not thought to be a direct spirochetal infection. The diagnosis is likely when there has been a tick bite with erythema marginatus or arthritis. Several of our cases have had almost simultaneous facial and sensory neuropathy. Human immunodeficiency virus (HIV) infection is an infrequent cause of facial palsy. The facial palsy of both Lyme and HIV infections is associated with a pleocytosis; serologic and CSF examination may be useful if there is a suspicion of either process. Rarely, chickenpox in children may be followed in 1 to 2 weeks by facial paralysis. Tuberculous infection of the mastoid and middle ear or of the petrous bone is a cause of facial paralysis in parts of the world where tuberculosis is particularly common. Facial palsy may occur in infectious mononucleosis and was observed occasionally in poliomyelitis.

The facial nerve is frequently involved in leprosy. Bilateral involvement of the facial nerve is commented on below. The Ramsay Hunt syndrome, due presumably to herpes zoster of the geniculate ganglion, consists of a facial palsy associated with a vesicular eruption in the external auditory canal, other parts of the cranial integument, and mucous membrane of the oropharynx. Often the eighth cranial nerve is affected as well, causing vertigo and deafness (see pages 169 and 799). Murakami et al have shown that the virus can be detected even before the emergence of typical vesicles by collecting exudate from the skin of the pinna on a Schirmer strip (otherwise used to quantitate tearing) and applying PCR techniques. In this way, in a manner of a few hours, they documented VZV infection in 71 percent of patients with Ramsay-Hunt syndrome without vesicles. Treatment with a combination of corticosteroids and acyclovir has been recommended based on a randomized trial (Whiteley et al).

Tumors of the parotid gland or ones that invade the temporal bone (carotid body, cholesteroloma, and dermoid) or granulomatosis at the base of the brain (histiocytosis) may produce a facial palsy; the onset is insidious and the course progressive. Fracture of the temporal bone (usually with damage to the middle or internal ear), otitis media, and middle ear surgery are relatively uncommon causes. Acoustic neuromas, neurofibromas, glomus jugulare tumors, and aneurysmal dissection of the internal carotid artery may be responsible for facial weakness in areas most often vascular or aneurysmal dissection of the internal carotid artery may cause facial palsy, usually in conjunction with other neurologic signs. Amyloidosis of the type associated with crystal lattice deposits in the cornea may involve the facial nerves. An autosomal dominant form of facial paralysis, multiple cranial-nerve palsies, and mild developmental delay have been described by Johnson and colleagues. Weakness only of a portion of the facial musculature, associated with numbness in the same region, may be the result of perineural tumor invasion by squamous cell or other skin cancers (see further on, under "Multiple Cranial Nerve Palsies").

Bell's palsy may be bilateral, but rarely is the involvement on the two sides simultaneous. Contemporaneous bilateral facial paralysis (facial diplegia) is most often a manifestation of sarcoidosis (facial hemiatrophy of Romberg). It occurs mainly in females and is characterized by a disappearance of fat in the dermal and subcutaneous tissues on one or both sides of the face. It usually begins in adolescence or early adulthood and is more progressive. In its advanced form, the affected side of the face is gaunt and the skin thin, wrinkled, and rather dark; the hair may turn white and fall out, and the sebaceous glands become atrophic; the muscles and bones are now reduced as a rule on the face or the affected side. The condition is a form of atrophy, but the localization within a dermatome indicates the operation of some neural factor (possibly a growth factor) from a known source. At a later stage, the facial muscles may be lost. The condition is a form of atrophy, but the localization within a dermatome indicates the operation of some neural factor (possibly a growth factor) from a known source.

An obscure disorder is the facial hemiatrophy of Romberg. It occurs mainly in females and is characterized by a disappearance of fat in the dermal and subcutaneous tissues on one or both sides of the face. It usually begins in adolescence or early adulthood and is more progressive. In its advanced form, the affected side of the face is gaunt and the skin thin, wrinkled, and rather dark; the hair may turn white and fall out, and the sebaceous glands become atrophic; the muscles and bones are now reduced as a rule on the face or the affected side. The condition is a form of atrophy, but the localization within a dermatome indicates the operation of some neural factor (possibly a growth factor) from a known source. At a later stage, the facial muscles may be lost. From patients with poliovirus, the finding of virus DNA was altogether lacking. The finding of virus DNA was altogether lacking.
Hemifacial Spasm

The facial muscles on one side may be involved in painless irregular contractions of varying degree (hemifacial spasm). This condition develops in the fifth and sixth decades, affects women more than men, and is usually without known antecedent cause. It usually proves to be due to a compressive lesion of the facial nerve (most often by a tortuous branch of the basilar artery that lies on the ventral surface of the pons and forms a loop under the proximal nerve, and rarely by a basilar artery aneurysm, or by a acoustic nerve tumor or meningoema). Less often it is a transient or permanent sequela of a Bell's palsy, as stated earlier. The spasm usually begins in the orbicularis oculi muscle and gradually spreads to other muscles on that side of the face, including the platysma. The paroxysm may be induced or aggravated by voluntary and reflexive movements of the face.

There was for a time controversy concerning the pathogenesis of “idiopathic” hemifacial spasm. Jennetta attributes all cases to a compression of the root of the facial nerve by an aberrant looped blood vessel. Microsurgical decompression of the root with the interposition of a pledget between the vessel and the root has relieved the facial spasm in most of his cases. These results were corroborated by Barker; and associates in a series of 705 patients, followed postoperatively for an average period of 8 years; 84 percent achieved an excellent result. Similar results were obtained in a prospective series of 83 patients by Illingworth and colleagues (cure of 81 of 83 patients).

The pathophysiology of the spasm is believed to be nerve root compression and segmental demyelination. The demyelinated axon is capable of activating adjacent nerve fibers by ephaptic transmission (“artificial synapse” of Grant et al). An added possible source of the spasm is ectopic excitation arising in injured fibers. Nielsen and Jannetta, who offer the same explanation (and treatment) for trigeminal neuralgia, have shown that ephaptic transmission disappears after the nerve is decompressed.

Surgical decompression of a vascular loop, which involves exploration of the posterior fossa, is not without risk. The facial muscles may be weakened, sometimes permanently. Another complication has been deafness due to injury of the adjacent eighth nerve. Also, there is a modest risk of recurrence of the spasms, usually within 2 years of the operation (Pliett and Wilkins). Operative success depends on tight dural closure to prevent CSF leakage from the posterior fossa.

The authors believe that patients with idiopathic hemifacial spasm should first be treated medically. Alexander and Moses noted that carbamazepine (Tegretol), in a dosage of 600 to 1200 mg/day, controlled the spasm in two-thirds of the patients. Baclofen or gabapentin can be tried if carbamazepine fails. Some patients cannot tolerate these drugs; others may have withdrawal symptoms if they are to be withdrawn rapidly.

The hemifacial spasms are relieved for 4 to 5 months and injections can be repeated without danger. Some patients have been injected repeatedly for more than 5 years without apparent adverse effects.

Other Disorders of the Facial Nerve

Facial myokymia is a fine rippling activity of all the muscles of one side of the face. It develops most often in the course of multiple sclerosis or a brainstem glioma. It has also been seen in the course of diseases of the facial nerve, e.g., in Guillain-Barré syndrome (GBS), in which case it usually is bilateral. We have seen it more often in the recovery stage than in the early phase of GBS. The fibrillatory nature of the involuntary movements and their arrhythmicity tend to distinguish them from the coarser intermittent facial spasms and myoclonus, tics, tardive dyskinesia, and clonus. The EMG pattern is one of spontaneously asynchronous discharge of adjacent motor units, appearing singly or in doublets or triplets at a rate varying from 30 to 70 cycles per second. Demyelination of the intrapontine part of the facial nerve and possibly supranuclear disinhibition of the facial nucleus may be the postulated mechanisms. But the observation of facial myokymia in GBS informs us that the abnormal movement may have its origin in a lesion at any point along the nerve (see pages 1467 and 1588 for further discussion of myokymia).

A clonic or tonic contraction of one side of the face is the sole manifestation of a cerebral cortical seizure. An involuntary recurrent spasm of both eyelids (blepharospasm) may occur with dystonia but is most frequent in elderly persons as an isolated phenomenon, and there may be varying degrees of spasm of the other muscles as well. The somatic efferent fibers of the ninth nerve are derived from the nucleus ambiguous, and the visceral efferent (secretory) fibers, from the inferior salivatory nucleus. These fibers contribute in a limited way to the motor innervation of the striated musculature of the pharynx (mainly of the stylopharyngeus, which elevates the pharynx), the parotid glands, and the glands in the parotid sialadenosis (see the discussion of swallowing on page 581).

It is commonly stated that this nerve mediates sensory impulses from the faucial tonsils, posterior wall of the pharynx, and part of the soft palate as well as taste sensations. The glossopharyngeal, vagus, and spinal accessory nerves leave the skull together through the jugular foramen and are then distributed peripherally. The ninth nerve is mainly sensory, with cell bodies in the internal or petrosal, ganglion (the central processes of which end in the nucleus saccularis) and the small superior ganglion (the central fibers of which enter the spinal trigeminal tract and nucleus). Within the nerve are af erent fibers from baroreceptors in the wall of the carotid sinus from and chemoreceptors in the carotid body. The baroreceptors are involved in the regulation of blood pressure, and chemoreceptors are responsible for the ventilatory responses to hypoxia. The somatic efferent fibers are derived from the nucleus ambiguous, and the visceral efferent (secretory) fibers, from the inferior salivatory nucleus. These fibers contribute in a limited way to the motor innervation of the striated musculature of the pharynx (mainly of the stylopharyngeus, which elevates the pharynx), the parotid gland, and the glands in the parotid sialadenosis (see the discussion of swallowing on page 581).

It is commonly stated that this nerve mediates sensory impulses from the faucial tonsils, posterior wall of the pharynx, and part of the soft palate as well as taste sensations. The glossopharyngeal, vagus, and spinal accessory nerves leave the skull together through the jugular foramen and are then distributed peripherally. The ninth nerve is mainly sensory, with cell bodies in the internal or petrosal, ganglion (the central processes of which end in the nucleus saccularis) and the small superior ganglion (the central fibers of which enter the spinal trigeminal tract and nucleus). Within the nerve are afferent fibers from baroreceptors in the wall of the carotid sinus from and chemoreceptors in the carotid body. The baroreceptors are involved in the regulation of blood pressure, and chemoreceptors are responsible for the ventilatory responses to hypoxia. The somatic efferent fibers are derived from the nucleus ambiguous, and the visceral efferent (secretory) fibers, from the inferior salivatory nucleus. These fibers contribute in a limited way to the motor innervation of the striated musculature of the pharynx (mainly of the stylopharyngeus, which elevates the pharynx), the parotid gland, and the glands in the parotid sialadenosis (see the discussion of swallowing on page 581).

The Tenth, or Vagus, Nerve

This nerve arises from the lateral surface of the medulla by a series of small roots that lie just rostral to those of the vagus nerve. The glossopharyngeal, vagus, and spinal accessory nerves leave the skull together through the jugular foramen and are then distributed peripherally. The ninth nerve is mainly sensory, with cell bodies in the internal or petrosal, ganglion (the central processes of which end in the nucleus saccularis) and the small superior ganglion (the central fibers of which enter the spinal trigeminal tract and nucleus). Within the nerve are afferent fibers from baroreceptors in the wall of the carotid sinus from and chemoreceptors in the carotid body. The baroreceptors are involved in the regulation of blood pressure, and chemoreceptors are responsible for the ventilatory responses to hypoxia. The somatic efferent fibers are derived from the nucleus ambiguous, and the visceral efferent (secretory) fibers, from the inferior salivatory nucleus. These fibers contribute in a limited way to the motor innervation of the striated musculature of the pharynx (mainly of the stylopharyngeus, which elevates the pharynx), the parotid gland, and the glands in the parotid sialadenosis (see the discussion of swallowing on page 581).

This nerve has an extensive sensory and motor distribution. It has two ganglia: the jugular, which contains the cell bodies of the somatic sensory nerves (innervating the skin in the concha of the ear), and the nodose, which contains the cell bodies of the afferent fibers from the pharynx, larynx, trachea, esophagus, and the thoracic and abdominal viscera. The central processes of these two ganglia terminate in relation to the nucleus ambiguus and the dorsal motor nucleus of the medulla—the nucleus ambiguus and the dorsal motor nucleus. The former supplies responsibility, the motor fibers of the vagus are derived from two nuclei in the medulla—the nucleus ambiguous and the dorsal motor nucleus. The former supplies...
somatic motor fibers to the striated muscles of the larynx, pharynx, and palate; the latter supplies visceral motor fibers to the heart and other thoracic and abdominal organs. The distribution of vagal fibers is illustrated in Fig. 47-4, and their participation in swallowing is described on page 581.

Figure 47-4 Anatomic features of the vagus nerve. Note the relationship to the spinal-accessory and glossopharyngeal nerves at the jugular foramen and the long course of the left recurrent laryngeal nerve, which is longer than the right.

Complete interruption of the intracranial portion of one vagus nerve results in a characteristic paralysis. The soft palate drops on the ipsilateral side and does not rise in phonation. The uvula deviates to the normal side on phonation, but this is an insensitive sign. There is loss of the gag reflex on the affected side and of the curtain movement of the lateral wall of the pharynx, whereby the faucial pillars move medially as the palate rises in saying “ah.” The voice is hoarse, often nasal, and the vocal cord on the affected side lies immobile in a “cadaveric” position, i.e., midway between abdution and adduction. With partial lesions, movements of abduction are affected more than those of adduction (Semon’s law). There may also be a loss of sensation at the external auditory meatus and back of the pinna. Usually no change in visceral function can be demonstrated. If the pharyngeal branches of both vagi are affected, as in diphtheria, the voice has a nasal quality, and regurgitation of liquids through the nose occurs during the act of swallowing.

Complete bilateral paralysis is said to be incompatible with life, and this is probably true if the nuclei are completely destroyed in the medulla by poliomyelitis or some other disease. However, in the cervical region, both vagi have been blocked with procaine in the treatment of intractable asthma, without mishap. Moreover, Johnson and Stern report a case of bilateral vocal cord paralysis in association with familial hypotrophic polyneuropathy, and Plotter relates the history of three brothers with congenital laryngeal abductor paralysis due to bilateral dysgenesis of the nucleus ambiguus. Bannister and Oppenheimer have called attention to defects of phonation and laryngeal stridor as early features of autonomic failure in multiple system atrophy (page 1137). We have seen several such patients in whom stridor was a prominent feature of the illness and required tracheostomy for survival.

The vagus nerve may be implicated at the meningeval level by tumors and infectious processes and within the medulla by vascular lesions (e.g., the lateral medullary syndrome of Wallenberg); or at the cervicomedullary junction, by motor system disease, and occasionally by tumors. Dysphagia is then invariably present. Herpes zoster may attack this nerve, either alone or together with the ninth nerve as part of a jugular foramen syndrome. The vagus is often affected along with the glossopharyngeal nerve by dissection of the carotid artery at the base of the skull. The vagus nerve may be damaged in the course of thyroid surgery and may be involved in cases of advanced alcoholic or diabetic neuropathy. Polymyositis and dermatomyositis, which cause hoarseness and dysphagia by direct involvement of laryngeal and pharyngeal muscles, may simulate disease of the vagus nerves.

A fact of some importance is that the left recurrent laryngeal nerve may be damaged as a result of thoracic disease. There is no dysphagia with lesions at this point in the nerve since the branches to the pharynx (but not to the larynx) have already been given off. An aneurysm of the aortic arch, an enlarged left atrium, mediastinal lymph nodes from bronchial carcinoma, and a mediatinal or superior sulcus lung tumor are much more frequent causes of an isolated vocal cord palsy than are intracranial diseases.

It is estimated that in one-quarter to one-third of all cases of paralysis of the recurrent laryngeal nerve no cause can be established, i.e., they are idiopathic. The highest incidence is in the third decade, and males are more susceptible than females. Of the 21 cases reported by Blau and Kapadia, 5 recovered completely and 5 partially within a few months; no other disease appeared in the 8-year period that followed. Palsies of the superior and recurrent laryngeal nerves, occurring as part of isolated vagal neuropathies, have been described by Berry and Blair. A few were bilateral, and again the majority of the cases were idiopathic and had much the same prognosis as isolated palsies of the recurrent laryngeal nerve.

Laryngeal neurolgia is a rare entity, in which paroxysms of pain are localized over the upper portion of the thyroid cartilage or hyoid bone on one or both sides. It is evoked by coughing, yawning, talking, or sneezing. In the case reported by Brownstone and coworkers it was relieved by carbamazepine.

When confronted with a case of vocal cord palsy, the physician must attempt to determine the site of the lesion. If it is intramedullary, there are usually ipsilateral cerebellar signs, loss of pain and temperature sensation over the ipsilateral face and contralateral arm and leg, and an ipsilateral Bernard-Homer syndrome. If the lesion is extramedullary but intracranial, the glossopharyngeal and spinal accessory nerves are frequently involved (jugular foramen syndrome, Table 47-1). If it is extracranial in the posterior lateralocodylar or retropharyngeal space, there may be a combination of ninth, tenth, eleventh, and twelfth cranial nerve palsies and a Bernard-Homer syndrome. Combinations of these lower cranial nerve palsies, which have a variety of eponymic designations (see Table 47-1), are caused by various types of tumor, both primary and metastatic, or by chronic inflammations or granulomas involving lymph nodes at the base of the skull. If there is no palatal weakness and no pharyngeal or palatal sensory loss, the lesion is below the origin of the pharyngeal branches, which leave the vagus nerve high in the cervical region. The usual site of disease is then the mediatinum.

The 11th, or Accessory, Nerve

This is a purely motor nerve, actually of spinal rather than cranial origin. Its fibers arise from the anterior horn cells of the upper four or five cervical segments and enter the skull through the foramen magnum. Intracranially, the accessory nerve travels for a short distance with the part of the 10th nerve that is derived from the caudalmost cells of the nucleus ambiguus; together, the two roots are referred to as the vagol-accessory nerve or cranial root of the accessory nerve. The two roots leave the skull through the jugular foramen. The aberrant vagus fibers then rejoin the main trunk of the vagus, and the fibers derived from the cervical segments of the spinal cord form the external ramus and innervate the sternocleidomastoid and trapezius muscles. Only the latter fibers constitute the accessory nerve in the strict sense. In patients with torticollis, however, division of the upper cervical motor roots or the spinal accessory nerve has often failed to ablate completely the contraction of the sternocleidomastoid muscle. This suggests a wider innervation of the muscle, perhaps by fibers of apparent vagal origin that join the accessory nerve for passage through the jugular foramen.

A complete lesion of the accessory nerve results in weakness of the sternocleidomastoid muscle and upper part of the trapezius (the lower part of the trapezius is innervated by the third and fourth cervical roots through the cervical plexus). This can be demonstrated by asking the patient to shrug his shoulders; the affected trapezius will be found to be weaker, and there will often be evident atrophy of its upper part. With the arms at the sides, the shoulder on the affected side droops and the scapula is slightly winged; the latter defect is accentuated with lateral movement of the arm (with serratus anterior weakness, winging of the scapula occurs on forward elevation of the arm). When the patient turns his head forcibly against the examiner’s hand, preferably from the deviated to the straight-ahead position, the sternomastoid of the opposite side does not contract firmly beneath the fingers. This muscle can be further tested by having the patient press his head forward against resistance or lift his head from the pillow.

Motor system disease, poliomyelitis, syringomyelia, and spinal cord tumors may involve the cells of origin of the spinal accessory nerve. In its intracranial portion, the nerve is usually affected along with the ninth and tenth cranial nerves by herpes zoster or by lesions of the jugular foramen (glomus tumors, neurofibromas, metastatic carcinoma, jugular vein thrombosis). Tumors at the foramen magnum may also damage the nerve. In the posterior triangle of the neck, the 11th nerve can be damaged during surgical operations and by external compression or injury. Compressive-invasive lesions of this nerve may be visualized by computed tomography (CT) or MRI of the posterior cervical space.
A benign disorder of the 11th nerve, akin to Bell's palsy, has been described by Spillane and by Eisen and Bertrand; it begins with pain that subsides in a few days and is followed by weakness and atrophy in the distribution of the nerve. Also, a recurrent form of spontaneous accessory neuropathy has been described (Chalk and Isaac). About one-quarter to one-third of 11th nerve lesions are estimated to be of this idiopathic type; most but not all of the patients recover. As in the case of idiopathic brachial plexopathy, ideas about its origin are speculative.

Bilateral sternomastoid and trapezius palsy, which occurs with primary disease of muscles—e.g., polymyositis and muscular dystrophy—may be difficult to distinguish from a bilateral affection of the accessory nerves or the motor nuclei (progressive bulbar palsy).

**Hypoglossal Nerve**

This is also a pure motor nerve, which supplies the somatic musculature of the tongue. It arises as a series of rootlets that issue from the medulla between the pyramidal and the olivocerebellar tracts. The nerve ascends in the skull through the hypoglossal foramen and innervates the genioglossus muscle, which acts to protrude the tongue; the styloglossus, which retracts and elevates its root; and the hypoglossus, which causes the upper surface to become convex. Complete interruption of the nerve results in paralysis of one side of the tongue. The tongue curves slightly to the healthy side as it lies in the mouth, but on protrusion it deviates to the affected side, owing to the unopposed contraction of the healthy genioglossus muscle. By pushing against the tongue in the cheek, one can judge the degree of one-sided weakness. The tongue cannot be moved to a normal position. The denervated side becomes wrinkled and atrophied, and fasciculations and fibrillations can be seen.

Lesions of the hypoglossal nerve roots are rare. Occasionally an intramedullary lesion damages the emerging fibers of the hypoglossal nerve, corticospinal tract, and motor nuclei of the seventh nerve. The result is paralysis and atrophy of the ipsilateral tongue, together with spastic paralysis and loss of vibration and position sense in the opposite arm and leg. Poliomyelitis is the most common intramedullary lesion, and may destroy the hypoglossal nucleus and the roots of the hypoglossal nerves (playfair's syndrome). Invasion of the occipital condyles, Paget's disease, which involves the nerve in its extramedullary course, and it is sometimes damaged in operations on the neck. A dissecting aneurysm of the carotid artery was shown by Goodman and coworkers to have compressed the hypoglossal nerve, with resultant weakness and atrophy. Lance and Anthony have described the following symptoms: nuchal-occipital pain and ipsilateral numbness of the tongue, provoked by the sudden, sharp turning of the head ("neck-tongue syndrome"). The phenomenon is attributed to compression in the atlantoaxial space, of the second cervical root, which carries some of the sensory fibers from the tongue, via the hypoglossal nerve, to the C2 segment of the spinal cord.

The tongue may be red and smooth in vitamin deficiency states. Glossodynia (burning pain of the tongue), a condition most frequently seen in the elderly, may or may not be accompanied by redness and dryness but not by weakness. A habit of tongue-thrusting and teeth-clenching is often associated. The facile ascription of these motor abnormalities to a psychogenic mechanism does no more than gratify the authors’ experience (see also Quinn).

**Syndrome of Bulbar Palsy**

This syndrome is the result of weakness or paralysis of muscles that are supplied by the motor nuclei of the lower brainstem, i.e., the motor nuclei of the fifth, seventh, and ninth to twelfth cranial nerves. (Strictly speaking, the motor nuclei of the fifth and seventh nerves lie outside the "bulb," which is the old name for the medulla oblongata.) Involved are the muscles of the jaw and face; the sternomastoids and upper parts of the trapezius; and the muscles of the tongue, pharynx, and larynx. If weakness develops rapidly, as may happen in Guillain-Barré syndrome, diphtheria, or poliomyelitis, there is no time for muscle atrophy. Myasthenia gravis and polymyositis may on rare occasions produce such a picture. The more chronic diseases—e.g., progressive bulbar palsy (a form of motor system disease) and the childhood form of Fazio-Londe—result in marked wasting and fasciculation of the facial, tongue, sternomastoid, and trapezius muscles. These disorders must be differentiated from pseudobulbar palsy (see page 517).

### MULTIPLE CRANIAL NERVE PALSY

As can be readily understood, several cranial nerves may be affected by a single disease process. One of the clinical problems that arises is whether the lesion lies within or outside the brainstem. Lesions lying on the surface of the brainstem are characterized by involvement of adjacent cranial nerves (often occurring in succession and often painful) and by late and only slight if any involvement of the long sensory and motor pathways and segmental structures lying within the brainstem. Involvement of the cranial nerve roots in the brainstem and the extraterritorial lesions, and intramedullary lesions are more likely to cause bone erosion or to be associated with encroachment on cranial nerves (seen radiographically). Lesions within the brainstem that involve cranial nerves often produce a crossed sensory or motor paralysis (cranial nerve signs on one side of the body and tracts signs on the opposite side). In this way, a number of distinctive syndromes, to which eponyms have been attached, are produced. These are listed in Table 47-2. The special problems of multiple cranial nerve palsies of the ocular motor nerves are addressed in Chap. 14.

**Involvement of multiple cranial nerves outside the brainstem is frequently the result of trauma (sudden onset), localized infections such as herpes zoster (less acute onset), Wegener granulomatosis, sarcoidosis, or other types of granulomatous disease (subacute onset), or compression by tumors and saccular aneurysms (chronic development).** The main causes of multiple cranial nerve palsies of extramedullary origin are listed in Table 47-3. The sequential painless affection of contiguous or noncontiguous nerves over several days or weeks is particularly characteristic of meningeval carcinomatosis or lymphomatosis. The eighth nerve is commonly involved in both types of meningeval infiltrations. Among the solid tumors that cause local compression of nerves, neurofibromas, schwannomas, meningiomas, cholesteatomas, carcinomas, cordomas, and chordomas have all been observed. Nasopharyngeal carcinoma (Schmincke tumor or lymphophlebitoma) may implicate several cranial nerves in succession (mainly the fifth and sixth), as do basilar invagination and adult-onset Chiari malformation. On occasion, several lower cranial nerves are involved on one side by a carotid artery dissection. In France, a successive involvement of all cranial nerves on one side is called the Garcia syndrome or hemibasilar syndrome. It has been reported in chordomas and chondrosarcomas of the clivus but presumably may occur with nasopharyngeal carcinomas as well.

Multiple or single cranial nerve palsies of abrupt onset may precede or accompany infectious mononucleosis and sometimes other viral or mycoplasmal diseases. DeSimone and Snyder have assembled a series of 20 such cases associated with mononucleosis; bilateral facial paralysis was the most common presentation, bilateral optic neuritis the next, and in three cases, three or four cranial nerves were involved. The prognosis is excellent. The main causes of bilateral facial palsy have been discussed earlier in the chapter. A purely motor disorder without atrophy always raises the question of myasthenia gravis. Owing to its anatomic relationships, the multiple cranial nerve palsies form a number of distinctive syndromes, listed in Table 47-1 and discussed in Chap. 31, on intracranial neoplasms (see also Table 31-4). MRI of cervical and basal cranial regions has greatly facilitated the diagnosis of tumors involving these nerves.

From time to time one observes a multiple cranial neuropathy of undetermined cause. Juncos and Beal have reported on 14 patients of this type, along with 6 well-documented cases of the Tolosa-Hunt orbiculocavernous sinus syndrome with oculomotor palsies. In the former group, the onset was with facial pain and headache (temporofrontal), followed within days by abducens palsy (12 of 14), oculomotor palsy (6 of 14), trigeminal palsy (5 of 14), facial weakness (4 of 14), and less often by involvement of the sixth, ninth, and tenth cranial nerves (unilaterally in most instances). Increased protein of CSF and pleocytosis occurred in several. The prompt relief of pain upon administration of steroids was similar to that obtained in the Tolosa-Hunt syndrome. The mode of recovery, which usually occurred within a few months, was also much the same in the two groups of patients. Juncos and Beal concluded that the clinical features of the two groups overlapped and that their separation into two syndromes was arbitrary. We have also seen a relapsing form of this illness in young adults, responsive on each occasion to steroids. Numerous tests of the CSF by the polymerase chain reaction revealed no viruses. Conceivably, some of these cases represent a variant form of the Guillain-Barré syndrome, inasmuch as they may be preceded by a nonspecific infection and accompanied by areflexia, evanescent paresthesias or weakness of the extremities, and an elevated CSF protein without pleocytosis. Others probably are examples of the same entity described by Juncos and Beal. As a more chronic affliction, we have observed 10 cases in which cranial nerves were affected sequentially over a period of many years (polynueraitis cranialis multiplex). Two were later found to have tumors in the temporal lobes. The nerve lesions are characteristic of, and unusual, localized sarcoidosis and syringomyelia, and are not a true paraneoplastic or paracrinic phenomenon. It is usually worth obtaining a biopsy of an enlarged cervical lymph node in these circumstances. Corticosteroid treatment seemed to have been helpful.

The special case of painless multiple oculomotor palsies is discussed in Chap. 14. The main causes are Guillain-Barré syndrome, botulism, myasthenia gravis, thyroid ophthalmopathy, and sphenoiditis. In cases of chronic evolution, oculopharyngeal dystrophy and mitochondrial myopathy (progressive external ophthalmoplegia) must also be considered.

The cavernous sinus syndrome, discussed on pages 268 and 911, consists of various combinations of oculomotor palsy and upper trigeminal sensory loss, usually accompanied by signs of increased intracranial pressure or inflammation of the venous sinus. Cranial nerves are affected first on one side only, but any of the processes that infiltrate or obstruct the sinus may spread to the other side. The main causes are septic or aseptic thrombosis of the venous sinus due to trauma, hypercoagulable
states or adjacent infections in adjacent structures, carotid artery aneurysm, and neoplastic infiltration. Keane has summarized his experience with 151 instances of cavernous sinus syndrome and found trauma and surgical procedures to be the commonest causes, followed by neoplasms (specifically those originating in the nasopharynx), pituitary tumors, metastases, and lymphomas.

A special cause of multiple cranial nerve palsies that has been brought to our attention is an infiltration along the distal nerves in the skin and subcutaneous tissues by squamous cell carcinomas of the face, especially the spindle cell and other atypical varieties. This type of perineural spread first causes unilateral palsies related to the superficial branches of the fifth and seventh cranial nerves in one region of the face and then extends to the base of the skull and to the ventral brainstem. According to Clouston and colleagues, who present five cases in detail, the initial symptoms are usually pain and numbness in the area underlining the skin lesion and facial weakness confined to the same regions of the face; this pattern is a result of the proximity of fifth and seventh nerve branches in the skin and subcutaneous tissues. Various combinations of oculomotor palsies may follow as a result of tumor entry into the orbit via the infraorbital branch of the maxillary nerve. Occasionally there is no pain. We have also observed a similar regional pattern of extracranial involvement of trigeminal and facial nerves with mixed cell tumors of the parotid gland.

The question of viral infections of cranial nerves is always raised by these acute palsies of the facial, trigeminal, and auditory nerves, especially when the affection is bilateral, involves several nerves in combination, or is associated with a pleocytosis. Actually, the only proved viral etiology in this group of cases is that of the herpes simplex and herpes zoster infections causing Bell's palsy, as discussed earlier in the chapter. Since perceptive deafness, vertigo, and other cranial nerve palsies have been observed in conjunction with the postinfectious encephalomyelitides of Mycoplasma, varicella, measles, rubella, mumps, and scarlet fever and also with GBS, an immune-mediated mechanism must be considered. However, as elaborated in Chap. 33 and Chap. 36, new techniques that identify small components of the genome of these organisms indicate that some cases formerly thought to be postinfectious in nature may be true infections of the nerve. The same may be said of the single and multiple cranial nerve palsies that are sometimes associated with HIV and CMV infections. Nothing is known of the pathology of the cranial nerve lesion nor has a virus been isolated in these latter diseases.

Treatment of the parainfectious cases is symptomatic; fortunately the prognosis for recovery is excellent.

In the Tolosa-Hunt cases in which the orbital or cavernous sinus has been invaded, a nonspecific granuloma has been found. Sarcoïd and tuberculosis have been the causes of a few cases, as noted above. In Wegener granulomatosis, multiple cranial nerve palsies, usually lower ones, are reported. The administration of cyclophosphamide has led to remission (page 1401).

Skeletal, or voluntary, muscle constitutes the principal organ of locomotion as well as a vast metabolic reservoir. Disposed in more than 600 separate muscles, this tissue makes up as much as 40 percent of the weight of adult human beings. An intricacy of structure and function undoubtedly accounts for its diverse susceptibility to disease, for which reason the following anatomic and physiologic facts are provided, as an introduction to the several chapters on muscle disease.

A single muscle is composed of thousands of muscle fibers that extend for variable distances along its longitudinal axis. Each fiber is a relatively large and complex multinucleated cell varying in length from a few millimeters to several centimeters (34 cm in the human sartorius muscle) and in diameter from 10 to 100 μm. Some fibers span the entire length of the muscle; others are joined end to end by connective tissue. Each muscle fiber is enveloped by an inner plasma membrane (the sarcolemma) and an outer basement membrane. The nuclei of each cell, which are oriented parallel to the longitudinal axis of the fiber and may number in the thousands, lie beneath the plasma membrane (sarcolemma)—hence they are termed subsarcolemmal or just sarcocellular nuclei.

The cytoplasm ( sarcoplasma) of the cell is abundant and contains myofilaments, various organelles such as mitochondria, and ribosomes; each myofibril is enveloped in a membranous net, the sarcoplasmic reticulum (Fig. 45-3). Extensions of the plasma membrane into the fiber form the transverse tubular system (T tubules), which are extracellular channels of communication with the intracellular sarcoplasmic reticulum (SR). The SR and T tubules are anatomically independent but functionally related systems. The junctional gap between the T tubules and SR is occupied by protein formations that are attached to the SR and are referred to as junctional feet; the latter have been identified as yanodine receptors and are responsible for the release of calcium from the SR ([Franzini-Armstrong]).

The myofilaments are composed of longitudinally oriented interdigitating filaments (myofilaments) of contractile proteins (actin and myosin) and regulatory proteins (tropomyosin, troponin, and nebulin). The series of biochemical events by which these proteins, under the influence of Ca ions, accomplish the contraction and relaxation of muscle is described in Chap. 45. Droplets of stored fat, glycogen, various proteins, many enzymes, and myoglobin, the latter imparting the red color to muscle, are contained within the sarcoplasm or its organelles.

Although the muscle fiber represents an indivisible anatomic and physiologic unit, disease may affect only one part of it, leaving the remainder to become dysfunctional or to atrophy, degenerate, or regenerate, depending on the nature and severity of the disease process.

The individual muscle fibers are enveloped by delicate strands of connective tissue (endomysium), which provide their support and permit unity of action. Capillaries, of which there may be several for each fiber, and nerve fibers lie within the endomysium. Muscle fibers are bound into groups or fascicles by similar reticular tissue and sheets of collagen (perimysium), which also bind together groups of fascicles and surround the entire muscle (epimysium). The latter connective tissue tunics are also richly vascularized; different types of muscle have different arrangements of arteries and veins; fat cells (lipocytes) are embedded within the interstices. The muscle fibers are attached at their ends to tendon fibers, which in turn connect with the skeleton. By this means muscle contraction maintains posture and imparts movement.

Other notable characteristics of muscle are its natural mode of contraction—i.e., through innervation—and the necessity of intact innervation for the maintenance of its normal trophic state. Each muscle fiber receives a nerve twig from a motor nerve cell in the anterior horn of the spinal cord or nucleus of a cranial nerve; the nerve fiber joins the muscle fiber at the neuromuscular junction or motor end plate. As was pointed out on page 47, groups of muscle fibers with a common innervation from one anterior horn cell constitute the motor unit, which is the basic physiologic unit in all reflex, postural, and voluntary activity.

Acetylcholine (ACh), receptors, and acetylcholinesterase (AChE), which play a special role in neuromuscular transmission, are concentrated at the neuromuscular junction. ACh is synthesized in the motor nerve terminal and stored in vesicles as packets, or “quanta,” each containing a relatively fixed number of molecules (about 10,000). Quanta of ACh are released at the nerve ending, diffuse into the nerve terminal through voltage-gated calcium channels, thereby triggering the release of much larger end-plate potential (EPP). This wave of depolarization is propagated along the sarclemma and transverse tubules to the interior of the fibers and leads to muscle contraction (see Chap. 45). The process of ACh release is terminated by action of the enzyme AChE, which breaks down ACh at the neuromuscular junction. For the details of the excytosis of the synaptic vesicles and their recipient, the reader is referred to the chapter on transmitter release in the text of Kandel and colleagues, listed in the References.

In addition to motor nerve endings, muscles contain several types of sensory endings, all of them acting as mechanoreceptors: free nerve endings subserve the sensation of deep pressure-pain; Ruffini and Pacinian corpuscles are pressure sensors; and the Golgi tendon organs and muscle spindles are tension receptors and participate in the maintenance of muscle tone and in reflex activity (page 48). The Golgi receptors are located mainly at the myotendinous junctions; pacinian corpuscles are also localized at the tendon site but are sparse in muscle itself. Muscle spindles, specialized groups of small muscle fibers, regulate muscle contraction and relaxation, as described on page 48. All these receptors are present in highest density in muscles that are involved in fine movements.

All muscles are not equally susceptible to disease, despite the apparent similarity of their structure. In fact, practically no disease affects all muscles in the body, and each disease has as one of its features a characteristic topography within the musculature. The topographic differences between diseases provide incontestable evidence of structural or physiologic differences between muscles that are not presently disclosed by the light or electron microscope. The factors responsible for the selective vulnerability of certain muscles are not known. Several hypothetical explanations come to mind. One factor may relate simply to fiber size: consider, for example, the large diameter and length of the fibers of the glutei and paravertebral muscles in comparison with the smallness of the ocular muscle fibers. The number of fibers composing a motor unit may also be of significance; in the ocular muscles, a motor unit contains only 6 to 10 muscle fibers (some even less), but a motor unit of the gastrocnemius contains as many as 1800 fibers. Also, the eye muscles have a much higher metabolic rate and a richer content of mitochondria than the large trunk muscles. Differences in patterns of vascular supply may permit some muscles to withstand the effects of hypoxia or vascular occlusion better than others. However, current studies of skeletal muscles have disclosed that within any one muscle, there are subtle metabolic differences between fibers—certain ones (type 1 fibers) being richer in oxidative and poorer in glycolytic enzymes, and others (type 2 fibers) being the opposite. The eye muscles do not contain dystrophin, a protein that is deficient in Duchenne and related forms of muscular dystrophy, which may explain the muscles' lack of involvement in these diseases. Doubtless other differences will be discovered.

These anatomic and biochemical properties of muscles suggest some ways of which this tissue may be affected by disease. Thus, one may envisage causative agents or genetic defects that affect different components of sarcoplasm: the filamentous proteins; the mitochondrial enzymes; the sarcoplasmic reticulum; the specialized channels for the entry of calcium, sodium, or chloride; the transverse tubules; or the sarcoclemma itself. The endomysial connective tissue could be the primary pathway in disease, since it so closely invests the muscle fiber. Endomysial fibroblasts of eye muscles contain an abundance of glycosaminoglycans, which
may render them susceptible to thyroid diseases. Finally, the nerve or its cell of origin in the spinal cord is known to bear the brunt of certain pathologic processes, paralyzing all the muscle fibers that it innervates and depriving them of the unique trophic influence that nerve normally has upon muscle.

Normal muscle possesses the capacity, albeit limited, to regenerate, a point often forgotten. Complete destruction of the muscle fiber is not followed by regeneration. Partial destructive processes of the muscle fiber, e.g., inflammatory or metabolic, are usually followed by fatty, connective tissue formation or muscle cell atrophy, so that some part of each fiber has survived and the endomysial sheaths of connective tissue have not been disrupted. Unfortunately, many pathologic processes of muscle are chronic and unrelenting. Under such conditions, any regenerative activity fails to keep pace with the disease and the loss of muscle fibers is permanent. The bulk of the muscle is then replaced by fat and collagenous connective tissue, as typically seen in the muscular dystrophies.

**APPROACH TO THE PATIENT WITH MUSCLE DISEASE**

The number and diversity of diseases of striated muscle greatly exceed the number of symptoms and signs by which they express themselves clinically; thus, different diseases share certain common symptoms and even syndromes. To avoid excessive repetition in the description of individual diseases, we shall discuss in one place all their clinical manifestations, a subject that is appropriately called clinical myology.

The physician is initially put on the track of a myopathic disease by eliciting complaints of muscle weakness or fatigue, pain, limpness or stiffness, spasm, cramp, twitching, or a muscle mass or change in muscle volume. Of these, the symptom of weakness is by far the most frequent and at the same time the most elusive. As remarked in Chap. 24, when speaking of weakness, the patient often means excessive fatigability. Although fatigability may be a feature of muscle diseases—particularly those affecting the neuromuscular junction, such as myasthenia gravis—it is far more frequently a complaint of patients with chronic systemic disease or with anxiety and depression. To distinguish between fatigability and weakness, one must assess the patient's capacity to perform certain common activities such as climbing stairs, arising from a sitting, standing, or reclining position. Difficulty in performing these tasks may reflect weakness rather than fatigue. The same is true of difficulty in working with the arms above shoulder level. Particular complaints may reveal a localized muscle weakness; e.g., drooping of the eyelids, diplopia and strabismus, change in facial expression and voice, and difficulty in chewing, closing the mouth, and swallowing indicate a paresis of the levator palpebrae, extracocular, facial, laryngeal, masseter, and pharyngeal muscles, respectively. Of course, these impairments of muscle function may be due to a neuropathic or central nervous system (CNS) disturbance rather than to a myopathic one, but usually these conditions can be separated by the methods indicated further on in this chapter and in Chap. 3 and Chap. 24.

**Evaluation of Muscle Weakness and Paralysis**

Reduced strength of muscle contraction—manifest by diminished power of single contractions and resistance to opposition (peak power) and by endurance during the sustaining contractions—is a cardinal sign of a muscle disease. In such a case, the problem is to elucidate the nature and extent of the disease process that is enlisting the patient's cooperation. The tentative, hesitant performance of the asthenic or hypotensive individual or the hysteric or malingerer poses difficulties that can be surmounted by the techniques described in Chap. 3. In infants and small children, who cannot follow commands, one assesses muscle power by their resistance to passive manipulation or observing their performance while they are engaged in certain activities. The patient may be reluctant to fully contract the muscles in a painful limb, and indeed pain itself may cause a slight reflex diminution in the power of contraction (algesic paresis). Estimating the strength of isometric contractions that do not require the painful part to be moved is a way around this difficulty. Sometimes the weakness of a group of muscles becomes manifest only after a period of activity; e.g., the feet and legs may “drag” only after the patient has walked a long distance. The physician, upon being told this by the patient, should conduct the examination under circumstances that duplicate the complaint(s).

Weakness of muscle contraction acquires added significance when it is associated with other abnormalities, such as tenderness or atrophy of muscle, change in tendon reflexes, twitching, and spasm. Also, severe weakness of certain muscle groups may result in abnormalities of posture and gait. A waddling gait indicates affection of the medial glutei (or dysplasia of hip joints); excessive lumbar lordosis and protuberance of the abdomen indicate weakness of the iliopsoas and abdominal muscles; kyphoscoliosis points to an asymptomatic weakness of the paravertebral muscles; and flaring of the shoulder blades is a sign of weakness of the lower trapezi, serratus magnus, and rhomboid muscles. Equinovarus deformities of the feet may be the result of fibrous contracture (pseudoncontracture) of the calf muscles.

Ascertaining the extent and severity of muscle weakness requires a systematic examination of the main groups of muscles from forehead to feet. The patient is asked to contract each group with as much force as possible, while the examiner opposes the movement and offers a graded resistance in accordance with the degree of residual power (isokinetic contraction). Alternatively, the patient is asked to produce a maximal contraction, and the examiner estimates power by the force needed to “break” or overcome it (isometric contraction or maximum voluntary isometric contraction). If the weakness is unilateral, one has the advantage of being able to compare it with the strength on the normal side. If it is bilateral, the physician must refer to a concept of what constitutes normalcy, based on experience in muscle testing. These methods of manual muscle testing, while adequate in most clinical situations, may not be sufficiently refined for the evaluation of certain muscle diseases.

In order to quantitate the degree of weakness, which indicates the severity of affection, and to compare one examination with another, which is necessary to determine the course of the disease and the effects of therapy, a rating scale should be used. Most widely used is the one proposed by the Medical Research Council (MRC) of Great Britain, which recognizes six grades of muscle strength, as follows: 0, complete paralysis; 1, minimal contraction; 2, active movement with gravity opposition; 3, weak contraction against gravity; 4, active movement against gravity and resistance; and 5, normal strength. Further gradations may be added, specified as 4+ for barely detectable weakness and 4− for easily detected weakness, 3+, 3−, and so on. This allows 10 gradations of power. With practice, one can distinguish true weakness from unwillingness to cooperate, feigned or neurasthenic weakness, and inhibition of movement by pain.

Ocular, facial, lingual, pharyngeal, laryngeal, cervical, shoulder, upper arm, lower arm and hand, truncal, pelvic, thigh, and lower leg and foot muscles are examined sequentially. The anatomic significance of each of the actions tested—i.e., what roots, nerves, and muscles are involved—can be determined by referring to Table 48-1. A practiced examiner can survey the strength of these muscle groups in 2 to 3 min. A word of caution: in manually resisting the patient's attempts to contract the large and powerful trunk and girdle muscles, the examiner may fail to detect slight degrees of weakness, particularly in well-muscled individuals. These muscle groups are best tested by having the patient squat and kneel and then assume the erect posture, arise from and step onto a chair without using the hands, walk on his toes and heels, and lift a heavy object (textbook of medicine) over his head. The strength of muscles of the hand can be quantified with a dynamometer; for research purposes, similar but more sophisticated devices exist for other muscle groups (see Fenichel et al.).

| Table 48-1 Actions of the principal muscles and their nerve root supply* |

| Qualitative Changes in the Contractile Process |

In the myasthenic state there is a rapid failure of contraction in the most affected muscles during sustained activity. For instance, after the patient looks at the ceiling for a few minutes, the eyelids progressively droop; after the patient closes his eyes and resists the lever palpable muscles, the ptosis lessens or disappears. Similarly, holding the eyes in a far lateral position will induce diplopia and strabismus. These effects, in combination with restoration of power by the administration of...
In addition to myasthenic weakness, there are other abnormalities that may be discovered by observing, during one or a series of maximal actions of a group of muscles, the speed and efficiency of contraction and relaxation. In myxedema, for example, a stiffness and slowness of contraction in a muscle such as the quadriceps may be seen on change in posture (progression of myxedema); often it is associated with a change in position of the tendon reflexes and myotonia, which can be elicited by direct percussion of a muscle. Slowness in relaxation of muscles is another feature of hypothyroidism, accounting for the complaint of uncomfortable tightness of proximal limb muscles. A curious "ripping phenomenon" in muscles called myokymia, inherited as an autosomal dominant trait, has been observed in several families (Chap. 56). After a period of relaxation, a stiffening and ripping occurs in the contracting or stretched muscles. The stiffness is reduced by intravenous diazepam and by tocainide. Acquired forms of myokymia are due to diverse processes including nerve injury and regeneration (particularly in the face), hypothyroidism, and obscure causes.

A prolonged failure of relaxation after fatigue is characteristic of the myotonic phenomenon, which typifies certain diseases—congenital myotonia (of Thomsen), myotonic dystrophy (of Steinert), and the paramyotony of von Eulenberg (Chap. 54). True myotonia, with its prolonged discharges of action potentials, requires strong contraction to elicit, is more evident after a period of relaxation, and tends to disappear with repeated contractions (pages 1363 and 1553). This persistence of contraction is demonstrable also by tapping a muscle (percussion myotonia), a phenomenon easily distinguished from the electrically silent local bulge (myotonia congenita) induced by tapping the muscle of a myotonic patient and from the brief fascicular contraction that is induced by tapping a normal partially denervated muscle; the latter is referred to as idiomuscular contraction. It should be noted that in patients with hyperactive tendon reflexes, striking the muscle rather than its tendon can elicit a stretch reflex. Paradoxical myotonia refers to an increase in the degree of myotonia during a series of contractions (the reverse of what happens in the usual type of myotonia). It occurs in some cases of von Eulenberg paramyotonia.

An increase in power with a series of voluntary contractions in the absence of myotonia is a feature of the inverse myasthenic (Lambert-Eaton) syndrome, which is associated in about 50 percent of cases with small-cell carcinoma of the lung. The same increase occurs in botulism. In both instances there is an electromyographic (EMG) equivalent—a rapid increase in the voltage of a series of action potentials with appropriate stimulation (pages 1539 and 1547).

The effect of cold on muscle contraction may also prove informative; either paresis or myotonia, lasting for a few minutes, may be evoked or enhanced by cold, as in the paramyotony of von Eulenberg.

Myotonia and myoedema must also be distinguished from the recruitment and spread of involuntary spasm induced by strong and repeated contractions of limb muscles in patients with mild or localized tetanus or with the "stiff-man" syndrome, and with dystonia. These are not primary muscle phenomena but are neural in origin, due to an abolition of inhibitory mechanisms.

The repeated contraction of forearm or leg muscles after the application of a tourniquet (exceeding arterial pressure) to the proximal part of a limb will often elicit latent tetany (cerebellar spasms). Its special mode of development in conditions that decrease the concentration of ionized calcium—as well as its duration, its enhancement by hyperventilation, and the association of tingling, prickling paresthesias—separate tetany from ordinary cramp and also from true physiologic contracture.

In practice, the term contracture is applied to all states of fixed muscle shortening. Several distinct types can be recognized. In true contracture a group of muscles, albeit a series of strong contractions, may remain shortened for many minutes because of failure of the metabolic mechanism necessary for relaxation; in this shortened state, the EMG remains relatively silent, in contrast to the high-voltage, rapid discharges observed with cramp, tetany, and tetanus. True contracture occurs in McArdle disease (phosphorylase deficiency), in which it is aggravated by arterial occlusion, but it has been seen in phosphofructokinase deficiency and possibly in another disease, as yet undefined, where the tourniquet has no effect and phosphorylase seems to be present. Yet another type of exercise-induced contracture, described originally by Brody, has been attributed by Karpali and coworkers to a deficiency of calcium adenine triphosphatase in the sarcoplasmic reticulum. These various forms of contracture are described further in Chap. 56. True contracture is to be distinguished from paradoxical myotonia (see above) and from cramp, in which certain conditions (dehiscence, tetany, pathologic cramp syndrome, amyotrophic lateral sclerosis) may be initiated by one or a series of strong voluntary muscle contractions.

It is appropriate here to comment on pseudocontracture (myostatic or fibrous contracture). This is the common form of muscle and tendon shortening that follows prolonged fixation and complete inactivity of the normally innervated muscle (as in a broken limb immobilized by a cast or flaccid weakness of a limb that is allowed to remain immobile). Here the shortened state of the muscle, which may persist for days or weeks, has no clearly established anatomic, physiologic, or chemical basis. Far more frequent is a fibrosis of muscle, a state following chronic fiber loss and immobility of muscle. Depending on the predominant position, certain muscles are both weakened and shortened. Flexor fibrous contracture of the arms is a prominent feature of the Emery-Dreifuss form of muscular dystrophy. It also accounts for the rigidity and kyphoscoliosis of the spine which are so frequently a part of myopathic diseases. The latter state is distinguished from amyotrophy by the springy nature of the resistance, coincident with increased tautness of muscle and tendon during passive motion, and from Volkman contracture, in which there is evident fibrosis of muscle and surrounding tissues due to ischemic injury, usually after a fracture of the elbow.

Arthrogryposis multiplex congenita, described on page 1530, is another form of fibrous contracture, involving multiple muscle groups. This syndrome appears in the newborn, in association with several different types of neuromuscular disease that have two features in common—onset during intrauterine life and a primary alteration of one of the components of the "final common motor pathway." Most often the cause is a loss or failure of development of anterior horn cells, as in Werdnig-Hoffman disease, but occasionally the abnormality is in the nerve roots, peripheral nerves, motor end plates, or muscle. Contractures and fixity of the limbs result from immobility of the developing joints, consequent upon muscle weakness during fetal development. The rigid spine syndrome is yet another form of fibrous contracture, due presumably to an unusual axial muscular dystrophy. Rigidity of the spine is a predominant and early feature.

Topography or Patterns of Myopathic Weakness

In almost all the diseases under consideration, some muscles are affected and others spared, each disease displaying its own pattern. Moreover, the topography or distribution of involvement tends to follow the same pattern in all patients with the same disease. Thus, topography or pattern of involvement becomes a central diagnostic attribute of muscular disease.

The following patterns of muscle involvement constitute a core of essential clinical knowledge in this field:

1. Ocular palsies presenting more or less exclusively as ptosis, diplopia, and strabismus, sometimes in association with exophthalmos and pupillary change. As a rule, primary diseases of muscle do not involve the pupil, and in most instances their effects are bilateral. In lesions of the third, fourth, or sixth cranial nerves, the neural origin is disclosed by the pattern of ocular muscle palsies, abnormalities of the pupil, or both. When weakness of the orbicularis oculi (muscles of eye closure) is added to weakness of eye opening (ptosis), it nearly always signifies a primary disease of muscle or of neuromuscular transmission.

In the more subacute and chronic development of relatively pure affection of eye muscles, myasthenia gravis, progressive external ophthalmoplegia (ocular myopathy), oculopharyngeal muscular dystrophy, and exophthalmic (hyperthyroid) ophthalmopathy are the most frequent causes. In the disorder known as progressive external ophthalmoplegia, only eye muscles may be affected. All the extracocular muscles, including the levators of the eyes, become paralysed over a period of years, but there is usually no diplopia, since the weakness evolves slowly and in a balanced pattern. Only many years later may other muscles be involved. This disorder has been shown in most cases to be a form of mitochondrial myopathy, but there appear to be other types as well. Oculopharyngeal dystrophy involves the levators of the eyelids and, to a somewhat lesser extent, other eye muscles and pharyngeal-upper esophageal striated muscles. It begins in middle or late adult life and later, and—like progressive external ophthalmoplegia—tends later to involve girdle and proximal limb muscles.

There are several other common chronic disorders in which external ophthalmoplegia is associated with involvement of other muscles or organs, namely, the congenital ophthalmoplegia of the Goldenhar-Gorlin syndrome (Alekset al); the Kearns-Sayre syndrome (retinitis pigmentosa, heart block, short stature, gonadal and ovarian weakness, and ovarian fibrotic cysts); other congenital myopathy of the mitochondrial myopathies; nuclear ophthalmoplegia with bilateral weakness (Möbius syndrome); and the myotonic dystrophy of Steinert. Rarely, eye muscle weakness may occur at a late stage in other dystrophies, such as the facioscapulohumeral type. Trichinosis is an occasional cause.

Acute bilateral ophthalmoplegia raises an entirely different set of diagnostic considerations. It may be an expression of the Fisher syndrome of ophthalmoplegia, areflexia, and ataxia (page 1381) and of other variants of the Guillain-Barré syndrome or of botulism, diptheria, rarely tick paralysis, and occlusion of the basilar...
2. Bilateral palsy presenting as an inability to smile, expose the teeth, and close the eyes. Varying degrees of bilateral weakness are observed in myasthenia gravis, usually conjoined with ptosis and ocular palsies. However, weakness of facial muscles may be combined with myasthenic weakness of the masseters and other bulbar muscles to affect two or more of the ocular muscles. The same is true of myopathic dystrophy. More severe or complete facial palsy occurs in facioscapulohumeral dystrophy, sometimes presenting several years before weakness of the shoulder girdle muscles. Bilateral weakness is also a feature of congenital myopathies (centronuclear, nemaline, carnitine deficiency) and the Möbius syndrome (in combination with abducens palsies).

More acute and subacute bilateral palsies are usually attributable to the Guillain-Barré syndrome (always with other signs of neuropathy), sarcoid, Lyme disease, tick paralysis, the Melkersson-Rosenthal syndrome (page 1454), AIDS, or polymyositis (rare), or are part of a cranial neuritis of unknown cause (page 1461), all discussed in the preceding chapter. Rarely, Bell's palsy is simultaneously bilateral (it is more often sequential), and these same considerations apply. Advanced scleroderma, Parkinson disease, or a pseudobulbar state can immobilize the face to the point of simulating myopathic or neuropathic paralysis, but always in a context that makes the cause obvious.

3. Bulbar (oropharyngeal) palsy presenting as dysphonia, dysarthria, and dysphagia with or without weakness of jaw or facial muscles. Myasthenia gravis is the most frequent etiology of this syndrome and must also be considered whenever a patient presents with the сочетted finding of a hanging jaw or fatigue of the jaw while eating or talking; usually, however, ptosis and ocular palsies are conjoined. Dysfunction may be an early and prominent sign of polymyositis as well as inclusion body myositis. It may appear in patients with myotonic dystrophy, due to upper esophageal atonia.

Combinations of these palsies are also observed as an acute or subacute syndrome in botulism, in brainstem stroke, and at the outset of the Guillain-Barré syndrome. Diplegia and bulbar polymyositis are now rare diseases that may present in this way. Progressive bulbar palsy (motor neuron disease) may also be the basis of this syndrome (page 1154); the diagnosis is most obvious when the tongue is weakened and twitching. Syringobulbia, basal invagination of the skull, and certain types of Chiari malformation may reproduce some of the findings of bulbar palsy by involving the lower cranial nerves. Rare cases of hereditary progressive aphponia include the X-linked Kennedy syndrome of bulbospinal atrophy (page 1161). Spastic bulbar paralysis, or pseudobulbar palsy, is readily distinguished by the presence of hyperactive facial and gag reflexes, lack of muscle atrophy, and the associated clinical findings (pages 517 and 547). One must also keep in mind restricted extrapyramidal syndromes, such as Wilson disease and dystonia, that cause the mouth to be kept open and the face and bulbar musculature to appear immobile. The mechanism of swallowing and the ways in which it is disturbed are discussed on page 581.

4. Cervical palsy presenting with inability to hold the head erect or to lift the head from the pillow. The patient may be unable to hold up his head, owing to weakness of the posterior neck muscles, or to lift it from a pillow because of weakness of the sternoclidomastoids and other anterior neck muscles. In advanced forms of this syndrome, the head may hang with chin on chest unless it is held up by the patient's hands.

The "hanging, or dropped, head syndrome" with weakness of the posterior neck muscles occurs most often in idiopathic polymyositis and inclusion body myositis and is rare in myasthenia gravis. The pattern of weakness points to an inflammatory polyneuropathy, since myasthenic patients commonly have a more diffuse weakness that is more likely to resolve later in the day; both flexors and extensors of the neck are found to be weak. The same symptom may be a feature of motor neuron disease, but it is rarely the presenting problem. Occasionally this pattern is observed in patients with nemaline rod myopathy or with a poorly defined local myopathic process that has no distinguishing histopathologic or histochemical features. The latter condition is observed not infrequently in elderly persons. There is severe but relatively nonprogressive weakness of the neck extensors and only mild weakness of shoulder girdle and proximal arm muscles. Katz and colleagues suggest the designation "isolated neck extensor myopathy" in preference to "dropped head syndrome."

The major types of progressive muscular dystrophy, when advanced, usually affect the anterior neck muscles disproportionately. Rarely, syringomyelia, spinal accessory neuropathy, some form of menengoradiculitis, and loss of anterior horn cells in conjunction with systemic lymphoma or carcinoma may differentially paralyze the various neck muscles.

5. Weakness of respiratory and trunk muscles. Usually the diaphragm and chest and trunk muscles are affected in association with shoulder and proximal limb muscles, but occasionally weakness of the respiratory muscles is the initial or the dominant manifestation of disease. Selective involvement of the intercostal muscles and diaphragm, giving rise to dyspnea and diminished vital capacity, may first bring the patient to the pulmonary clinic. We have observed this to happen in patients with motor system disease, glycogen storage disease (acid maltase deficiency), and polymyositis. Unilateral paralysis of the diaphragm may result from compression of the phrenic nerve in the thorax by tumor or aortic aneurysm; an idiopathic or postinfectious variety may be related to brachial plexitis. The paravertebral muscles may be severely affected in some types of muscular dystrophy, but usually in association with pelvicural and shoulder muscle weakness. Nocturnal dyspnea, sleep apnea, and respiratory arrest may occur, particularly in myasthenics and patients with glycogen storage myopathies. And, of course, respiratory failure may threaten life in severe myasthenia gravis and Guillain-Barré syndrome, as it can in polymyositis. As a general rule, in the acute neuromuscular paralyses, the cervical and shoulder muscles and the diaphragm, all of which share a common innervation, show a similar degree of weakness. Asking the patient to expand his chest and count aloud a consecutive series of numbers on one breath (less than 20 equals with a vital capacity of less than 1500 mL) can help to detect this pattern of muscle weakness. Paradoxical inward movement of the abdomen with inspiration is another sign of diaphragmatic weakness. Disorders of breathing and ventilation are also discussed on pages 576 to 581.

6. Bibrachial palsy, sometimes presenting as a dangling arm syndrome. Weakness, atrophy, and fasciculations of the hands, arms, and shoulders characterize the common form of motor system disease, namely, amyotrophic lateral sclerosis. Primary diseases of muscle hardly ever weaken these parts disproportionately. Rarely, a patient may complain that both arms and the shoulder muscles may occur in the early stages of Guillain-Barré syndrome, paraneoplastic disease, and amyloid neuropathy, in special forms of IgM-related paraproteinemic or inflammatory neuropathy, and in porphyric polynuropathy, but it soon becomes part of a more generalized paralysis.

7. Bulbar palsy presenting as lower leg weakness with inability to walk on the heels and toes, or as paralysis of all leg and thigh muscles. Symmetrical weakness of the lower legs is usually due to polynuropathy, although peroneal, anterior tibial, and thigh muscles are often weakened in muscular dystrophy. Diabetic polyneuropathy or carotomuslosic radiculopathy may cause asymmetrical weakness of thigh and pelvic muscles, often with pain and little sensory change. The examination of both lower limbs (polyneuropathy) (CS/P) may do the same. In total leg and thigh weakness, one first thinks of a spinal cord disease, in which case there is usually impaired sphincteric function of the bladder and bowel as well as loss of sensory function below a certain level on the trunk. Motor system disease may begin in the legs, asymptomatically and distally as a rule, and affect them out of proportion to other parts. Thus the differential diagnosis of leg weakness involves more diseases than are involved in the restricted paralyses of other parts of the body.

8. Limb-girdle paralyes presenting as inability to raise the arms or to arise from a squatting, kneeling, or sitting position. Polymyositis, inclusion body myositis, dermatomyositis, and the progressive muscular dystrophies most often manifest themselves in this fashion. The Duchenne, Becker, and limb-girdle types of dystrophy tend to affect the muscles of the pelvic girdle, gluteus region, and thighs, resulting in a lumbar lordosis and scoliotic deformity, a waddling gait, and difficulty in arising from the floor and climbing stairs without the assistance of the arms. Facioscapulohumeral dystrophy affects the muscles of the face and shoulder girdles foremost and is manifest by incomplete eye closure, inability to whistle and to raise the arms above the head, winging of the scapulae, and thinness of the upper arms ("Popeye" effect). In the milder forms of polymyositis, weakness may be limited to the neck muscles or those of the shoulder or pelvic girdle. In a similar vein, early or minor weakness of the dystrophies may selectively involve only the peroneal and scapular muscles (scapuloperoneal dystrophy). A number of other diseases of muscle may express themselves by a disproportionate weakness of girdle and proximal limb musculature. A metabolic myopathy, such as the adult form of acid maltase deficiency and the familial (hypokalemic) type of periodic paralysis, may affect only the pelvic and thigh muscles. In a number of the congenital polymyopathies (central core, nemaline, myotubular, etc.), a relatively normal proximal weakness affects muscles more than distal ones. These are discussed in Chap. 52. Proximal muscles are occasionally implicated in progressive spinal muscular atrophy, as in the syndrome first described by Wohlfart and coworkers and by Kugelberg and Welander, which unfortunately adds to confusion in diagnosis.

Similarly, a pure quadriiceps femoris weakness may be the expression of several diseases. If bilateral, it usually indicates a polymyositis, an early stage of inclusion body myositis (may be unilateral or asymmetrical), or a restricted dystrophy. In thyroidic and steroid myopathies, the major effects are on the quadriceps muscles. If unilateral or bilateral with loss of paretic reflex and sensation over the inner leg, this condition is due most often to a femoral neuropathy, as from diabetes, or to an upper lumbosacral plexus lesion. Injuries to the hip and knee cause rapid disuse atrophy of the quadriceps muscles.

9. Distal bilateral leg palsies presenting usually as foot drop with steppage gait (with or without pes cavus), weakness of all lower leg muscles, and later wrist drop and weakness of hands. The principal cause of this neuromuscular syndrome is a familial neuropathy, such as the peroneal muscular atrophy of Charcot-Marie-Touhy or the hypertrophic neuropathy of Dejerine and Sottas (see Chap. 46). Chronic nonfamilial neuropathies, particularly paraproteinemic and inflammatory ones
and exceptionally some forms of familial progressive muscular atrophy and distal types of progressive muscular dystrophy (Gowers, Milhorat, Weinblatt, and Miyoshi types) may also present in this way. In myotonic dystrophy, there may be weakness of the leg muscles as well as the forearms, sternomastoids, face, and eyes. Despite these exceptions, the generalization that girdle weakness without sensory changes is indicative of myopathy and that distal weakness is indicative of neuropathy is clinically useful.

10. Generalized or universal paralysis: limb (but usually not cranial) muscles, involved either in attacks or as part of a persistent, progressive deterioration. When acute in onset and episodic, this syndrome is usually a manifestation of familial hypokalemic or hyperkalemic periodic paralysis. One variety of the hypokalemic type is associated with hyperthyroidism, another with hyperaldosteronism (Chap. 54). In a setting of a critical illness with multiple organ failure or sepsis, generalized weakness of varying degree may occur from either myopathy (“critical illness myopathy”) or a severe and widespread myopathy that is thought to be caused by the use of high doses of corticosteroids, perhaps exaggerated by the concomitant use of neuromuscular blocking agents. Generalized paralyses (rather than paralysis) that has an acute onset and lasts many weeks is at times a feature of a severe form of idopathic or parasitic (trichinosis) myositides and rarely of pharmaceutical agents, particularly those used to reduce hypercholesterolemia. Idopathic polymyositis and rarely inclusion body myositis may involve all limb and trunk muscles but usually spare the facial and ocular muscles, whereas the weakness in trichinosis is mainly in the ocular and lingual muscles. In infants and young children, a chronic and persistent generalized weakness of all muscles except those of the eyes always raises the question of Werdnig-Hoffman spinal muscular atrophy or, if mild in degree and relatively nonprogressive, of congenital myopathy or neuromyopathy. In these diseases of infancy, paucity of movement, hypotonia, and retardation of motor development may be more obvious than weakness. As a rule, universal weakness of muscle does not occur in the muscular dystrophies.

Changes in Muscle Volume

Muscle Fatigue, Lack of Endurance, and Exercise Intolerance

As stated in an earlier part of this chapter and in Chap. 24, fatigue is an abstruse symptom, always needing analysis and interpretation. When not attended by manifest reduction in muscle power, it is usually nonmuscular in origin. It may, on medical investigation, prove to be a manifestation of infection, metabolic or endocrine disorder, or neoplasia. More often, when expressed as a feeling of weakness and disinclination to undertake or sustain mental and physical activity, it is indicative of neurasthenia, a psychiatric manifestation common to states of chronic anxiety and depression or simply to boredom and lack of purpose. Recently, the elusive syndrome of lifelong exercise intolerance, often accompanied by muscle cramps during exercise, has been traced in a limited number of cases to mutations in the gene for mitochondrial DNA (Andrew et al), and syndromes have been attributed to a deficiency of myoadenylate—but these are very rare. The subject of fatigue as a physiologic phenomenon and as a clinical feature of many psychoses and medical diseases, including those that are predominantly myopathic, is considered fully in Chap. 24.

Muscle Tone

All normal muscles display a slight resistance to stretch when fully relaxed. When stretched to their limit and released, they recoil, mainly because of the elasticity of the fibers and their connective tissue sheaths. In addition, the trunk and proximal limb musculature is intermittently or constantly activated in the maintenance of attitudes and postures. To relaxants, i.e., to completely disengage a muscle from all its excitatory activities—requires practice and seems increasingly difficult in the elderly, in whom it merges with oppositional, or paratonic, rigidity (“gegenhalten,” page 77). A reduced innervation of muscle, atrophy, or loss of contracting fibers are causes of “hypotonia.” In infants this state has come to be accepted as a mark of neuromuscular disease; the infant is said to be “floppy.”

The assessment of muscle tone is of special importance in infants (the “floppy baby”), mainly because of the difficulty in testing strength at this age. Tone can be assessed by lifting the infant in a prone position; if the child is hypotonic, the head and legs cannot be supported against gravity and therefore dangle. Or, when held under the arms, the hypotonic infant slips along the examiner’s hands. André-Thomas introduced the term passivité to refer to the amplitude of the flapping movement when the limbs are extended. A state of passivité is noted if there is no resistance of a muscle to slow passive stretching of the limb. The converse opinion these are but different ways of testing muscle tone. Diminution in tone is observed in infants suffering from Werdnig-Hoffman disease or the congenital myopathies as well as in those with a benign type of hypotonia; diminished tone may also be seen in sickly infants with a variety of systemic diseases. In adults, hypotonia is a feature of many of the myopathies and neuromyopathies, all of which reduce the number of contracting motor units.

The finding of generalized excessive tone, apart from that observed in states of extrapyramidal rigidity, is rare in infants. A purely myopathic form of hypotonia is difficult to substantiate (the exceptions being tetanus and hypocalcemic tetany). A variety of types may lead to fibrous contracture and arthropathy, as stated earlier. An axial myopathy is the basis of the “rigid spine syndrome.” For the most part, the muscle stiffness syndromes are due to continuous overactivity of motor units, the extreme forms being the “stiff-man” and the leaacs syndromes and several related conditions (Chap. 56).

Changes in Muscle Volume

Diminution or increase in muscle bulk stands as another feature of disease that can be observed in all except the most obese patients. There are, of course, innate differences in muscle development, a greater salience of muscle in the male than in the female, and differences due to use and disuse. In general, the relative size of muscles is a genetic trait; in some families, muscles, like the skeleton, are large and in others, small. Greatly increased size and strength of muscles (hypertrophia musculorum vera) is observed in cultists devoted to bodybuilding (although, as a rule, they are exercising muscles that are large from birth); in congenital myotonia (a form of hereditary myotonia dystrophy) and occasionally in dystrophic myopathies, as in the dermopathy, or severe hypophosphatemia. Certain inflammatory neuromyopathies evolve subacutely, and this may also be true in patients undergoing peritoneal dialysis for end-stage renal failure or with toxic exposure to certain heavy metals. An even more insidious onset and slow (months to years) progression of paralysis, atrophy, and fasciculation of limb and trunk muscles without sensory loss characterize motor system disease. Here the eye muscles are always spared. Mild degrees of generalized weakness are features of nemaline and central core myopathy as well as a number of metabolic myopathies, such as thyrotoxic myopathy, glycogen storage diseases, and rickets.

11. Paralysis of single muscles or a group of muscles. This is usually myopathic, less often spinal or myopathic. Muscle disease does not need to be considered except possibly in cases of pressure-ischemic necrosis of muscle, as in so-called monoplectic alcoholic myopathy or diabetic muscle infarction and focal inclusion body myositis, which has a predilection for certain sites, namely parts of the quadriceps and the forearm muscles, particularly the long finger flexors (flexor digitorum profundus).

From this exposition of the topographic aspects of weakness, one can appreciate that each neuromuscular disease exhibits a predilection for particular groups of muscles. As a corollary, a given pattern of weakness should always suggest certain possibilities of disease and exclude others.

Of course, just as in the neuromyopathies, diagnosis also depends on features of the paralysis other than its topography—the age of onset and tempo of progression, the coexistence of medical disorders, and certain laboratory findings (serum concentrations of muscle enzymes, EMG, and biopsy findings) and particularly its genetic determinants also figure prominently in the delineation of muscle diseases.
hypothyroidism, and Addison disease.

Witches, Spasms, and Cramps

Fasciculare twitching at rest. (Fasciculations) is, if pronounced and combined with muscular weakness and atrophy, usually signify motor neuron disease (amyotrophic lateral sclerosis, progressive muscular atrophy, or progressive bulbar palsy); but they may be seen in other diseases that involve the gray matter of the spinal cord (e.g., syringomyelia or tumor) as well as in lesions of the anterior roots (e.g., protruded intervertebral disc) and in certain peripheral neuropathies. Widespread fasciculations may occur with severe dehydration and electrolyte imbalance after an overdose of narcotics or with organophosphate poisoning. Slow and persistent fasciculations, spreading in a wave-like pattern along the entire length of a muscle and associated with slight reduction in the speed of contraction and relaxation, are part of the syndrome of continuous muscular activity (page 1568).

Fasciculations that occur with muscular contraction, in contrast to those at rest, indicate a state of heightened irritability of muscle; this may occur for no discernible reason or as a sign of disease that depletes the muscle of some essential nutrient or of the enzyme system that is needed to maintain the spontaneous activity of the motor end-plates. When fasciculations are observed in the presence of normal motor end-plates and when the fasciculations involve several adjacent muscles, one should suspect a disease of the anterior horn cells or a lesion of the peripheral nerves. Fasciculations are described as being either apparent or demonstrable by palpation, or both. They may be painless and may be so frequent as to be a source of annoyance to the patient.

Cramps

Muscle cramps, despite their common occurrence, are a poorly understood phenomenon. They occur at rest or with movement (action cramps) and are frequently reported in motor system disease, tetany, dehydration after excessive sweating and salt loss, metabolic disorders (uremia and hemolytic-anemia, hypocalcemia, hypothyroidism, and hypoglycemia), and certain muscle diseases (e.g., rare cases of Becker muscular dystrophy and congenital myopathies). Gospe and colleagues have reported a familial (X-linked recessive) type of myalgia and cramps associated with a deletion of the first third of the dystrophin gene, the one lacking in Duchenne dystrophy; strangely, there was no weakness or evidence of dystrophy. Lifelong, severe cramping of undefined type has also been seen in a few families. Far more frequent than all these types of cramping is the benign form (idiopathic cramp syndrome), in which no other neuromuscular disturbance can be found. Most often cramps in otherwise normal individuals occur at night and affect the muscles of the calf and foot, but they may occur at any time and may involve any muscle group. Some patients state that cramps are more frequent when the legs are cold and daytime activity has been excessive. Cramps of this type are extremely common; they are provoked by the abrupt stretching of muscles, are very painful, and tend to wax and wane before they disappear. The EMG counterpart is a high-frequency discharge. Although of no pathologic significance, the cramps in extreme cases are so persistent and so readily provoked by innocuous movements as to be disabling. Cramps of all types need to be distinguished from sensations of cramp without muscle spasm. The latter is a dyesthetic phenomenon.

In contrast to cramp is the physiologic contracature, observed in McArdle disease and carnitine palmitoyltransferase deficiency, in which increasing muscle shortening and pain gradually develop during muscular activity. Unlike cramping, it does not occur at rest, the pain is less intense, and the EMG of the contracted muscle is relatively silent.

Cramps are also to be distinguished from the malignant and progressive form of painful spasm known as the already mentioned stiff-man syndrome; this appears to be a disease of the spinal interneurons (page 1568). Continuous spasm intensified by the action of muscles and with no demonstrable disorder at a neuromuscular level is a common manifestation of localized tetanus and also follows the bite of the black widow spider. These disorders must be differentiated from a rare but distinctive form of encéphalomyalgie of unknown cause, characterized by intense rigidity and myotonic jerking of trunk and limbs and painful spasms evoked by tactile and other stimuli. Damage is thought to be mainly to spinal interneural muscles, with disinhibition of anterior horn cells (Howell et al, see also page 1314). There may also be difficultly distinguishing cramps and spasms from the onset of a dystonic illness.

All the aforementioned phenomena are elaborated in Chap. 55.

Palpable Abnormalities of Muscle

Altered structure and function of muscle are not accurately revealed by palpation. Of course, the difference between the firm, hypertrophied muscle of a well-conditioned athlete and the slack muscle of a sedentary person is as apparent to the palpating fingers as to the eye, as is also the persistent contraction in tetanus, cramp, contracture, and extrapyramidal rigidity. The muscles in dystrophy are said to have a "doughy" or "elastic" feel, but we find this difficult to judge. In the Pompe type of glycogen storage disease, attention may be attracted to the musculature by an unnatural firmness and increase in bulk. The swollen, edematous, weak muscles in acute paroxysmal myoglobinuria or severe polymyositis may feel taut and firm but are usually not tender. Areas of tenderness in muscles that otherwise function normally, a state called myalgosis, have been attributed to fibrositis or fibromyositis, but their nature has not been divulged by biopsy.

A tumorous mass may develop in part of a muscle or throughout a muscle, posing a series of special clinical problems discussed on page 1573.

Muscle Pain

Notably, few of the primary muscle diseases are painful. When pain is prominent and continuous during rest and activity, there will usually be evidence of disease of the peripheral nerves, as in alcoholic-nutritional neuropathy, or of adjacent joints and ligaments (rheumatoid arthritis, polymyalgia rheumatica, etc.). Severe pain localized to a group of muscles is a feature of applying orthotic devices and other dystonias and of dermatomyositis. Other familiar painful disorders are acute brachial neuritis (neuritic myositis), radiculitis, and Bohnholm disease, or pleuropenia, but actually little is known of the cause of the pain in any of them. The same is true of the muscular discomfort that characterizes the early stages of Guillain-Barré syndrome and of paralytic poliomyelitis. Intense pain is a prominent complaint in most of the muscle spasm and cramp syndromes mentioned above. Also, persistently contracted muscle is usually painful. The degree of tenderness of muscle is variable in these two different function types. Individuals tend to be more definite in polyneuritis, poliomyelitis, and polyarteritis nodosa than in polymyositis, the various forms of dystrophy, and other myopathies. If pain is present in polymyositis, it usually indicates coincident involvement of connective tissues and joint structures. Hypothyroidism, hypophysopathemia, and hyperparathyroidism are other sources of a myalgic myopathy. Certain drugs produce muscle aches in susceptible individuals. They include the "statin" lipid-lowering drugs, clofibrate, captopril, lithium, colchicine, beta-adrenergic blocking drugs, penicillamine, cimetidine, suxamethonium, and numerous others (see the table in the review by Mastaglia and Laiing). The myalgic states are considered further in Chap. 55.

There are probably several mechanisms of muscle pain. Prolonged and sustained contraction gives rise to a deep aching sensation. Contraction under ischemic conditions, as when the circulation is occluded by tourniquet, induces pain; the pain of intermittent claudication is supposedly of this type and is not accompanied by cramp. It is postulated that lactic acid or some other metabolite accumulates in muscles and activates pain receptors, but this is unproven. The delayed pain, swelling, and tenderness that occur after sustained exercise of unconditioned muscles are evidently due to fiber necrosis (Armstrong). Nonmuscular Abnormalities in Muscular Diseases

Clinical studies have divulged the involvement of many organs in certain diseases formerly thought to be purely myopathic. Some of the nonmuscular abnormalities, such as dislocation of the hips in several of the congenital myopathies, are probably secondary to the inadequate action of immature muscles. More important is the evidence that an abnormal gene and a deletion or other abnormality of the gene product has affected many systems to such a degree that they assume diagnostic importance. For example, in congenital dystrophy of the Fukuyama type and in Duchenne and myotonic dystrophies, cerebral development is impaired, with resulting mental retardation. In congenital muscular dystrophy of the Walker-Warburg and the Santavuori types, there is maldevelopment of both eye and brain. The cardiac muscle or conducting system is often damaged in Duchenne dystrophy, myotonic dystrophy, Kearn-Sayre disease, and some other adult dystrophies, and a myocarditis may be quite prominent in polymyositis. The retinas, eighth nerves, and ovaries are simultaneously involved in Kearns-Sayre disease, and the cerebellum and some of the brainstem myopathies. In several of the mitochondrial diseases there may be mild dysmorphic features of the cranial and endocrine abnormalities in addition to the aforementioned ovarian changes. Highly arched palate, long face, protruding jaw, and dental malocclusion are features of nemaline myopathy and myotonic dystrophy. Testicular atrophy and gynecomastia accompany the X-linked bulbospinal muscular atrophy described by Kennedy.

DIAGNOSIS OF MUSCLE DISEASE

The aforementioned symptoms and signs are most helpful when considered in connection with the age of the patient at the time of onset, their mode of evolution and course, and the presence or absence of familial occurrence. Since many diseases of muscle are hereditary, a careful family history is important. Stated differently, the
familial occurrence of a muscle disease practically always indicates a genetic causation. The pattern of inheritance has diagnostic significance, and if genetic counseling or prenatal diagnosis is a consideration, a detailed genealogic tree becomes essential. Historical data may be insufficient; it is necessary to examine siblings and parents of the proband. The molecular genetics and other genetic aspects of the heritable muscle diseases—subjects of intense interest in recent years—are discussed at appropriate points in the chapters that follow.

As stated earlier, of importance from a diagnostic standpoint is the principle that primary diseases of muscle seldom if ever are the cause of acute, widespread paralysis. Paralytic states evolving over the period of a few days are usually due to the Guillain-Barré syndrome, less frequently to other neuropathies, and now very rarely to polymyositis; one must also consider certain spinal cord diseases (Chap. 44 and Chap. 46). Nevertheless, there are exceptions to this clinical rule, the most notable being disorders of neuromuscular transmission and the myopathy in critically ill patients who have been exposed to high doses of corticosteroids. Botulinum toxin can paralyze muscles within a few hours by blocking ACh release, and rarely myasthenia gravis or a myasthenic syndrome related to aminoglycoside antibiotic therapy may develop over several days. Also, in the rare disorder known as "thyroid storm," there may be the rapid evolution of widespread muscle weakness, the defect evidently being in the contractile mechanism of the muscle fibers. Hypokalemical paralysis, as in hyperaldosteronism, and an attack of familial periodic paralysis—due to either hypo- or hyperkalemia—may come on within a few hours. Finally, a paroxysm of myoglobinuria, due to an infection or a metabolic myopathy, especially if there has been unusually strenuous exertion, may be followed within hours by a rapidly developing paralysis of limb muscles, usually in association with pain in the muscles.

Thus the occurrence of acute paralysis is given the consideration more of neurologic than of myologic disease. In the relatively rare instances of the latter, diagnostic suspicions are affirmed by measurements of electrolytes, muscle enzymes (CK and aldolase), and thyroid hormones in the serum and by nerve conduction studies and needle electrode examination of muscles. These are summarized by MASTAGLIA and LAING and described in Chap. 45.

In summary, the clinical recognition of myopathic diseases is facilitated by a prior knowledge of a few syndromes, of the age of onset of the illness, of a familial occurrence of the same or similar illnesses, and of the medical setting in which weakness evolves. A description of these syndromes and the diseases of which they are manifestations forms the content of the chapters that follow. Diagnostic accuracy is aided by the intelligent use of the laboratory examinations mentioned above.

CHAPTER REFERENCES

Chapter 49

THE INFLAMMATORY MYOPATHIES

The discovery that striated skeletal muscle and cardiac muscle could be the sole targets of a number of infectious diseases came about during the era of the development of microbiology and occupied the attention of many prominent clinicians, including Osler. As these diseases were being characterized, however, a number of other inflammatory states affecting muscle were found for which there was no infectious cause. Later, an autoimmune mechanism was postulated for this group of diseases, but even today this is not securely established. This latter group figures so prominently in clinical myology that the authors feel justified in devoting a chapter to the subject. First, the infections of muscle are discussed.

THE INFECTIVE (AND PRESUMABLY INFECTIVE) FORMS OF POLYMYOSITIS

Included here are trichinosis, toxoplasmosis, parasitic and fungal infections, and a number of viral infections.

Trichinosis

This parasitic disease is caused by the nematode *Trichinella spiralis*. Its general features have been discussed in Chap. 32 (page 777). With respect to the myopathic aspect of the illness, the authors have been most impressed with the ocular muscle weakness, which results in strabismus and diplopia; with weakness of the tongue, resulting in dysarthria; and with weakness of the masseter and pharyngeal muscles, which interferes with chewing and swallowing. The affection of limb muscles is usually mild, but more severe proximally than distally. The diaphragm may be involved, as well as the myocardium. The affected muscles are slightly swollen and tender in the acute stage of the disease. Often, there is concomitant orbital, and facial edema, sometimes accompanied by subconjunctival and subungual splinter hemorrhages. As the trichinae become encysted over a period of a few weeks, the symptoms subside and recovery is complete. Many, perhaps the majority, of the infected patients are asymptomatic throughout the invasive period, and as much as 1 to 3 percent of the population in certain regions of the country will be found at autopsy to have calcified cysts in their muscles, with no history of parasitic illness. Heavy infestations may on rare occasions end fatally, usually from cardiac and diaphragmatic involvement. In the more massive infections, the brain also may be involved, probably by emboli that arise in the heart from an associated myocarditis.

Clinically, one should suspect the disease in a patient who presents with a puffy face and tender muscles. An eosinophilia (>700/mm³) is practically always present, although the sedimentation rate is often normal. The CK level is usually moderately elevated. A skin test using *Trichinella* antigen is available but unreliable. The enzyme-linked immunosorbent assay (ELISA) is more reliable but becomes positive only after 1 or 2 weeks of illness. Biopsy of almost any muscle (usually the deltoid or gastrocnemius), regardless of whether it is painful or tender, is the most reliable confirmatory test. More than 500 mg of muscle may be required to demonstrate larvae, but smaller specimens will almost invariably show an inflammatory myopathy. Muscle fibers undergo segmental necrosis, and the interstitial inflammatory infiltrates contain a predominance of eosinophils. This accounts for the edema, pain, and tenderness of heavily infested muscles. The capsules of the larvae gradually thin in the first month of the infection and then calcify. The electromyogram (EMG) may exhibit profuse fibrillation potentials, probably because of the disconnection of segments of muscle fibers from their end plates (Gross and Ochoa).

No treatment is required in most cases. In patients with severe weakness and pain, a combination of thiabendazole 25 to 50 mg/kg daily in divided doses for 5 to 10 days and prednisone 40 to 60 mg/day is recommended. Albendazole, in a single oral dose of 400 mg daily, is equally effective but is not available in the United States except by special request (from Smith Kline Beecham).

Recovery is complete as a rule except in the rare patients with cerebral infarcts.

Toxoplasmosis

This is an acute to subacute systemic infection due to the encephalitotoxon *Toxoplasma gondii*. Most infections with *Toxoplasma*, which occur in 10 to 30 percent of the population, are asymptomatic, but some present with fever and with varying degrees of involvement of the skin, lymph nodes, retina, myocardium, liver, brain, and muscle. In one such case, *Toxoplasma* organisms and pseudocysts were detected in skeletal muscle (see Kass et al) wherever the pseudocyst had ruptured, there was focal inflammation. Some muscle fibers had undergone segmental necrosis, but this was not prominent, accounting for the relative paucity of muscle symptoms.

With the advent of acquired immunodeficiency syndrome (AIDS), many more toxoplastic infections, including those of skeletal muscle, are being seen (Gherardi et al), although primary AIDS-related myopathy is more common (see below); brain infestation with *Toxoplasma* is also many times more common. The myopathy, which occurs in the context of fever, lymphopenia, and failure of other organs, consists of weakness, wasting, myalgias, and elevated CK levels. The immunocompromised patient is unable to respond to protozoan infections, and latent infections are reactivated. Sulfadiazine, in combination with pyrimethamine or trimethoprim, which act synergistically against the toxoplastic trophozoites, improves the muscle symptoms and reduces serum creatine kinase (CK). Folic acid must be given in addition.

The subject of AIDS and toxoplastic infection is discussed more fully on pages 774 and 805.

Other Parasitic and Fungal Infections

Echinococcosis, cysticercosis, trypansomiasis (Chagas disease), sparganosis, toxocariasis, and actinomycosis are all known to affect skeletal muscle on occasion, but the major symptoms relate more to involvement of other organs. Only cysticercosis may first claim the attention of the clinical myologist because of a dramatic pseudohypertrophy of thigh and calf muscles. Hydatid infest paravertebral and lumbar girdle muscles in 5 percent of cases. Coenurus and sparganosis are causes of movable lumps in the rectus abdominis, thigh, calf, and pectoralis muscles. Protozoan infections of muscle—microsporidiosis, African and American trypanosomiasis—which occurred only rarely until a decade ago, are now being observed in immunosuppressed (HIV-infected) individuals in endemic areas. The reader who seeks more details may refer to the chapter on parasitic myositis by Banker (see References).

Viral Infections of Muscle

HIV and HTLV-I Myositis It now seems clear that human immunodeficiency virus (HIV) and human T-lymphotropic virus type I (HTLV-I) are the most common causes of viral myositis (Engel and Emrslie-Smith). Moreover, it is widely believed that zidovudine (ZVD), the drug most commonly used to treat HIV infections, may itself induce an inflammatory myopathy, with myalgia and weakness (Dalakas et al). Whether this occurs is not altogether certain; in a recent multicenter trial of antiretroviral drugs there was no increase in myopathy in patients who were treated with ZVD or any other drug in its class (Simpson et al). Inflammatory myopathy develops early in the course of HIV infection and may rarely be the initial manifestation. The pattern is like that of idiopathic polymyositis, with painless weakness of the girdle and proximal limb muscles. Reflexes are diminished in most cases, but this is difficult to interpret in view of the high incidence of concomitant polyneuropathy. Serum CK is elevated, and the EMG shows an active myopathy with fibrillations, brief polyphasic motor units, and complex repetitive discharges.

The myopathologic changes in AIDS are also like those of idiopathic polymyositis. Additionally, in some cases, electron microscopy discloses the presence of
Polymyositis

These are relatively common diseases that affect primarily the striated muscle and skin and sometimes connective tissues as well. The term used varies according to the tissues involved. If the inflammatory changes are restricted clinically to the striated muscles, the disease is called polymyositis (PM); if, in addition, the skin is involved, it is called dermatomyositis (DM), although the two diseases are quite distinct. If either is associated with a connective tissue disorder, the designation is PM or DM with rheumatoid arthritis, rheumatic fever, lupus erythematosus, scleroderma, Sjögren syndrome, or mixed connective tissue disease, as the case may be. There is also an inconsistent relationship to systemic carcinoma, as discussed further on.

These diseases have been known since the nineteenth century. Polymyositis was first described by Wagner in 1863 and 1887, and dermatomyositis was established as an entity by Unverricht in a series of articles written from 1887 to 1891. References to the original articles and a survey of the literature since that time can be found in the monograph of Adams and Kakulas and in the chapter on the polymyositis and dermatomyositis syndromes by Engel and colleagues.

Polymyositis

This is a subacute to chronic symmetrical weakness of proximal limb and trunk muscles without dermatitis. The onset is usually insidious and the course progressive over a period of several weeks or months. It may develop at almost any age and in either sex; however, a majority of patients are 60 to 60 years of age, and a smaller group has a peak incidence at 15 years. Females predominate in all age groups. A febrile illness or infection may precede the weakness, but in most patients the first symptoms develop in the absence of these or other apparent initiating events.

The usual mode of onset is with a painless weakness of the proximal limb muscles, especially of the hips and thighs and to a lesser extent the shoulder girdles. Certain actions—such as arising from a deep chair or from a squatting or kneeling position, climbing or descending stairs, walking, putting an object on a high shelf, or combing the hair—become increasingly difficult. Pain of an aching variety in the buttocks, calves, or shoulders is experienced by only about 15 percent of patients and is less pronounced than in patients with chronic denervation atrophy or with inclusion body myositis (see further on). When reflexes are disproportionately reduced, one must think of systemic cancer with polymyositis and dermatomyositis or of a postinfectious polymyositis. The existence of a postinfectious polymyositis is also unsettled.

Dermatomyositis

In contrast to PM, DM affects children and adults about equally. Among adults, PM is more frequent in females. In childhood DM, males and females are affected equally. The presentation of muscle weakness is similar to that of PM. Sometimes, skin and muscle changes evolve together over a period of 2 or 3 weeks, with the muscles becoming increasingly difficult to move. Pain of an aching variety in the buttocks, calves, or shoulders is experienced by only about 15 percent of patients and is less pronounced than in patients with chronic denervation atrophy or with inclusion body myositis (see further on). When reflexes are disproportionately reduced, one must think of systemic cancer with polymyositis and dermatomyositis or of a postinfectious polymyositis. The existence of a postinfectious polymyositis is also unsettled.
Dermatomyositis of Childhood Idiopathic PM occurs in children, but much less frequently than in adults. Some of the myositis illnesses in children are relatively benign and do not differ from those in adults. Far more frequently there is a distinctive syndrome, described by Banker and Victor, which is designated as dermatomyositis of childhood. In some respects, the disease in the adult form of the disease and in children there is a greater involvement of blood vessels in the connective tissue of multiple organs as well as in skin and muscle. The childhood form of DM is equally distributed between the sexes. It begins, as a rule, with rather typical skin changes, accompanied by anorexia and fatigue. Erythematous discoloration of the upper eyelids, frequently with edema, is a particularly characteristic initial sign. The erythema spreads to involve the periorbital regions, nose, malar areas, and upper lip as well as the skin over the knuckles, elbows, and knees. Cullar overgrowth, subungual telangiectasia, and ulceration of the fingertips are frequent findings. Capillary prominence in the neonatal skin and avascular regions in the cutis have been cited as characteristic and should be sought with a magnifying lens or ophthalmoscope. Symptoms of weakness, stiffness, and pain in the muscles usually follow but may be concomitant with or rarely precede the skin manifestations. The muscular weakness is generalized but always more severe in the muscles of the shoulders and hips and the proximal portions of the limbs. A tight, rubbery consistency of the skin, tendon reflexes are depressed, atrophic or abolished, commensurate with the degree of muscle weakness. Intermittent low-grade fever, subternal and abdominal pain (like that of peptic ulcer), menela, and hematemesis from bowel infarction are common symptoms, the result of an accompanying systemic vasculitis.

The mode of progression of DM of childhood, like that of the adult form, is variable. In some cases, the weakness advances rapidly, involving all the muscles—including those of chewing, swallowing, talking, and breathing—and leading to total incapacitation. Perforation of the gastrointestinal tract (with or without the contributing effects of steroids or gastric intubation) is usually the immediate cause of death. In other patients there is slow progression or arrest of the disease process, and in a small number there may be a remission of muscle weakness. Flexion contractures at the elbows, hips, knees, and ankles and subcutaneous calcification and ulceration of the overlying skin, with extrusion of calcific debris, are common manifestations in the later stages of the disease.

Connective Tissue Diseases with Polymyositis and Dermatomyositis Often, in both PM and DM, the inflammatory changes are not confined to muscle but are seen also in skin, joints, and other organs. In some patients, there may be a variant of muscle weakness. Flexion contractures at the elbows, hips, knees, and ankles—features of dermatomyositis—may be observed. Sometimes the diagnosis must depend on muscle biopsy, EMG findings, and measurements of muscle enzymes in the serum. Malaise, aches, and pains may be the only symptoms in some of the early stages of the disease. In these complicated cases, the myositis may accompany the connective tissue disease or occur many years later.

Carcinoma with Polymyositis or Dermatomyositis The reported incidence of an associated malignancy with PM and DM varies considerably from one series to another (see Engel et al). In the large series of Sigurgeirsson et al, 9 percent of 396 patients with PM were found to have carcinoma, either at the time of diagnosis of the muscle disease or within 5 years of it; among 392 patients with DM, carcinoma was found in 15 percent. DeVere and Bradley reported that 29 percent of the overall group of PM patients had an associated adenocarcinoma, this figure rose to 40 percent if the patient was over 40 years of age and to 66 percent if the patient was between 60 and 70 years old. The evidence is strong that both adenocarcinoma and the muscle disease are linked most often with carcinomas of the lung and colon in men and breast and ovary in women. However, the tumors have arisen in nearly every organ of the body. The muscle and skin tissues contain no tumor cells. In about half the cases, the PM or DM antedates the clinical manifestations of the malignancy, sometimes by 1 to 2 or more years. The relationship is not understood. The morbidity and mortality of this combination is usually determined by the nature of the underlying tumor and its response to therapy. Occasionally, excision of the tumor is attended by remission of the myositis.

Laboratory Findings in PM and DM In the majority of patients with PM and DM, regardless of the clinical associations, serum levels of creatine kinase (CK) and other muscle enzymes, such as aldolase, are elevated. The sedimentation rate may be normal or elevated. Tests for circulating rheumatoid factor and antinuclear antibody (as in lupus erythematosus) are positive in far fewer than half the cases. A high titer of antineutrophil antibody (ANA), particularly with a homogeneous pattern, suggests the coexistence of systemic lupus or mixed connective tissue disease. It must be emphasized that absent or low-titer ANA and a normal sedimentation rate do not exclude the diagnosis of PM—a fact that limits the usefulness. One-third of the PM patients have antibodies to cytoplasmic RNA synthetases (called anti-Jo1). However, anti-Jo1 positivity, when present, is specific for PM (and DM) and is particularly frequent in a syndrome that combines polymyositis, arthritis, and the Raynaud phenomenon and in PM with pulmonary fibrosis. Myoglobinuria can be detected in the majority of patients with acute necrotizing muscle disease provided that a sensitive immunoassay procedure is used.

The EMG can be helpful in diagnosis but has been normal in about 10 percent of our cases. It discloses a typical "myopathic pattern," i.e., many, abnormally brief action potentials of low voltage and, in addition, numerous fibrillation potentials, trains of positive sharp waves, occasional polyphasic units, and myotonic activity reflecting minor degrees of denervation from damage in terminal axons (see Chap. 45). These findings are most apparent in weak muscles and are almost always seen in the proximal portions of the limbs. An abnormal EMG is well developed in the affected muscles. In the absence of signs of muscle wasting, there may be no abnormality. In cases in which biopsy of muscle and wasting have been performed, EMGs may show polyphasic units that simulate denervation-reinnervation changes alongside myopathic motor units. EMG is also helpful in choosing a biopsy site for biopsy sampling, but care must be taken not to obtain tissue from a site of recent EMG needle insertion. As stated, the electrocardiogram has been abnormal in about 80 percent of our cases. MRI shows an increased signal intensity of the affected muscles and immediate surrounding tissues and may be a useful though expensive means of monitoring the effects of therapy. The muscle biopsy, if taken from an affected muscle, usually demonstrates the typical pathologic changes described below.

Pathologic Changes in PM and DM The principal changes in idiopathic PM consist of widespread destruction of segments of muscle fibers, with the expected cellular reaction, i.e., phagocytosis by mononuclear cells and infiltration with a varying number of lymphocytes and lesser numbers of other mononuclear cells, leukocytes, and plasma cells. Evidence of regenerative activity in the form of proliferating sarcolemmal nuclei, basophilic (ribonucleic acid–rich) sarcoplasm, and new myofibrils is almost invariable. The remaining residual muscle fibers are small, with increased numbers of collagenous matrix. Some of the small fibers are in clusters, the result of splitting of regenerating fibers. Either the degeneration of muscle fibers or the infiltration of inflammatory cells may predominate in any given biopsy specimen, though both types of change are in evidence at autopsy.

Probably because of sampling error, only part of the complex of pathologic changes may be divulged in any one biopsy specimen. There may be necrosis and phagocytosis of individual muscle fibers without infiltration of inflammatory cells, or the reverse may be observed. However, in serial sections, muscle necrosis is always seen to be near inflammatory infiltrates. Repeated attacks of a necrotizing myositis appear to exhaust the regenerative potential of the muscles, so that fiber loss, fibrosis, and residual thin and large fibers in haphazard arrangement may eventually impart a dystrophic aspect to the lesions. For all these reasons the pathologic picture can be correctly interpreted only in relation to the clinical and other laboratory data.

In patients with DM, there are several other distinctive histopathologic changes. In contrast to the single-fiber necrosis of PM, DM is characterized by perifascicular muscle fiber atrophy and, on electron microscopy, by the presence of tubular aggregates in the endothelial cells. Moreover, the inflammatory infiltrates in DM predominate in the perimysial connective tissue rather than in the muscle itself. PM and DM are similar in that there is a fiber membrane and to the endomysium.

The muscle lesions in dermatomyositis of childhood are similar to those of the adult form, only greatly accentuated. Perifascicular degeneration and atrophy of muscle fibers are particularly prominent. The fundamental changes are in the small intramuscular blood vessels. Vasculitis, endothelial alterations (tubular aggregates of the endothelial cytoplasm), and occlusion of vessels by fibrin thrombi are the main abnormalities. Occlusion of small vessels also involves the intramuscular vasculature, of which affected vessels have the same pathologic features as those seen in the adult form. In dermatomyositis of childhood, the affected muscles may show weakness only of infarction and denervation atrophy. The same vascular changes underlie the lesions in the connective tissue of skin, subcutaneous tissue, and gastrointestinal tract.

Etiology and Pathogenesis The cause of idiopathic PM and DM, as the term indicates, is unknown. All attempts to isolate an infective agent have been unsuccessful. Several electron microscopy studies have disclosed virus-like particles in muscle fibers, but their causative role has not been proved. Consistent rises of antibody titers have not been demonstrated, nor has a polymyositis illness been induced in animals by injections of affected muscle.

That an autoimmune mechanism might be operative in PM and DM is suggested by the association of these disorders with a number of more clearly established autoimmune diseases, such as myasthenia gravis, Hashimoto thyroiditis, scleroderma, Sjögren disease, Waldenstrom macroglobulinemia, monoclonal gammopathy,
and agrammaglobulinemia and others mentioned earlier. Immunopathologic studies have substantiated this idea and have suggested in addition that PM and DM can be distinguished from one another on the basis of their immune characteristics. In DM, immune complexes, IgG, IgM, complement (C3), and membrane-attack complexes are deposited in the walls of venules and arterioles, suggesting that the immune response is directed primarily against intramuscular blood vessels (Whitaker and Engel; Kissel et al). Such a response is lacking in PM. Also, Engel and Arahata have demonstrated a difference between the two disorders on the basis of tissue samples of the subtypes of inflammatory aggregates found in PM, the endothelial and inflammatory exudate in PM was found to contain a large number of activated T cells, mainly of the CD8 class, whereas B cells were sparse; T cells, accompanied by macrophages, enclosed and invaded necrotic muscle fibers. In DM, very few fibers were similarly affected, and the percentage of B cells at all sites was significantly higher than in PM. Engel and Arahata interpreted these differences as indicating that the effector response in DM is predominantly humoral, whereas in PM the response is mediated by cytoytic T cells, clones of which had been sensitized to a surface antigen on the muscle fiber.

Diagnosis This is secure if there is a subacutely evolving proximal weakness with dysphagia and dysphonia (with or without dermatitis), typical changes in the muscle biopsy, EMG abnormalities of myopathic type with fibrillation potentials, and elevated serum levels of CK. All these criteria have been satisfied in only 25 to 30 percent of our cases, even in those responsive to steroids (see below). One must often accept the diagnosis, therefore, when only some of the criteria are met.

The following problems arise repeatedly in connection with the diagnosis of polymyositis:

1. The patient with proximal muscle weakness incorrectly diagnosed as having progressive muscular dystrophy. Points in favor of polymyositis are (a) lack of family history; (b) older age at onset; (c) more rapid evolution of weakness; (d) evidence, past or present, of other connective tissue diseases; (e) high serum CK and aldolase values; (f) many fibrillation potentials on EMG; (g) marked degeneration and regeneration in muscle biopsy; and finally, if there is still doubt, (h) unmistakable improvement with therapy. In polymyositis, the value of CK may be higher in PM than in DM because of the widespread single-fiber necrosis in the former. However, in DM, if there are infants in muscle or acute perifascicular degeneration, CK levels will be moderately elevated as well.

2. The patient with a connective tissue disease (rheumatoid arthritis, scleroderma, lupus erythematosus, Sjögren syndrome) suspected of having polymyositis in addition. Pain in rheumatoid arthritis prevents strong exertion (algesic pseudoparesis). Points against the coexistence of polymyositis are (a) lack of weakness out of proportion to muscle atrophy, (b) normal EMG, (c) normal serum CK and aldolase, and (d) normal muscle biopsy except possibly for infiltrations of chronic inflammatory cells in the endomyial and perimysial connective tissue (intertitial nodular myositis). More importantly, when muscle pain is a feature, polymyagia rheumatica must be differentiated. This syndrome is characterized by pain, stiffness, and tenedness in the muscles of the neck, shoulders, and arms and sometimes of the hips and thighs in association with a high sedimentation rate; biopsy of the temporal artery frequently discloses a giant-cell arteritis, but CK levels—and of course muscle biopsy—are normal. Rapid disappearance of pain with administration of prednisone is also diagnostic of the latter disease.

3. The patient with restricted muscle weakness. Weakness or paralysis of the posterior neck muscles, with inability to hold up the head, restricted bilateral quadriceps weakness, and other limited pelvic-rural palsies are examples. Most often, the head-hanging or head-tolling syndrome proves to be due to polymyositis and other syndromes to restricted forms of dysphoria and neural atrophy. Inclusion-body myositis is the main alternative consideration. Muscle enzymes in the serum may be relatively normal. Electromyography and biopsy are helpful in diagnosis.

4. The patient with diffuse myalgia and fatigability. Features that exclude a polymyositis are (a) lack of reduced peak power of contraction and (b) normol EMG, serum enzymes, and muscle biopsy. Hypothyroidism, McArde disease, hyperparathyroidism, steroid myopathy, adrenal insufficiency, hyperinsulinemia, and early rheumatoid arthritis must be ruled out by appropriate studies (see Chap. 51). Most of our patients with diffuse myalgia and fatigability have proved to be neuroathenic or depressed and rarely myopathic.

5. The patient with a clinical picture of polymyositis in which the muscle biopsy discloses a noncaseating granulomatous reaction consistent with sarcoid (see further on, page 1490).

Treatment Corticosteroids are the first line of therapy for both PM and DM. Prednisone, 1 mg/kg, is given in three or four divided doses per day. The response to corticosteroids is monitored by careful testing of strength and measurement of CK. In patients who respond, the serum CK decreases before the weakness subsides; with relapse before weakness subsides. Once the dosage has been adjusted, the patient is changed to an alternate-day schedule with double this amount (i.e., 40 mg). This schedule reduces the side effects of corticosteroids. With cautious reduction of prednisone over a period of 6 months or a year, the patient can usually be maintained on doses of 7.5 to 20 mg daily, with the aim of eventual discontinuation of the drug. Corticosteroids should not be discontinued prematurely, for the relapse that may follow is often more difficult to treat than the original symptoms. In acute and particularly severe cases, treatment may be facilitated by the use initially of high-dose pulse methylprednisolone (1 g infused over 2 h each day for 3 days). This form of treatment should be regarded as a temporary measure until oral prednisone becomes effective.

Some patients who cannot tolerate or are refractory to prednisone may respond favorably to oral azathioprine (150 to 300 mg/day), with care being taken to keep the white blood cell (WBC) level above 3000/mm3, or to methotrexate (5 to 10 mg/week in three divided oral doses, increased by 2.5 mg per week, to a total dose of 20 mg weekly). Preferably the methotrexate or azathioprine should be given along with relatively small daily doses (15 to 25 mg) of prednisone. Some clinicians favor, from the beginning, a combination of prednisone in low dosage and one of the immunosuppressant drugs; this approach is generally necessary when systemic vasculitis or interstitial pneumonitis is coupled with DM. The corticosteroids sparing effects of azathioprine may also be useful in patients requiring long-term immunosuppressant therapy. Cyclophosphamide, which is a useful drug in the treatment of Wegener granulomatosis, polyarteritis, and perhaps other vasculitides, is said to be of lesser value in PM, but several of our rheumatologist colleagues recommend it and we have seen good responses in adults. Cyclosporine has also been used in recalcitrant cases, it has no advantages over other immunosuppressant drugs but has a number of potentially serious side effects, including nephrotoxicity.

In patients with DM who respond poorly to corticosteroids and other immunosuppressants or are severely affected early on, the addition of intravenous immunoglobulin infusions (IVIG) often proves to be effective—although several courses of treatment at monthly intervals may be required to achieve sustained improvement. In several controlled studies of small numbers of DM patients (Osakasu, Mastaglia et al.), practically all showed improvement in muscle strength and skin changes and a reduction in CK concentration. The drug has also been reported to respond favorably to treatment with IVIG, but further controlled studies are required to corroborate these reports and to establish, in both PM and DM, optimal doses and modes of administration. It is noteworthy that IVIG has rarely been effective in PM or DM when used alone or as initial therapy. Whole-body radiation is said to be helpful in a few drug-resistant cases, but the side effects of this treatment are forbidding.

Prognosis Except for patients with malignancy, the prognosis in adult PM and DM is favorable. Only a small proportion of patients with PM succumb to the disease, and death is usually usually from a pulmonary or cardiac complication. The period of activity of disease varies considerably but is usually around 2 years in both the child and adult groups. As indicated above, the majority improve with corticosteroid therapy, but many are left with varying degrees of weakness of the shoulders and hips. Approximately 20 percent of our patients have recovered completely, and long-term remissions have been achieved in about an equal number. The extent of recovery is usually correlated with duration and severity of symptoms prior to institution of therapy. Patients with early symptoms of acute or subacute PM in whom treatment is begun soon after the onset of symptoms have the best prognosis. In the series of DeVer and Bradley, in which patients were treated early, there was remission in over 50 percent of cases, whereas in the series of Riddoch and Morgan-Hughes, who were treated more than 2 years after onset of the disease, the remission rate was considerably lower.

In patients with a coexistent malignancy, muscle weakness may lessen and serum enzyme levels decline in response to corticosteroid therapy, but weakness returns after a few months and may then be resistant to further treatment. As already stated, if the tumor is successfully removed, the muscle symptoms may remit. The mortality after several years ranges around 15 percent, being higher in childhood DM, in PM with connective tissue diseases, and, of course, with malignancy.

INCLUSION BODY MYOSITIS

Inclusion body myositis (IBM) is the third major form of idiopathic inflammatory myopathy (after PM and DM). Its defining features, the intracytoplasmic and intranuclear inclusions, were first described in 1965 by Adams and colleagues, who also drew attention to a number of clinical features now considered characteristic of this myopathy. Since then many cases have been reported, and we are seeing more instances of this disease than of PM and DM combined. Garlepp and Mastaglia concluded that approximately one-third of the cases of inflammatory myopathy, especially in men, are of this type. By 1994, more than 240 sporadic cases and 55 familial ones had been recorded in the medical literature (Mikut and Engel). A set of clinical and pathologic diagnostic criteria for the disease has recently been proposed by Griggs et al.
The disease predominates in males (in a ratio of 3:1) and has its onset in middle or late adult life. Practically all instances occur sporadically, but inherited forms, both autosomal recessive and dominant, have been reported (Cole et al, Neville et al). The muscle weakness in familial IBM begins in early childhood and usually spares the quadriceps. Also, muscles in the familial form, unlike in the sporadic cases, lack inflammatory changes—for which reason the designation familial inclusion body myopathy is appropriate. Many but not all forms of familial inflammatory inclusion body myopathy are gene defined (Rahier et al). One must express some skepticism about the validity of linking sporadic and familial cases on the basis of the histopathologic findings. Diabetes, a variety of autoimmune diseases, and a relatively mild polyneuropathy are associated in about 20 percent of the sporadic cases, but an association with malignancy or connective tissue disease has not been established.

Clinical Manifestations

The illness is characterized by a steadily progressive, painless muscular weakness and atrophy which may be generalized or affect the limbs selectively and often asymptomatically. Either the proximal or distal muscles may be mainly affected, or the limbs may be involved more or less evenly. In about 20 percent of cases, the disease begins with focal weakness of the quadriceps, finger or wrist flexors, or lower leg muscles on one or both sides and spreads to other muscle groups only after many months or years. A slow and weakening of the flexor pollicis longus is particularly characteristic. The tendon reflexes are normal initially but diminish in about half the patients with progression of the disease. Interestingly, the knee jerks may be depressed or lost even without severe quadriiceps weakness. Dysphagia is common (Wintzen et al; et al), and some type of cardiovascular abnormality is seen in a few cases.

Laboratory and Muscle Biopsy Features

The CK is normal or slightly elevated. The EMG abnormalities are much like those found in PM (see above). In addition, a small proportion of IBM patients display a neuropathic EMG pattern, mainly with fibrillation potentials, particularly in the distal limb muscles.

Diagnosis ultimately depends on the muscle biopsy, which discloses structural abnormalities of muscle fibers and inflammatory changes, identical to but usually of lesser severity than those observed in idiopathic PM. The infiltrating cells are particularly T cells of the CD8 type. However, definitive diagnosis depends upon the finding, by histochromic techniques, of intracytoplasmic vacuoles and eosinophilic inclusions in both the cytoplasm and nuclei of degenerating muscle fibers. The vacuoles contain and are rimmed by basophilic granular material, a point of difference from the vacuoles seen in some cases of PM. The inclusions are collagenic, i.e., they stain positively for b-amyloid protein, the detection of which is enhanced by the use of fluorescence illumination (Aikin et al). Ultrastructural studies show that this protein accumulates at or near foci of abnormal tubulofilamentous structures in both the nuclei and cytoplasm. The nature of these diverse myopathic changes is obscure. The tubulofilamentous inclusions have suggested a viral origin, but a virus has never been isolated and serologic studies have failed to substantiate a viral causation except for one patient in whom adenovirus type 2 was isolated from a biopsy specimen (Mikli and Engel).

Treatment

Inclusion body myositis has not responded in any consistent fashion to treatment with corticosteroids or other immunosuppressive drugs or to IVIG. Indeed, the disease should be suspected in recalcitrant cases of apparent polymyositis. Because a few patients improve slightly or cease worsening with steroids, a small proportion of physicians still recommend this treatment (Licht et al). The level of CK and the degree of leukocytosis, infiltration of muscle diminish with corticosteroid treatment despite a lack of clinical improvement. On this basis, Barohn and coworkers suggest that the inflammatory response is not a primary cause of muscle destruction. Sayres and colleagues concluded in a review of 32 patients that low-dose methotrexate and corticosteroids may slow the progression of disease, but this regimen has not been widely adopted. In a few cases there has been improvement in response to IVIG, especially in the weakened muscles involved in swallowing. The disease in most patients is relentlessly progressive, however, and no method of treatment has altered the long-term prognosis. Plasma exchange and leukocytopheresis have been tried, with generally discouraging results.

Other Inflammatory Myopathies

Included under this heading is a large number of unrelated myositis—certain rare forms of focal myositis and relatively minor changes in muscle that occur in the course of inflammatory diseases of blood vessels or disseminated or systemic infections or thymoma. Most of them do not warrant consideration in a textbook of neurology but are described in detail in monographs devoted to muscle disease (see Bernter).

We have made exceptions of three diseases, eosinophilic myositis and fasciitis, orbital myositis, and sarcoid, which are described below.

Eosinophilic Myositis and Fasciitis

This term has been applied to four separable but possibly overlapping clinical entities: (1) eosinophilic fasciitis, (2) eosinophilic mononositis (sometimes multiplex), (3) eosinophilic polymyositis, and (4) the eosinophilia-myalgia syndrome.

Eosinophilic Fasciitis

This condition was originally reported by Shulman in 1974. He described two men with a scleroderma-like appearance of the skin and flexion contractures at the knees and elbows associated with hyperglobulinemia, elevated sedimentation rate, and eosinophilia. Biopsy revealed greatly thickened fascia, extending from the subcutaneous tissue to the muscle and infiltrated with plasma cells, lymphocytes, and eosinophils; the muscle itself appeared normal and the skin lacked the characteristic histologic changes of scleroderma. One of Shulman's patients recovered completely in response to prednisone.

The many reports that followed have fully substantiated and amplified Shulman's original description. The disease predominates in men, in a ratio of 2:1. Symptoms appear between the ages of 30 and 60 years in most cases and are often precipitated by heavy exercise (Michel et al). Initially there may be low-grade fever and myalgia, followed by the subacute development of diffuse cutaneous thickening and limitation of movement of small and large joints. In some patients, proximal muscle weakness and eosinophilic infiltration of muscle can be demonstrated (Michel et al). Repeated examinations of the blood disclose an eosinophilia in most but not all patients.

In many patients the disease remits spontaneously or responds well to corticosteroids. A small number relapse and do not respond to treatment, and some have developed aplastic anemia and a form of lympho- or myelodysplastic disease.

Eosinophilic Mononositis

Painful swelling of a calf muscle or, less frequently, some other muscle has been the chief characteristic of this disorder. A painful mass forms within the muscle. Biopsy discloses inflammatory necrosis and edema of the interstitial tissues; the infiltrates contain variable numbers of eosinophils. This disorder is typified by one of our cases—a young woman who developed such an inflammatory mass first in one calf and then, 3 months later, in the other. The response to prednisone in this patient was dramatic; the swelling and pain subsided in 2 to 3 weeks, and power of contraction was then found to be normal. When the connective tissue and muscle are both damaged, a chaotic regeneration of fibroblasts and myoblasts may occur, forming a pseudotumor mass that may persist indefinitely.

Eosinophilic Polymyositis

Lazyer and associates have described a third form of this disorder, which they classified as a true subacute polymyositis. Their patients were adults in whom a predominantly proximal weakness of muscles had evolved over a period of several weeks. The other features of the muscle disorder were also typical of polymyositis except that the inflammatory infiltration was predominantly eosinophilic. Moreover, in each case the muscle disorder was part of a severe and widespread systemic illness typical of the hypereosinophilic syndrome. The systemic manifestations included a striking eosinophilia of the blood (20 to 55 percent of the WBCs), cardiac involvement (conduction disturbances and congestive failure), vascular disorder (Raynaud phenomenon, subungual hemorrhages), pulmonary involvement, stomatitis, nephropathy, and leptomeningeal involvement. The muscle was swollen and painful. There was a favorable response to corticosteroids in two patients, but in a third the outcome was fatal within 9 months. Lazyer and associates related the syndrome to eosinophilic pulmonary disease. They felt that a lack of necrotizing arteritis distinguished it from polyarteritis nodosa and Churg-Strauss disease. No infective agent could be isolated. An allergic mechanism seems likely a cause of the lesions, and in the present authors' view one cannot exclude an angitis as a cause of all of the lesions.

The last two of these syndromes (mono- and polymyositis) have overlapping features, as shown by Stark's cases, in which a monomyositis was accompanied by several of the systemic features described by Lazyer et al.

The Eosinophilia-Myalgia Syndrome

Beginning in 1980, a number of sporadic reports documented a lingering systemic illness characterized by severe generalized myalgia and eosinophilia of the peripheral blood following the ingestion of L-tryptophan. In late 1989 and early 1990, there occurred a massive outbreak of eosinophilia-myalgia, as this syndrome came to be called, 1269 cases being reported to the Centers for Disease Control (Medsger). The outbreak was traced to the use of nonprescription L-tryptophan tablets supplied by a single manufacturer and contaminated by a distylophen annial of acetylaldehyde (Mayeno et al).

The syndrome was more frequent in women. The onset was relatively acute, with fatigue, low-grade fever, and eosinophilia (>1000/mm3). Muscle pain and tenderness, cramps, weakness, paresthesias of the extremities, and induration of the skin were the main clinical features. A severe axonal neuropathy with slow and incomplete recovery was associated in some cases. Biopsies of the skin fascia, muscle, and peripheral nerve disclosed a microangiopathy and an inflammatory reaction in connective tissue structures—changes like those observed in scleroderma, eosinophilic fasciitis, and the toxic oil syndrome. The latter syndrome, caused
by the ingestion of contaminated rapeseed oil (in Spain, 1981), gave rise to a constellation of clinical and pathologic changes that were similar if not identical to those caused by L-tryptophan (Ricoy et al; page 1281). The two syndromes are also closely linked chemically. Mayeno and colleagues have identified two trace contaminants in the L-tryptophan consumed by patients with the eosinophilia-myalgia syndrome.

The cutaneous symptoms and eosinophilia of this syndrome responded to treatment with prednisone and other immunosuppressive drugs, but other symptoms did not. The severe axonal neuropathy in our patients improved over several years, but incompletely and leaving patients chairbound.

Acute Orbital Myositis Among the many cases of idiopathic orbital inflammatory disease (pseudotumor of the orbit, page 287), there is a small group in whom the inflammatory process appears to be localized to the extraocular muscles. To this latter group the term acute orbital myositis has been applied. The abrupt onset of orbital pain that is made worse by eye motion, redness of the conjunctiva adjacent to the muscle insertions, diplopia caused by restrictions of ocular movements, lid edema, and mild proptosis are the main clinical features. It may spread from one orbit to the other. The erythrocyte sedimentation rate is usually elevated and the patient may feel generally unwell, but only rarely can the ocular disorder be related to a connective tissue disease or any other specific systemic disease. Computed tomography and magnetic resonance imaging have proved to be particularly useful in demonstrating the swollen ocular muscles or muscle and separating orbital myositis from the many other remitting inflammatory orbital and retro-orbital conditions (Dua et al). As a rule, acute orbital myositis resolves spontaneously in a matter of a few weeks or a month or two, although it may recur in the same or the opposite eye. Administration of steroids appears to hasten recovery.

Sarcoid Myopathy, Granulomatous Myositis, and Localized Nodular Myositis Although there are undoubted examples of muscle involvement in patients with sarcoidosis, they seem to us to be less frequent and less certain than would appear from the medical literature. In some cases, sarcoid myopathy becomes evident as a slowly progressive, occasionally fulminating, painless proximal weakness. The CK and angiotensin-converting enzyme levels are elevated. Muscle biopsy discloses the presence of numerous noncaseating granulomas. It is important to note that such lesions may also be found in patients with sarcoidosis who have no weakness. Treatment with moderate doses of corticosteroids (prednisone, 25 to 50 mg daily) is usually effective, but in patients who do not respond, an immunosuppressive agent such as cyclophosphamide may have to be given in addition.

Much more puzzling to the authors have been cases of myopathy with the clinical features of idiopathic polymyositis and the presence of noncaseating granulomas in the muscle biopsy but with no evidence of sarcoidosis of the nervous system, lungs, bone, skin, or lymph nodes. Such cases call into question the validity of a muscle granuloma as a criterion of sarcoidosis, but the matter cannot be settled until we have better laboratory tests than are now available. These cases are presently being classified as granulomatous myositis and, if limited to one or a small group of muscles, localized nodular myositis (Cumming et al). We suspect that such lesions have several clinical associations. In one syndrome, described by Namba and colleagues, this type of myositis was combined with myasthenia gravis, myocarditis, and a granulomatous infiltrate in the lungs. As a rule, acute orbital myositis resolves spontaneously in a matter of a few weeks or a month or two, although it may recur in the same or the opposite eye. Administration of steroids appears to hasten recovery.

CHAPTER REFERENCES

The muscular dystrophies are progressive hereditary degenerative diseases of skeletal muscles. The innervation of the affected muscles, in contrast to that of the neuropathic and spinal atrophies, is sound. Indeed, final proof that these disorders originate in muscle itself comes from the demonstration of intact spinal motor neurons, muscular nerves, and nerve endings in the presence of severe degenerative changes in the muscle fibers. The symmetrical distribution of muscular weakness and atrophy, intact sensibility, preservation of cutaneous reflexes, and heredofamilial incidence are the characteristic features of this group of diseases and serve to set them apart on clinical grounds alone.

Some clinicians and researchers have applied the term muscular dystrophy to other degenerative diseases of muscle, such as those in animals due to vitamin E deficiency and the coxackieviruses and certain inherited metabolic diseases in humans; we would discourage this practice as one leading to terminologic confusion. The intensity of the degenerative changes and cellular response and the vigor of the regenerative changes distinguish the latter diseases histologically and also imply a fundamental difference in pathogenesis. We therefore reserve the term dystrophy for purely degenerative muscular disease of hereditary type and refer to the others as myopathies or polymyopathies. The more benign and relatively non-progressive myopathies—such as central core, nema line, mitochondrial, and centronuclear diseases—present a greater difficulty in classification. Like the dystrophies, they are primarily diseases of muscle and are heredofamilial in nature; but again we prefer to place them in a separate category because of their nonprogressive or slowly progressive course and the distinctive histochemistry and ultrastructure (Chap. 52).

Historical Background The differentiation of dystrophic diseases of muscle from those secondary to neuronal degeneration was an achievement of neurologists of the second half of the nineteenth century. Isolated cases of muscular dystrophy had been described earlier, but no distinction was made between neuropathic and myopathic disease. Thus, Little had described what appears to be Duchenne muscular dystrophy in lectures given at the Royal Orthopedic Hospital in 1843 and 1844. Meryon in 1852 gave the first clear description of progressive weakness and atrophy of muscle in young boys who, at autopsy, had an intact spinal cord and nerves—a fact that led him to postulate an "idiopathic disease of muscles, dependent perhaps on defective nutrition." In 1855, the French neurologist Duchenne described the progressive muscular atrophy of childhood that now bears his name. However, it was not until the second edition of his famous monograph in 1861 that the "hypertrophic paraplegia of infancy" was recognized as a distinct syndrome of unknown etiology, with speculation about the nature of hypertrophy of muscles. By 1868 he was able to write a comprehensive description of 13 cases and recognized that the disease was muscular in origin and restricted to males. Gowers in 1879 gave a masterful account of 21 personally observed cases and called attention to the characteristic way in which such patients arose from the floor (Gowers sign).

L eyden in 1876 and Möbius 1879 reported a nonhypertrophic form of disease that began in the pelvic girdle muscles and could affect both sexes. Erb, in 1891, crystallized the clinical and histologic concept of a group of diseases due to primary degeneration of muscle, which he called muscular dystrophies. The first descriptions of facioscapulohumeral dystrophy were published by Landouzy and Dejerine in 1894; of progressive ocular myopathy, by Fuchs in 1890; of myotonic dystrophy, by Steinert and Batten and Gibb in 1909; of distal dystrophy, by Gowers in 1888, by Milhorat and Wolff in 1943, and by Welander in 1951; and of oculopharyngeal dystrophy, by Victor, Hayes, and Adams in 1962.

In addition to these classic forms of dystrophy, a number of variant syndromes have come to light. Bramwell in 1922 described hereditary quadriiceps myopathy; Drellius in 1961 and Emery in 1966 placed on record a sex-linked humenoperoneal dystrophy; and Seitz in 1957 distinguished a form of scapuloperoneal dystrophy with cardiomyopathy from the larger group of scapuloperoneal syndromes. References to these and other writings of historical importance can be found in the works of Kakulas and Adams, of Walton et al., and of Engel and Franzini-Armstrong (see References).

In the more recent history of the dystrophies, the most notable event has been the discovery by Kunkel, in 1986, of the dystrophin gene and its protein product. Since then there has been an extraordinary accumulation of molecular-genetic, ultrastructural, and biochemical information about the muscular dystrophies which has greatly broadened our understanding of their mechanisms and causation. It has also clarified a number of uncertainties as to their clinical presentations and has necessitated a revision of traditional forms of classification. Newer classifications (Table 50-1) separate the muscular dystrophies according to the conventional clinical types and their patterns of mendelian inheritance as well as to the presence and locus of the abnormal gene and the defective gene product. Each type of dystrophy is described below, in accordance with this scheme.

### Duchenne Muscular Dystrophy (Severe Generalized Muscular Dystrophy of Childhood)

This is the most frequent and best known of the 100,000 yearly or about one in 3300 live male births in every part of the world. There is a strong familial liability; since the disease is transmitted as an X-linked recessive trait, it occurs predominantly in males. Approximately 30 percent of patients have a negative family history and are said to represent spontaneous mutations. However, careful examination of their mothers will show slight involvement in as many as half of the so-called mutant cases, as pointed out by Roses and coworkers.

Occasionally a severe proximal muscular dystrophy occurs in young girls. This may have several explanations: (1) If the female has only one X chromosome, as occurs in the Turner (XO) syndrome; and if that chromosome carries the defective gene, she would develop the same affection as the male. (2) This could also happen through operation of the so-called Lyon principle, i.e., inactivation of the normal paternal X chromosome in a large proportion of embryonic cells. However, most cases of female childhood dystrophy prove to be of autosomal recessive limb-girdle type.

#### Clinical Features

Duchenne muscular dystrophy is usually recognized in the third year of life and almost always before the sixth year, but nearly half of the patients...
show evidence of disease before beginning to walk. Many of them are backward in other ways (psychomotor retardation), and the muscle weakness may at first be overlooked. An elevated creatine kinase (CK) may be the first clue. In another group of young children, an indisposition to walk or run when they would be expected to do so brings them to medical attention; or, having achieved these motor milestones, they appear to be less active than usual and are prone to falls. Increasing difficulty in walking, running, and climbing stairs, swayback, and waddling gait become ever more obvious as time passes. The iliopsoas, quadriceps, and gluteal muscles are involved initially; then the pretibial muscles weaken (foot drop and toe walking). Muscles of the pectoral girdle and upper limbs are affected; later the pelvic girdle and posterior calf muscles are involved; the sartorius, lower parts of pectoral, latissimus dorsi, biceps, and brachioradialis muscles are affected, more or less in the order mentioned.

Enlargement of the caulis and certain other muscles is progressive in the early stages of the disease, but most of the muscles, even those that are originally enlarged, eventually decrease in size; only the gastrocnemius, and to a lesser extent the lateral vasti and deltoids, are consistently lost, and this peculiarity may attract attention before the weakness becomes evident. The enlarged muscles have a firm, resilient ("rubbery") feel and as a rule are slightly less strong and more hypotonic than healthy ones (pseudohypertrophy). Rarely, all muscles are at first large and strong, even the facial muscles, as in one of Duchenne's cases (a "Farnese Hercules"); this is a true hypertrophy.

Muscules of the pelvic girdle, lumbosacral spine, and shoulders become weak and wasted, accounting for certain clinical peculiarities. Weakness of abdominal and paravertebral muscles accounts for the lordotic posture and protuberant abdomen when standing and the rounded back when sitting. Bilateral weakness of the extensors of the knees and hips interferes with efforts to climb stairs or rise from a chair or from a stooped posture. In standing and walking, the patient places his feet wide apart in order to increase his base of support. To rise from a sitting position, he first flexes his trunk at the hips, puts his hands on his knees, and pushes the trunk upward by working the hands up the thighs. In rising from the ground, the child first assumes a four-point position by placing his arms and hands to the fullest possible extent and then works each hand alternately up the corresponding thigh (a sign traditionally attached to Gowers' name). In getting up from a recumbent position, the patient turns his head and trunk and pushes himself sideways to a sitting position. S. A. K. Wilson used an alliterative phrase to describe the characteristic abnormalities of stance and gait—the patient "straddles as he stands and waddles as he walks." The waddling is due to bilateral weakness of the gluteus medius. Calf pain is an inoffensive complaint. Weakness that fixes the scapulae to the thorax (serratus anterior, lower trapezius, rhomboids) causes a winging of the scapulae, and the scapular angles can sometimes be seen above the shoulders when one is facing the patient.

Later, weakness and atrophy spread to the muscles of the legs and forearms. The muscles that are selectively affected include the neck flexors, wrist extensors, brachioradialis, costal part of the pectoralis major, latissimus dorsi, biceps, triceps, anterior tibial, and peroneal muscles. The ocular, facial, bulbar, and hand muscles are usually spared, although weakness of the facial and sternomastoid muscles and of the diaphragm occurs in the late stages of the disease. As the trunk muscles atrophy, the bones stand out like those of a skeleton. The distances between the lower ribs and iliac crests diminishes with affection of the abdominal muscles.

The limbs are usually loose and slack, but as the disability progresses, fibrous contractures appear as a result of the limbs remaining in one position and the imbalance between agonists and antagonists. Early in the ambulatory phase of the disease, the feet assume an equinovarus position due to shortening of the posterior calf muscles, which act without the normal opposition of the pretil and peroneal muscles. Later, the hamstring muscles become permanently shortened because of a lack of counteraction of the weaker quadriceps muscles. Similarly, contractures occur in hip flexors because of the relatively greater weakness of hip extensors as compared to hip flexors. This lack of counteraction of the iliobibial bands to movements of the hip and thigh, together with the actions of the gluteus maximus and the iliotibial band, account for the posture of the hip and leg. Contractures of the fingers and toes are readily apparent, but the calf muscles do not contract similarly. Early in the disease, the toes may be passively extended by doctor’s pressure, but they cannot actively be extended. Gradually, the lower limbs are drawn up, so that the patient is not only bedridden but often becomes bedfast.

As mentioned above, Roses and colleagues have studied the female carriers of the disease (i.e., the mothers of affected boys) and report a slight weakness and enlargement of the calves as well as elevated CK values and muscle biopsy—although not in all carriers. In 1955, Becker and Keiner proposed that the latter be separated as a distinct entity; it is now known as Becker muscular dystrophy. Its diagnostic information is particularly helpful in genetic counseling.

Becker-Type Muscular Dystrophy

This is another well-characterized dystrophy, closely related to the Duchenne type. It has long been noted that mixed with the Duchenne group of cases were certain represented females and males. Becker and Keiner (1953) noted that some of these cases were indistinguishable from the Duchenne type, except as a distinct entity; it and that some carried the disease as a recessive X-linked trait. Its incidence is difficult to ascertain, probably 3 to 6 per 100,000 male births. Like the Duchenne form, it is an X-linked disorder, practically limited to males and transmitted by females. It causes weakness and hypertrophy in the same muscles as the Duchenne dystrophy, but the onset is much later (mean age, 12 years; range, 5 to 21 years). Contractures are noted at an average age at which the normal person would be able to walk to 25 to 30 years. Death usually occurs in the fifth decade. Many patients live to an advanced age. If maternal uncles are affected by the disease and are still walking, the diagnosis is relatively easy. Cardiac involvement is less frequent than in Duchenne dystrophy and mentation is usually normal. Kuhn and associates have added a genealogy in which early myocardial disease and cramping myalgia were prominent features.

The serum CK values are 25 to 200 times normal, which, with the EMG and muscle biopsy findings, helps to exclude a hereditary spinal muscular atrophy. The EMG shows fibrillations, positive waves, low-amplitude and polyphasic motor unit potentials, and sometimes high-frequency discharges. The female carrier may occasionally display the same abnormalities as in Duchenne dystrophy, but to a much milder degree.

Pathology

In the early stages of Duchenne dystrophy, the most distinctive features are prominent segmental degeneration and phagocytosis of single fibers or groups of fibers and evidence of regenerative activity (basophilic of sarcoplasm, hyperplasia and nucleolation of sarcoplasmic nuclei, and the presence of myotubes and myocytes). The necrosis excites a regenerative or restorative process, which explains the forking of fibers and clustering of small fibers with prominent nuclei. The sarcoplasm and sarcolemma are removed by mononuclear phagocytic (macrophage) cells. There may also be a few T lymphocytes in the region; the blood vessels are normal. There is a hyalinization of the sarcoplasm of many degenerating and nondegenerating fibers. In longitudinal sections, these are seen as "contraction bands," expressive of the irritability of dystrophic muscle. This phenomenon may be present before there is any significant degree of degeneration and is more prominent in Duchenne dystrophy than in any of the other dystrophies. In cross sections of fibers showing varying degrees of dystrophic changes, there are variations of dystrophic changes: loss of muscle fibers, residual fibers of larger and smaller size than normal—all in haphazard arrangement, and increase in lipocytes and fibrosis.

Hypertrophy of muscle is believed to be a result of work-induced enlargement of sound fibers in the face of adjacent fiber injury. But examples of true hypertrophy of entire muscles prior to the first sign of weakness and contraction occur and are difficult to explain. The rare fibers that may be present in a few hypertrophic fibers are present. Pseudohypertrophy is due to lipocytic replacement of degenerated muscle fibers, but in its earlier stages the presence of many enlarged fibers contributes importantly to the enlargement of muscle. Thus a true hypertrophy appears to give way to pseudohypertrophy. The increase in lipocytes, fibrosis, and thickening of the walls of blood vessels are secondary changes. Smallness of residual fibers (possibly atrophy) is a prominent histologic feature. It is uncertain if this contributes importantly to the enlargement of muscle. Thus a true hypertrophy appears to give way to pseudohypertrophy. The increase in lipocytes, fibrosis, and muscle of the pectoral girdle and upper limbs are affected; more or less in the order mentioned.

In the late stage of the dystrophic process, only a few scattered muscle fibers remain, almost lost in a sea of fat cells. It is of interest that the late or burned-out stage of chronic polymyositis resembles muscular dystrophy in that the fiber population is depleted, the residual fibers are of variable size but otherwise normal, and fat cells surround them. Scarring tissue is present and lacking only in the deep peripheries of fibers of dystrophy. This resemblance informs us that many of the typical changes of muscular dystrophy are nonspecific, reflecting only the chronicity of the myopathic process. Finally, it should be restated that in all forms of muscular dystrophy the spinal neurons and their axons in the roots and peripheral nerves are essentially normal.
dystrophies has been the discovery by Kunkel of the abnormal gene on the X chromosome that is shared by these disorders and of the gene product. Dystrophin is the name that has been applied to the protein encoded by the affected gene (Hoffman et al.). The biochemical assay of this protein and its histochromical demonstration near the sarcolemma have made possible the accurate diagnosis of the Duchenne and Becker phenotypes and have clarified the relationship between these two disorders. Whereas dystrophin is absent in patients with the Duchenne phenotype, it is present but structurally abnormal in the Becker type. Moreover, the phenotype that falls between the classic Duchenne and Becker forms (intermediate or “outlier” types) is characterized by a lower than normal amount of dystrophin.

As noted, the Duchenne and Becker dystrophies and their intermediate forms are spoken of as dystrophinopathies.

A slightly different form of dystrophin, originating in a different part of the gene, is found in neurons of the cerebellum and brainstem and in astrocytes, Purkinje cells, and Schwann cells at nodes of Ranvier (Harris and Cullen). A deficiency of this dystrophin may in some way explain the mild mental retardation. It will be interesting to learn how such a deficiency might impede brain development and whether it might explain some cases of mental deficiency without muscular dystrophy. The identification of dystrophin has made possible a number of highly refined tests for the diagnosis of Duchenne and Becker dystrophies as well as the carrier state. Analysis of the dystrophin gene, in DNA obtained from white blood cells or 50 mg of skeletal muscle, can demonstrate the gene mutations in Duchenne and Becker patients and discriminate between these diseases with great accuracy. Analysis of dystrophin protein by immunostaining and immunoblot methods is the definitive method for discriminating between Duchenne, Becker, the carrier state, and other muscle disorders. Byers and colleagues have developed an enzyme-linked immunosorbent assay (ELISA) to measure the dystrophin levels in muscle biopsy samples. This assay is a rapid and relatively inexpensive tool for establishing the diagnosis of Duchenne-Becker muscular dystrophy and distinguishing it from unrelated disorders.

Other Dystrophinopathies

Refined testing for the dystrophin protein has also brought to light several rarer types of dystrophin abnormalities. One, described by Gospe and coworkers, takes the form of a familial X-linked myalgic-cramp-myoglobinuric syndrome, with a deletion of the first third of the dystrophin gene at the Xp21 locus. The muscle changes are mild and relatively nonprogressive. Another dystrophinopathy takes the form of an X-linked cardiomyopathy, characterized by progressive heart failure in young persons without clinical evidence of skeletal muscle weakness; biopsy of skeletal muscle reveals reduced immunoreactivity to dystrophin (Jones and de la Monte). In yet another type, a glycerol-kinase deficiency is associated with varying degrees of adrenal hypoplasia, mental retardation, and myopathy. A number of defects in the glycoproteins that are associated with the dystrophin complex but do not involve dystrophin per se are described further on.

Emery-Dreifuss Muscular Dystrophy

This is another X-linked muscular dystrophy, relatively benign in comparison with the Duchenne type. It was described originally by Emery and Dreifuss and more recently by Hopkins and by Merlini and their colleagues. The age of onset varies from childhood to late adolescence or adulthood. The weakness affects first the upper arm and pectoral girdle musculature and later the pelvic girdle and the distal muscles in the lower extremities. A consistent and distinguishing feature of the Emery-Dreifuss syndrome is the presence of myotonic dystrophy at the electromyographic level. The muscle changes are mild and relatively nonprogressive. Another dystrophinopathy takes the form of an X-linked cardiomyopathy, characterized by progressive heart failure in young persons without clinical evidence of skeletal muscle weakness; biopsy of skeletal muscle reveals reduced immunoreactivity to dystrophin (Jones and de la Monte). In yet another type, a glycerol-kinase deficiency is associated with varying degrees of adrenal hypoplasia, mental retardation, and myopathy. A number of defects in the glycoproteins that are associated with the dystrophin complex but do not involve dystrophin per se are described further on.

Emery-Dreifuss Muscular Dystrophy

This is another X-linked muscular dystrophy, relatively benign in comparison with the Duchenne type. It was described originally by Emery and Dreifuss and more recently by Hopkins and by Merlini and their colleagues. The age of onset varies from childhood to late adolescence or adulthood. The weakness affects first the upper arm and pectoral girdle musculature and later the pelvic girdle and the distal muscles in the lower extremities. A consistent and distinguishing feature of the disease is the presence of myotonia at the electromyographic level. The muscle changes are mild and relatively nonprogressive. Another dystrophinopathy takes the form of an X-linked cardiomyopathy, characterized by progressive heart failure in young persons without clinical evidence of skeletal muscle weakness; biopsy of skeletal muscle reveals reduced immunoreactivity to dystrophin (Jones and de la Monte). In yet another type, a glycerol-kinase deficiency is associated with varying degrees of adrenal hypoplasia, mental retardation, and myopathy. A number of defects in the glycoproteins that are associated with the dystrophin complex but do not involve dystrophin per se are described further on.

Faciescapulohumeral Muscular Dystrophy (Landouzy-Déjerine, Relatively Mild Restricted Muscular Dystrophy; FSH)

This is a slowly progressive dystrophy involving primarily the musculature of the face and shoulders, often with long periods of nearly complete arrest. The pattern of inheritance is usually autosomal dominant.

Although less common than the Duchenne and myotonic dystrophies, this disease is not rare (an estimated yearly incidence rate of 5/100,000). The age of onset is usually between 6 and 20 years, cases with onset in early adult life are occasionally encountered. As a rule, the first manifestations are difficulty in raising the arms above the head and winging of the scapulae, although in many cases bicipital weakness may have attracted attention, even in early childhood. There is involvement especially of the orbicularis occuli, the zygomaticus, and the orbicularis oris, whereas the masseters as well as the temporals, extracurricular, pharyngeal, and respiratory muscles are spared. Weakness and atrophy of the involved muscles are the major physical findings; pseudohyopertrophy occurs only rarely and is slight. There is an inability to close the eyes firmly, to purse the lips, and to whistle; the lips have a peculiar looseness and tendency to protrude. The lower parts of the trapezius muscles and the sternal parts of the pectorals are almost invariably affected. By contrast, the deltoids may seem to be unusually large and strong, an appearance that may be mistaken for pseudohyopertrophy. The advancing atrophic process involves the sternomastoid, serratus magnus, rhomboid, erector spinae, latissimus dorsi, and eventually the deltoid muscles. The bones of the shoulders become salient; the scapulae are winged and elevated (“angel-wing” appearance), and the clavicles may be mistaken for pseudohypertrophy. The X-linked muscular dystrophy described by Gilchrist and Leshner is phenotypically much the same as the Emery-Dreifuss syndrome, though it is genetically distinct, with a deletion of the first third of the dystrophin gene at the Xp21 locus. The muscle changes are mild and relatively nonprogressive. Another dystrophinopathy takes the form of an X-linked cardiomyopathy, characterized by progressive heart failure in young persons without clinical evidence of skeletal muscle weakness; biopsy of skeletal muscle reveals reduced immunoreactivity to dystrophin (Jones and de la Monte). In yet another type, a glycerol-kinase deficiency is associated with varying degrees of adrenal hypoplasia, mental retardation, and myopathy. A number of defects in the glycoproteins that are associated with the dystrophin complex but do not involve dystrophin per se are described further on.

Facioscapulohumeral Muscular Dystrophy (Landouzy-Déjerine, Relatively Mild Restricted Muscular Dystrophy; FSH)

This is a slowly progressive dystrophy involving primarily the musculature of the face and shoulders, often with long periods of nearly complete arrest. The pattern of inheritance is usually autosomal dominant.

Although less common than the Duchenne and myotonic dystrophies, this disease is not rare (an estimated yearly incidence rate of 5/100,000). The age of onset is usually between 6 and 20 years, cases with onset in early adult life are occasionally encountered. As a rule, the first manifestations are difficulty in raising the arms above the head and winging of the scapulae, although in many cases bicipital weakness may have attracted attention, even in early childhood. There is involvement especially of the orbicularis occuli, the zygomaticus, and the orbicularis oris, whereas the masseters as well as the temporals, extracurricular, pharyngeal, and respiratory muscles are spared. Weakness and atrophy of the involved muscles are the major physical findings; pseudohyopertrophy occurs only rarely and is slight. There is an inability to close the eyes firmly, to purse the lips, and to whistle; the lips have a peculiar looseness and tendency to protrude. The lower parts of the trapezius muscles and the sternal parts of the pectorals are almost invariably affected. By contrast, the deltoids may seem to be unusually large and strong, an appearance that may be mistaken for pseudohyopertrophy. The advancing atrophic process involves the sternomastoid, serratus magnus, rhomboid, erector spinae, latissimus dorsi, and eventually the deltoid muscles. The bones of the shoulders become salient; the scapulae are winged and elevated (“angel-wing” appearance), and the clavicles are prominent. The anterior axillary folds slope down and out as a result of wasting of the pectoral muscles. Usually the biceps weight less than the triceps, and the brachioradialis muscles even less, so that the upper arm may be thinner than the forearm (“Popeye” effect). Pelvic muscles are involved later and to a milder degree,
giving rise to a slight lordosis and pelvic instability. The pretibial muscles weaken, and foot drop is added to the waddling gait. Beevor's sign, an upward movement of the umbilicus on flexing the neck due to weakness of the lower abdominal muscles, is reportedly common (Awerbuch et al), but we have not seen it in early cases.

Early in the disease, the muscular weakness may be asymmetrical (wringing of only one scapula). Many patients with milder degrees of this form of dystrophy are muscular forms of amyotrophic lateral sclerosis (ALS). This was true of nearly half of the very large series of patients described by Tyler and Stephens in the Utah Mormon population. At any one point the disease may become virtually arrested. Nevertheless, 15 to 20 percent of patients eventually become wheelchair-bound (Tawil et al).

An occasional feature of this group of diseases is the congenital absence of a muscle (one pectoral, brachial, or biceps femoris) or part of a muscle in patients with this type of muscular dystrophy. Also, the muscular weakness is known to become affected occasionally, late in the illness. Cardiac involvement is rare, but in a few of the cases tachycardia, cardiomyopathy, and arrhythmias (ventricular and atrial extrasystoles) have occurred. Mental function is normal. Serum CK values are normal or slightly elevated.

At a molecular level, facioscapulohumeral dystrophy is now defined by its consistent association with deletions of variable size on chromosome 4q. No genes have been identified despite extensive sequencing of the deleted region, and it is postulated that the deletions interfere with the expression of a gene or genes located proximal to the deletions (see Tawil et al).

A probable variant is characterized by an early onset and relatively rapid progression and an association with facial diplegia, sensorineural deafness, and sometimes exudative retinal detachment (Coats disease). Using fluorescein angiography, Fitzsimmons and others found a variety of other retinal abnormalities—comprising telangiectasias, occlusion, leakage, and microaneurysms—in 56 of 75 persons with the usual form of facioscapulohumeral dystrophy, suggesting that these retinal abnormalities are an integral part of the disease.

Scapuloperoneal Muscular Dystrophy

Beginning with Brossard in 1886, there have been numerous reports of a distinctive pattern of progressive muscular weakness and wasting that typically involves the muscles of the neck, shoulders, and upper arms and anterior tibial and peroneal groups, causing foot drop. The nature of this disorder has been a matter of controversy, some claiming it to be a progressive muscular dystrophy and others, a muscular atrophy of spinal or neuropathic type. Probably both are correct in that either process can produce the same pattern of weakness. Davidson, who wrote extensively on this subject, described a form of familial scapuloperoneal weakness and atrophy associated with areflexia and distal sensory loss (a spinal-neuropathic form), and others have confirmed these findings (see discussions of Thomas et al and of Munsat and Sarratrice). Nevertheless, Thomas and colleagues (1975) established a myopathic form. The onset of symptoms in their six patients was in early or middle adult life, with difficulty in walking due to bilateral foot drop; symptoms referable to sarcoglycanopathy involvement came later. Progression was slow and none of the patients became severely incapacitated. Autosomal dominant inheritance seemed likely.

More recently, Wilhelmsen and associates have defined the genetic defect in a large family with autosomal dominant scapuloperoneal syndrome (14 affected persons in a 44-member pedigree). Onset was in early adult life with difficulty in walking and climbing stairs, due to foot drop, followed by weakness of the proximal arm muscles. The disease was not progressive. Also, the weakness was not debilitating, but in the others it was relatively benign. In addition to the nonspecific histologic features of muscular dystrophy, some fibers showed eosinophilic hyaline inclusions and rimmed vacuoles. Linkage analysis has localized the gene to chromosome 12, proving that it is not simply an allelic variant of facioscapulohumeral or other type of muscular dystrophy.

Limb-Girdle Muscular Dystrophies (Scapulohumeral and Pelvicfemoral Muscular Dystrophies; Erb-Type Dystrophies; LGMD Types 1A-B and 2A-E)

(See Table 50-1.) Clearly there is a large group of patients with muscular dystrophy who do not fit into the Duchenne-Becker, facioscapulohumeral, or scapuloperoneal categories described above. Children of both sexes in this group lack the hypertrophy of calves and other muscles; adults with late-onset forms have either pelvic or shoulder girdle involvement or both, and their facial muscles are spared. Insofar as Wilhelm Erb first called attention to these types of dystrophy, they were classified by Walton and Nattrass as the “limb-girdle dystrophies of Erb.” This grouping has been problematic from the time it was proposed, because, like the scapuloperoneal group, it is heterogenous—the only unifying feature being the presence of limb-girdle weakness with sparing of the facial muscles. The inheritance has been reported as autosomal recessive. The autosomal recessive forms are the most common. Either the shoulder girdle or pelvic girdle muscles may be first affected (traditionally these forms have been referred to as the Erb juvenile atrophic and Leyden-Möbius types, respectively). The weakness and atrophy may become evident during either during late childhood or early adult life and spread from shoulders to hips or vice versa.

The later the onset of this group of disorders, the more likely the course will be benign; dominant inheritance and lack of family history are also features favoring slow progression. In the latter group, while the EMG is myopathic, the CK values are only moderately elevated and may even be normal in the most chronic forms. Cardiac involvement is infrequent, and mental function is normal.

As indicated earlier in this chapter, the status of this group of limb-girdle dystrophies as a clinical-genetic entity is being steadily eroded. The delineation of the progressive muscular atrophic dystrophies and the congenital and metabolic myopathies has considerably narrowed the category of limb-girdle dystrophies as originally described. During the past decade, with the application of molecular genetic techniques, progress in this direction has accelerated greatly. At the time of writing, at least 24 forms of autosomal recessive and 3 forms of autosomal dominant limb-girdle dystrophies have been defined—most with a distinct chromosomal locus and gene and, in seven of them, an identifiable gene product (Bushby). This information is summarized in Table 50-1 and the better-characterized types are discussed below.

Severe Childhood Autosomal Recessive Muscular Dystrophy (Sarcoglycanopathy; SCARMD; LGMD 2C, D, and E) This is perhaps the best-defined form of limb-girdle dystrophy. Clinically it resembles the severe form of Duchenne dystrophy in practically all respects, including the presence of calf hypertrophy, cardiomyopathy, and marked elevation of CK in the early stages of the illness. The obvious distinction from Duchenne dystrophy is the autosomal recessive pattern of inheritance (affection of both boys and girls in the same sibship). The largest and best-studied group of this severe, recessive pelvic-patellar dystrophy (99 children in 28 families), has come from Tunisia (BenHamida et al). It also occurs commonly in other Arab countries and has been observed repeatedly in Brazil but less in Europe and North America.

The basic defect in SCARMD is in one of three dystrophin-associated glycoproteins (DAGs)—a, b, and g-sarcoglycan (see Fig. 50-1): a-sarcoglycan (50 DAG) is also called adhalin, from the Arabic word adhal, meaning muscle. A primary deficiency of adhalin is due to a defective gene mapped to chromosome 17q21 (Roberts et al). A primary defect in b-sarcoglycan (43 DAG or heretosin) has been mapped to chromosome 4q12, and of g-sarcoglycan (35 DAG) to the pericentromeric region of chromosome 13q. When SCARMD is due to a primary defect in 43 DAG or 25 DAG, it may in addition show a deficiency of adhalin, but the latter is incomplete and represents a secondary effect, possibly explained by the proximity of the defective genes to the adhalin gene.

From a practical point of view, there is no difficulty in distinguishing SCARMD from a dystrophinopathy. In addition to the difference in inheritance, the former can be readily diagnosed by showing a loss of sarcolemmal immunostaining for adhalin. Clinically it is not possible to distinguish one sarcoglycanopathy from another; this can be accomplished only by appropriate immunostaining.

Autosomal Recessive Muscular Dystrophy Linked to Chromosomes 15q and 2p (LGMD 2A and B) These forms of limb-girdle dystrophy have been described in several large groups in Indiana (among the Amish people), on the Island of Réunion in the Indian Ocean, and in Brazil, affecting males and females equally. Both the shoulder and pelvic girdles were affected. The weakness varied considerably in severity but differed from SCARMD in its later age of onset (usually between 8 and 15 years) and loss of ambulation (around 30 years). In one form of the disease, called LGMD 2A, the abnormal gene has been mapped to chromosome 15q and the gene product has been identified as calcium-activated neutral protease, or calpain. This “calpainopathy” accounts for about 40 percent of patients with LGMD.

Frequently, and early in the course of disease, there are Achilles tendon contractures and very high serum CK levels (at least 10 times normal)—features that may permit distinction from the sarcoglycanopathies on clinical grounds.

Yet another gene for a recessive limb-girdle dystrophy of slow progression has been identified in a Palestinian and Sicilian family and mapped to chromosome 2p. The gene product appears to be the protein dysferlin, which localizes to the muscle fiber membrane. Noteworthy is the fact that this same protein is also involved in the predominantly distal form of Miyoshi muscular dystrophy, described further on. Early involvement of the gastrocnemius muscle (inability to walk on tiptoe) and extraordinarily high levels of CK, as in cpainopathy, are clues to the latter.

Autosomal Dominant Limb-Girdle Dystrophies Localized to Chromosomes 21q and 5q (LGMD 1B) In 1976, Bethlehem and van Wijngaarden described an
autosomal dominant, early-onset limb-girdle dystrophy in 28 members of three unrelated Dutch families. Flexion contractures of the elbows, ankles, and interphalangeal joints of the fingers were present from the beginning stages of weakness but neither the weakness nor the contractures were disabling. Unlike Emery-Dreifuss dystrophy, contractures of the neck and spine were not present. Uniformity of clinical expression, slow progression with long periods of arrest, and normal longevity are other important features of the illness. Mohr and coworkers have proposed the designation Bethlem myopathy. A similar disease has now been recognized in the United States. Linkage analysis has assigned the locus of this dystrophy to the distal part of chromosome 21q. The Dutch families described by van der Kooi et al were also shown to have an autosomal dominant pattern of inheritance. Clinically the dystrophy was much the same as described by Bethlem, except that more than half of the affected members in van der Kooi’s families developed abnormalities of cardiac rhythm in their later years, necessitating pacemaker implantation. In the latter cases the gene abnormality has been localized to chromosome 1q.

Yet another type of autosomal limb-girdle dystrophy of late onset has been found in a large North Carolina family (49 affected members in a pedigree of 218 persons). Mean age at onset was 27 years. Proximal leg weakness, with or without proximal arm weakness, and elevated CK values were the main clinical characteristics. Spreer and colleagues have linked the abnormal gene to chromosome 5q.

Progressive External Ophthalmoplegia (Ocular Myopathy of von Graefe-Fuchs; Kearns-Sayre syndrome; PEO)

This is a slowly progressive myopathy primarily involving and often limited to the extracocular muscles. Usually the levators of the eyelids are the first to be affected, causing ptosis, followed by this disorder of progressive ophthalmoplegia. This disorder usually begins in childhood, sometimes in adolescence, and rarely in adult life (as late as 50 years). Males and females are equally affected; the pattern of inheritance is autosomal dominant in some and recessive or uncertain in others. Once started, the disease progresses relentlessly until the eyes are motionless. Simultaneous involvement of all extracocular muscles permits the eyes to remain in a central position, so that the distance between the eyes is no greater than the distance between the pupils. In the later stages of this disease the ptosis occurs only one eye is affected before the diplopia is uncompliant attempts to raise his eyelids and to see under them, the head is thrown back and the frontalis muscle is contracted, wrinkling the forehead (hutchinsonian facies). The eyelids are abnormally thin because of atrophy of the levator muscles. The orbicularis ocularis muscles are frequently involved in addition to the extracocular muscles. Thus, in progressive external ophthalmoplegia, as in myotonia congenita and myotonic dystrophy, there is a characteristic combination of weakness of eye closure and eye opening, a combination that is nearly always myopathic. Other facial muscles, masseters, sternomcleidomastoids, deltoids, or peronei are variably weak and wasted in about 25 percent of cases.

The absence of myotonia, cataracts, and endocrine disturbances distinguishes progressive external ophthalmoplegia from myotonic dystrophy, with which it might be confused because of the ptosis. The more extensive forms of the disease may resemble a mild form of facioscapulohumeral muscular dystrophy, and, indeed, Landouzy and Déjérine described ocular palsy in one of their cases. The characteristic feature of progressive external ophthalmoplegia is that ptosis and ocular paralysis precede involvement of other muscles by many years. The relatively early age of onset and absence of myotonia set it apart from the oculopharyngeal form of dystrophy, and the lack of retinal degeneration and the normality of growth, muscle, and cerebrospinal fluid (CSF) protein distinguish it from the refractory mitochondrial disorder, Kearns-Sayre syndrome.

Opinions vary as to whether all cases of progressive external ophthalmoplegia should be assigned a myopathic origin. Dystrophy and partial denervation are difficult to distinguish on the basis of the appearance of the biopsied eye muscle, as pointed out by Ringel and associates. (Denervation of eye muscles does not result in grouped atrophy.) The categorization of progressive external ophthalmoplegia is complicated further by its frequent association with a variety of neurologic abnormalities and atypical pigmented degeneration of the retina. This has led to the reclassification of many of these cases as mitochondrial diseases. The purely myopathic origin of some cases is proven by inactivity of neurons in the brainstem nuclei and normality of the cranial nerves. From the available data, the authors believe it possible to separate at least two distinctive syndromes from this group. One of these is the restricted oculopharyngeal dystrophy of late onset, which is described below. Another rather uniform syndrome comprises childhood ophthalmoplegia, pigmentary degeneration of the retina, varying degrees of heart block, short stature, and elevated CSF protein (Kearns and Sayre). Because of its special histopathologic features, this latter syndrome is discussed with the congenital mitochondrial myopathies (page 1043).

Oculopharyngeal Dystrophy

This disease is inherited as an autosomal dominant trait and is unique in respect to its late onset (usually after the 45th year) and the restricted muscular weakness, manifest mainly as a bilateral ptosis and dysphagia. E. W. Taylor first described the disease in 1915 and assumed that it was due to a nuclear atrophy (oculomotor-vagal complex); Victor and colleagues, in 1962, showed that the descendants of Taylor’s cases had a late-life myopathy (myotonic EMG and biopsy). One of the families that we described was subsequently traced through 10 generations to an early French-Canadian immigrant, who was the progenitor of 249 descendants with the disease (Barbeau). Other families showing a dominant (rarely recessive) pattern of inheritance and a number of sporadic cases have been observed in many parts of the world.

Associated with slowly progressive ptosis is difficulty in swallowing and change in voice. Swallowing becomes so difficult that food intake is limited, resulting in cachexia. The latter is ameliorated by cutting the cricopharyngeus muscles and, failing this measure, by a gastrostomy or nasogastric tube. Later in the disease, in some families, the external ocular muscles and shoulder and pelvic muscles become weakened and atrophic to a varying extent. In the few autopsied cases, a loss of fibres and some atrophy was widespread in the saccus and other muscles. Rimmed vacuoles and, by electron microscopy, intracellular tubular filamentary are characteristic but not specific histologic findings (these features are seen in several other myopathies, particularly in inclusion body myositis). The brainstem nuclei and cranial nerves are normal. As in the other mild and restricted muscular dystrophies, the serum CK and aldolase levels are normal, and the EMG is altered only in the affected muscles. The gene locus has been mapped to chromosome 14q (Barbeau et al), and DNA testing is now available. The gene product remains to be identified.

Myotonic Dystrophy (Dystrophia Myotonica)

This, the commonest adult form of muscular dystrophy, was described in 1909 by Steinert, who considered it to be a variant of congenital myotonia (Thomsen disease), and, in the same year, by Batten and Gibb, who recognized it as a separate clinical entity. It is distinguished by an autosomal dominant pattern of inheritance with a high level of penetrance, a unique topography of the muscle atrophy, and an associated myotonia, and the occurrence of dystrophic changes in nonmuscular tissues (lens of eye, testicle and other endocrine glands, skin, esophagus, heart, and, in some cases, the cerebrum). Certain muscles—namely the levator palpebrae, facial, masseter, sternomclastoid, and forearm, hand, and pretibial muscles—are consistently involved in the dystrophic process. In this sense, dystrophy myotonica is a distal type of myopathy. It is possible that Gowers’ case of an 18-year-old youth with weakened and wasted anterior tibial and forearm muscles and sternomcleidomastoids, in conjunction with paresis of the orbicularis and frontalis muscles, was an example of this disease, differing from the simple distal muscular dystrophy described later by Welander and others (see further on).

Despite the clinical variability of myotonic dystrophy, the defective gene segregates as a single locus at chromosome 19q13.3 in every population that has been studied. In the specific myotonic locus (cytosine, thymine, guanine, or CTG) that is larger in affected individuals than in normal siblings or unaffected control subjects. Myotonic protein kinase is the product encoded by the myotonic dystrophy gene. The size of this lengthened DNA fragment (the “fat gene”) varies among affected siblings and increases in size through successive generations, in parallel with earlier occurrence and increasing severity of the disease (genetic anticipation).

Clinical Features

In most instances of myotonic dystrophy, the muscular wasting does not become evident until early adult life, but it may present in childhood, usually with facial weakness and ptosis. Also, a severe, neonatal (congenital) form of the disease is now well known and is described further on.

In the common early-adult form of the disease, the small muscles of the hands along with the extensor muscles of the forearms are often the first to become atrophied. In other cases, ptosis of the eyelids and thinness and slackness of the facial muscles may be the earliest signs, preceding other muscular involvement by many years. Atrophy of the masseters leads to narrowing of the lower half of the face, and the mandible is slender and malpositioned so that the teeth do not occlude properly. This—along with the ptosis, frontal baldness, and wrinkled forehead—imparts a distinctive physiognomy that, once seen, can be recognized at a glance. The sternomcleidomastoids are almost invariably thin and weak and are associated with an exaggerated forward curvature of the neck (“swan neck”). Atrophy of the anterior tibial muscle groups, leading to foot drop, is an early sign in some families.

Pharyngeal and laryngeal weakness results in a weak, monotonous, nasal voice. The uterine muscle may be weakened, interfering with normal parturition, and the esophagus is often dilated because of loss of muscle fibers in the striated as well as smooth muscle parts. Megacolon occurs in some patients. Diaphragmatic weakness and alveolar hypventilation, resulting in chronic bronchitis and bronchiectasis, are common features, as are cardiac abnormalities; the latter are most often
due to disease of the conducting apparatus, giving rise to bradycardia and a prolonged PR interval. Patients with extreme bradycardia or high degrees of atrioventricular block may die suddenly; for such subjects, insertion of a pacemaker has been recommended (Moorman et al). Mitral valve prolapse and left ventricular dysfunction (cardiomyopathy) are less frequent abnormalities.

The disease progresses slowly, with gradual involvement of the proximal muscles of the limbs and muscles of the trunk. Tendon reflexes are lost or much reduced. Contracture is rarely seen, and the thin, flattened hands are consequently soft and pliable. Most patients are confined to a wheelchair or bed within 15 to 20 years, and death occurs before the normal age from pulmonary infection, heart block, or heart failure.

The phenomenon of myotonia, which expresses itself in prolonged idiomuscular contraction following brief percussion or electrical stimulation and in delay of relaxation after strong voluntary contraction, is the third striking attribute of the disease. Not as widespread as in myotonia congenita (Thomsen disease—see page 1553), it is, nonetheless, easily elicited in the hands and tongue in almost all cases and in the proximal limb muscles in half of the cases. Gentle movements do not evoke it (eye blinks, movements of facial expression, and the like are not impeded), whereas strong closure of the lids and clenching of the fist are followed by a long delay in relaxation.

Myotonia may precede weakness by several years. Indeed, Maas and Paterson claimed that many cases diagnosed originally as myotonia congenita eventually prove to be examples of myotonia dystrophica. Of interest is the fact that in congenital or infantile cases of myotonia dystrophy, the myotonic phenomenon is not elicited until later in childhood, after the second or third year of life (see below). Moreover, the patient often becomes accustomed to the myotonia and does not complain about it. The relation of myotonia to the dystrophy is not direct. Certain muscles that show the myotonia best (tongue, flexors of fingers) are seldom weak and atrophic. There may be little or no myotonia in certain families that show the other characteristic features of myotonic dystrophy.

The four major characteristic is the association of dystrophic changes in nonmuscular tissues. The most common of these are lenticular opacities, which are found by slit-lamp examination in 90 percent of patients. At first dust-like, they then form small, regular opacities in the posterior and anterior cortex of the lens just beneath the capsule; under the slit lamp they appear blue, blue-green, and yellow and are highly refractive. Microscopically, the crystalline material (probably lipids and cholesterol, which cause the iridescence) lies in vacuoles and lacunae among the lens fibers. In older patients a stellate cataract slowly forms in the posterior cortex of the lens.

Mild to moderate degrees of mental retardation are not infrequent, and the brain weight in several of our patients was 200 g less than in normals of the same age. Late in adult life, some patients become suspicious, argumentative, and forgetful. In some families, a hereditary sensorimotor neuropathy may be added to the muscle disease (Cros et al).

Other nonspecific abnormalities, such as hyperostosis of the frontal bones and calcification of the basilar ganglia, both readily discerned by CT scanning, seem to be more common in patients with myotonic dystrophy than in normal persons.

Progressive frontal atopia, beginning at an early age, is a characteristic feature in both men and women with this disease. Testicular atrophy with androgenic deficiency, reduced libido or impotence, and sterility are frequent manifestations. In some patients gynecomastia and elevated gonadotropin excursions are found. Testicular biopsy may show atrophy and hyalinization of tubular cells and hyperplasia of Leydig cells. Thus all the clinical characteristics of the Klinefelter syndrome may be present. However, the nuclei of skin or bone marrow cells only rarely show the "sex chromatin mass" (Barr body). The majority of patients have the usual sex chromosome constitution 47,XXY. Ovarian deficiency occasionally develops in the female patient but is seldom severe enough to interfere with menstruation or fertility. The prevalence of clinical or chemical diabetes mellitus is only slightly increased in patients with myotonic dystrophy, but an increased insulin response to a glucose load has proved to be a common abnormality. Numerous surveys of other endocrine functions have yielded rather little of significance.

In an extensive clinical experience with this form of dystrophy, we have observed the variability of its clinical expression. In many patients, intelligence has been unimpaired and the myotonia and muscle weakness have been so mild that the patients were unaware of any difficulty. Pruse-Phillips and associates emphasized these features in their description of a large Labrador kindship in which 27 of 133 patients had only a partial syndrome and only minor muscle symptoms at the time of examination.

Pathologic Features There are several unusual myopathologic features. Peripherally placed sarcoplasmic masses and circular bundles of myofibrils (ringbinden) are common. Central nucleation may be marked. In many of the muscle spindles there is an excess of intramuscular fibers (particularly in the congenital form, see below). In addition, one observes necrosis of single muscle fibers and many atrophic fibers. Many of the terminal arborizations of the peripheral nerves are unusually elaborate and elongated. The spindle and nerve changes may be secondary to the myotonia or to an associated terminal neuropathy.

Congenital Myotonic Dystrophy Brief reference was made earlier to this distinctive and potentially lethal form of myotonic dystrophy. That it occurs not infrequently is evident from Harper's (1975) study of 70 personally observed patients and 56 others gathered from the medical literature. Profound hyptonia and facial diplegia at birth are the most prominent clinical features; myotonia is notable for its absence. The drooping of the eyelids, the tented upper lip ("carm mouth"), and the open jaw impart a characteristic appearance, which allows immediate recognition of the disease in the newborn infant and in the child. Difficulty in sucking and swallowing, bronchial aspiration (due to palatal weakness), and respiratory distress (due to diaphragmatic and intercostal weakness and pulmonary immaturity) are present in varying degrees of severity; the latter disorders are responsible for a previously unrecognized group of neonatal deaths (24 such deaths among sibs of affected patients in Harper's study). In surviving infants, delayed motor and speech development, swallowing difficulty, mild to moderately severe mental retardation, and tapers or generalized arthrogryposis are common. Once adolescence is attained, the disease follows the same course as the later form. As stated above, clinical myotonia in the congenital form of the disease becomes evident only later in childhood, although EMG study may disclose myotonic discharges in early infancy. The diagnosis may be suspected by the simple test of eliciting myotonia in the mother. Electrophysiologic changes occur in one-third of the patients.

The affected parent in the congenital form of the disease is always the mother, in whom the disease need not be severe; electrophysiologic testing will bring out the myotonic phenomenon. Ovarian deficiency occasionally develops in the female patient but is seldom severe enough to interfere with menstruation or fertility. The prenatal diagnosis of myotonic dystrophy is readily accomplished by examination for CTG repeats in the amniotic fluid or in a biopsy of chorionic villi. However, it is not possible to predict whether a fetus with an expanded mutation will have congenital myotonic dystrophy or myotonic dystrophy of other type.

Proximal Myotonic Myopathy (PROMM) Under this title, Ricker and colleagues have described a myopathy characterized by autosomal dominant inheritance, proximal muscle weakness, myotonia, and cataracts. Seventeen families, containing 50 affected members, have been studied by these authors. Onset was between 20 and 40 years, with intermittent myotonic symptoms of the hands and proximal musculature, followed by a mild, slowly progressive weakness of the proximal limb muscles without significant atrophy. Cataracts developed in half the patients and cardiac arrhythmias in only two. Ptosis, weakness of facial, jaw, and distal limb muscles, and mental abnormalities were not notably absent.

Histologically the appearance was that of a nonspecific myopathy. Numerous surveys of other endocrine functions have yielded rather little of significance.

The Distal Muscular Dystrophies (Welandar, Miyoshi Types) Included under this heading is a group of slowly progressive distal myopathies with onset principally in adult life. Weakness and wasting of the hands, forearms, and lower legs, especially the extensors, are the main clinical features. Although cases such as these had been reported by Gowers and others, their differentiation from myotonic dystrophy and peroneal muscular atrophy was unclear until relatively recent times.

One type of distal dystrophy, inherited as an autosomal dominant trait, was recorded by Mithorat and Wolff in 1943. They studied 12 individuals of one family affected by "a progressive muscular dystrophy of atrophic distal type." The onset was between 26 and 43 years; within 5 to 15 years the patients had become disabled. There was one autopsy, confirming the dystrophic nature of the disease.

Welandar's account of a similar disorder, based on the study of 249 patients from 72 Swedish pedigrees, appeared in 1951 (not to be confused with the Kugelberg-Welandar juvenile spinal muscular atrophy affecting proximal muscles—see page 1161). In her series, the mode of inheritance was also autosomal dominant. Weakness developed first in the small hand muscles and then spread to the distal leg muscles, causing a steppage gait. Fasciculations, cramps, pain, sensory disturbances, and myotonia were notably absent. Senile cataracts appeared after the age of 70 in three patients and can be discounted as having special
significance. No endocrine disorders were detected. Dystrophic changes were demonstrated in three autopsies and 22 biopsy specimens. The central nervous system and peripheral nerves were normal. Progression of the disease was very slow, after 10 years or so some wasting of proximal muscles was seen in a few of the patients. Markesbery and colleagues reported a late-onset distal myopathy in which weakness began in the distal leg muscles and later spread to the hands; there was also cardiomyopathy and heart failure.

A second type of distal dystrophy characterized by an autosomal recessive pattern of inheritance is particularly prevalent in Japan (Miyoshi et al., Nonaka et al.). Onset of the disease is in early adult life, with weakness and atrophy of the leg muscles, most prominent in the peroneal or the gastrocnemius and soleus muscles. Over many years the weakness extends to the thighs, gluteal muscles, and arm muscles, including the proximal ones. Serum CK concentrations are greatly increased in the early stages of the disease. In this “Miyoshi type” of dystrophy, gene linkage to chromosome 2p12-14 has been established; the mutation leads to an absence of the muscle protein dystrophin, a membrane protein that is not thought to be part of the dystrophin complex (Matsuda et al.). Of interest is the fact, mentioned earlier, that one of the limb-girdle dystrophies (2B) has been linked to the same chromosomal locus and also lacks the dystrophin protein (Table 50-1).

An apparently separate form of distal myopathy with autosomal dominant inheritance and onset before 2 years of age has been described by Magee and DeJong and by van der Does de Willebois and coworkers. Whether these infantile-onset cases represent a true muscular dystrophy has not been established beyond doubt.

### Congenital Muscular Dystrophy (Fukuyama, Walker-Warburg, Merosin Deficient, Rigid Spine, and Other Types)

Early in the twentieth century there were scattered reports of congenital myopathy, but the status of this condition was difficult to evaluate, mainly because of a lack of completeness of pathologic examinations. Some cases may have represented congenital myotonic dystrophy, described above, or one of the congenital myopathies discussed in Chapter 52. In 1957 Banker and her associates described two patients (siblings), one dying 1 1/2 h after birth and the other at the age of 10 months of a congenital muscular dystrophy with arthropathy. The pathologic changes consisted of muscle fiber degeneration, variation in fiber size, fibrosis, and fat cell replacement. The central and peripheral nervous systems were intact. The severity of the degenerative changes was such that a developmental disorder of muscle could be excluded.

Pearson and Fowler, in 1963, reported a brother and sister with similar clinical and pathologic findings, and Walton et al described yet another patient, aged 4 years. In 1967 Vassella and colleagues were able to collect 27 cases from the medical literature and to add 8 cases of their own. The high incidence of sibling involvement pointed to an autosomal recessive inheritance.

Defined as a muscle dystrophy already present at birth, often with contractures of proximal muscles and trunk, the severity of the weakness and degree of progression have varied widely. Of the eight cases reported by Roththauer and others, one had a benign course, but the others all had weakness and hypotonia at birth, and difficulty in sucking and swallowing had intervened with nutrition. The clinical course varied from 14 and 23 years, and several others had walked, but at a late age. In the Finnish series of Donner and associates, congenital dystrophy accounted for 9% of the 160 cases of neuromuscular disease seen at their hospital over a decade. The weakness and hypotonia were generalized, and three had ECG abnormalities. The CK values were elevated and the EMGs were myopathic.

In the 1960s a series of papers issued from Japan relating the details in over 100 patients with congenital dystrophy (Fukuyama et al.). A feature of these cases was the coexistence of severe mental retardation and developmental anomalies of the cerebral cortex. Hyperlucency in the periventricular white material (by computed tomography) was frequently observed in these patients. In another group of cases, congenital muscular dystrophy was associated with lissencephaly as well as congenital anomalies (Walker-Warburg syndrome; see Dobyns et al.). In a series of 19 Finnish cases reported by Santavuori and colleagues, congenital muscular dystrophy was associated with retinal degeneration and optic atrophy, hydrocephalus, pachygyria-polymicrogyria, and hypoplastica or absent septum pellucidum and corpus callosum (“muscle-eye-brain disease”). Lebenthal and colleagues described a large Arab pedigree with congenital muscular dystrophy and patent ductus arteriosus. Some patients had contractures at birth; in others contractures developed at a later age. The EMG disclosed a myopathic pattern, and CK levels were moderately elevated.

In recent years the classifications of the congenital muscular dystrophies have been clarified to some extent by a number of molecular genetic studies (see Table 50-1). The most frequent congenital muscular dystrophy in the Caucasian population is the classic (Occidental) type, so called because it is characterized exclusively by muscle involvement. (Occasionally there are abnormal white matter signals on magnetic resonance imaging.) Tomi and others have shown that in approximately half such patients, merosin is completely absent (merosin-negative). Merosin, the predominant isoform of a-laminin in the basement membrane of the muscle fiber, is closely bound to a-dystroglycan, which in turn is bound to the dystrophin cytoskeleton (Fig. 50-1). An absence of merosin interrupts this linkage and leads to muscle degeneration. The diagnosis of merosin deficiency can be made by immunostaining of chorionic villi cells prenatally and skeletal muscle postnatally. Merosin-negative congenital muscular dystrophy has been mapped to chromosome 6p22, clearly distinguishing it from the Fukuyama, or merosin-positive, type on both genetic and clinical grounds (Table 50-1).

An additional member of the group of merosin-positive congenital muscular dystrophies is one termed rigid spine syndrome. The term was first proposed by Dubowitz and the clinical syndrome, as outlined by Flanagan et al., consists of (1) infantile hypotonia with early weakness of neck muscles and poor head control; (2) stabilization with only slight decrease of muscle strength but marked loss of muscle bulk; (3) prominent contractures of spiral muscles, resulting in scoliosis and rigidity of the thoracic cage, to a lesser extent, contractures of the knee and elbow joints; (4) respiratory insufficiency (rarely seen before adolescence); and (5) normality of intellectual and cardiac function. Recently the locus for congenital muscular dystrophy with rigid spine syndrome (CMD-RSS) was mapped to 1p35–36 (Mohandas et al.).

In the Fukuyama type of congenital muscular dystrophy, the abnormal gene has been mapped to kq31–33, and the altered gene product has been identified (fukutin). The so-called muscle-eye-brain disease (MEB) is genetically distinct; the chromosomal locus is at 1p32–34 (Miyoshi et al). Onset of the disease may begin to cause symptoms or to worsen in adult years. These include central core and nemaline myopathy. Examples of mild forms of acid maltase or debrancher enzyme deficiency with glycogenosis, progressive late-stage hypokalemic polymyopathy, mitochondrial myopathy, and carnitine polymyopathy have been reported in the adult. Muscle biopsy and histochemical staining of the muscle usually provide the correct diagnosis. However, there may still be uncertainty, in which instance a trial of prednisone is indicated for a period of 6 months. Unmistakable improvement favors polymyositis; no improvement or worsening points to dystrophy. The main points that help to distinguish polymyositis from dystrophy have been outlined in Chap. 52. In most cases, at least the clinical presentation strongly favors polymyositis; however, a few cases of a muscle biopsy, molecular genetic studies, and other tests are sometimes required to rule out polymyositis.

Problems in Diagnosis

The following are some of the common problems that arise in the diagnosis of muscular dystrophy:

1. The diagnosis of muscular dystrophy of a child who has just begun to walk or in whom walking is delayed. Tests of peak power on command cannot be used with reliability in small children. The most helpful points in identifying Duchenne dystrophy are: (a) unusual difficulty in climbing stairs or arising from a couch or from a recumbent position on the floor, showing greater weakness at the hips and knees than at the ankles; (b) unusually large, firm calves; (c) male sex; (d) high serum CK, aldolase, and myoglobin; (e) myopathic EMG; (f) biopsy findings; and (g) special methods of testing for dystrophin protein (see previous discussions).

2. The adult patient with diffuse or proximal muscle weakness of several months' duration, raising the question of polymyositis versus dystrophy. Even biopsy may be misleading in showing a few inflammatory foci in an otherwise dystrophic picture. The main points that help to distinguish polymyositis from dystrophy have been indicated in Chap. 49. As a rule, polymyositis evolves more rapidly than dystrophy and is associated with high CK and aldolase values (higher than any dystrophy except the Duchenne and distal Miyoshi types), and the EMG shows many fibrillation potentials (rare in adults of muscular dystrophy). With these points in mind, there may still be uncertainty, in which instance a trial of prednisone is indicated for a period of 6 months. Unmistakable improvement favors polymyositis; questionable improvement (physician's and patient's judgment not in accord) leaves the diagnosis unsettled.

3. An adult with a slowly evolving proximal weakness. In addition to facioscapular and limb-girdle dystrophies, several of the congenital polymyopathies discussed in Chap. 52 may begin to cause symptoms or to worsen in adult years. These include central core and nemaline myopathy. Examples of mild forms of acid maltase or debrancher enzyme deficiency with glycogenosis, progressive late-stage hypokalemic polymyopathy, mitochondrial myopathy, and carnitine polymyopathy have been reported in the adult. Muscle biopsy and histochemical staining of the muscle usually provide the correct diagnosis.

4. The occurrence of subacute or chronic symmetrical proximal weakness in an adolescent or adult that raises the question of spinal muscular atrophy (Kugelberg-Welander type—see page 1161) as well as of polymyositis and muscular dystrophy. Electromyography and muscle biopsy usually settle the matter.

5. Weakness of a shoulder or one leg of some weeks' standing, with increasing atrophy. Here one must differentiate between a mononeuropathy or radiculitis, the beginning of motor system disease (progressive spinal muscular atrophy), and rarely the early stage of a muscular dystrophy. The first two may develop silently, in mild form, and attract notice only when wasting begins (denervation atrophy takes 3 to 4 months to reach its peak). Points in favor of these acquired diseases are: (a) confinement of the disease to muscles originally affected and sparing of other muscles and (b) an EMG showing denervation effects. Biopsy is seldom performed...
under such circumstances, for, by temporizing, the problem eventually settles itself. Invariably muscle dystrophy becomes bilateral and symmetrical; mononeuropathies stabilize and recovers; and spinal muscular atrophy declares itself by the presence of fasciculations and relatively rapid progression of weakness.

6. The distinction, in the child or adolescent, between dystrophy and one of the congenital myopathy is considered in relation to the latter disorders (Chap. 52).

Treatment There is no specific treatment for any of the muscular dystrophies; the physician is forced to stand by helplessly and witness the unrelenting progression of weakness and wasting. The various vitamins (including vitamin E), amino acids, testosterone, and drugs such as penicillamine, recommended in the past, have all proved to be ineffective. The administration of prednisone appears to retard the tempo of progression of Duchenne dystrophy for a period of up to 3 years (Fenichel et al). The optimal dose is 0.75 mg/kg given daily, but it must often be reduced because of intolerable side effects (weight gain, cushingoid appearance, behavioral and gastrointestinal disorders).

Quinine has a mild curare-like action at the motor end plate and thus relieves myotonia. Although symptomatic relief of the myotonia is usually achieved, the drug has no effect on progression of the muscle atrophy or other degenerative aspects of myotonic dystrophy. The usual dose is 0.3 to 0.6 g orally, repeated as needed about every 6 h. Mild toxic symptoms such as tinnitus may develop before enough quinine has been given to relieve the myotonia. Some patients find the side effects more disturbing than the myotonia and prefer not to take quinine except on occasions when the myotonia is troublesome in a particular activity. Also, procainamide (0.5 to 1 g four times daily) and phenytoin are sometimes useful in alleviating myotonia, but the former is dangerous, even in patients with a pacemaker. Quinine and procainamide slow conduction through the AV node, whereas phenytoin does not have this effect. Testosterone has been found to increase muscle mass and create excitation in patients with myotonic dystrophy but was of no value in preserving strength or lessening myotonia (Griggs et al).

Respiratory failure occurs in virtually all patients affected with Duchenne dystrophy after they become wheelchair-bound as well as in some of the other dystrophic diseases. It may be so insidious as to become evident only as sleep apnea, as a retention of carbon dioxide that causes morning headache, or as a progressive weight loss that reflects the excessive work of breathing. If there are frequent episodes of oxygen desaturation, some improvement in daytime strength and alertness can be attained by assisted ventilation at night. This may be accomplished in early stages by a negative-pressure cuirass-type of device that expands the chest wall periodically or, more conveniently, by nasal positive pressure (so-called NIPPV or BPAP) and later by positive-pressure ventilation through a fenestrated tracheostomy that allows nighttime ventilation but leaves the patient free to speak and breathe through normal mechanisms during the day. However, in patients free of respiratory failure, with vital capacities between 20 and 50 percent of predicted values, a randomized trial of nasal mechanical ventilation failed to demonstrate improvement in prolonged survival (Rashfeld et al). In sum, the clinical impression remains that more severely affected patients can be managed at home for prolonged periods with respiratory assistance. Needless to say, the common complications of muscular dystrophy—notably pulmonary infections and cardiac decompensation—must be treated symptomatically. Surgical management of cataracts is indicated when they become mature.

In recent years there has been a flurry of interest in the injection of human myoblasts with a full complement of dystrophin into the muscles of Duchenne patients. The difficulties of injecting every dystrophic muscle are obvious, and no convincing evidence of the efficacy of such injections even into individual muscles has been forthcoming.

Until such time as gene therapy becomes practical for muscular dystrophy, physicians must rely on physical methods of rehabilitation. Vignos, who reviewed the studies that evaluated muscle-strengthening exercises, has offered evidence that maximal resistance exercises, if begun early, can strengthen muscles in Duchenne, limb-girdle, and facioscapulohumeral dystrophies. None of the muscles were weaker at the end of a year than at the beginning. Cardiorespiratory function after endurance exercise was not significantly improved. Contractures were reduced by passive stretching of the muscles 20 to 30 times a day and by splinting at night. If contractures have already formed, fasciotomy and tendon lengthening are indicated in patients who are still ambulatory. Maintenance of ambulation and upright posture will delay scoliosis. Preventive measures were more successful than restorative ones.

From such observations it is concluded that two factors are of importance in the management of patients with muscular dystrophy: avoiding prolonged bed rest and encouraging the patient to maintain as full and normal a life as possible. These help to prevent the rapid worsening associated with inactivity and to conserve a healthy attitude of mind. Obesity should be avoided; this requires careful attention to diet. Swimming is a useful exercise. Massage and electrical stimulation are

THE METABOLIC AND TOXIC MYOPATHIES

PRIMARY METABOLIC DISORDERS OF MUSCLE

The chemical energy for muscle contraction is provided by the hydrolysis of adenosine triphosphate (ATP) to adenosine diphosphate (ADP); ATP is restored by phosphocreatine and ADP acting in combination. These reactions are particularly important during brief, high-intensity exercise. During periods of prolonged muscle activity, phosphorylation requires the availability of carbohydrates, fatty acids, and ketones, which are catabolized in mitochondria. Glycogen is the main sarcoplasmic store of carbohydrate, but blood glucose (from the catabolism of liver glycogen) also moves freely in and out of muscle cells as needed during sustained exercise. The fatty acids in the blood, derived mainly from adipose tissue and intracellular lipid stores, constitute the other major source of energy. Carbohydrate is metabolized during aerobic and anaerobic phases of metabolism, the fatty acids only aerobically.

Resting muscle derives approximately 70 percent of its energy from the oxidation of long-chain fatty acids. As stated above, during a short period of intense exercise, the muscle utilizes carbohydrate derived from glycogen stores; myophosphorylase is the enzyme that initiates the metabolism of glycogen. With longer aerobic exercise, blood flow to muscle and the availability of glucose and fatty acids is increased. At first, glucose is the main source of energy; later, with exhaustion of the glycogen stores, energy is provided by oxidation of fatty acids.

Thus, muscle failure at a certain phase of exercise is predictive of the type of energy failure. A rising blood concentration of β-hydroxybutyrate reflects the increasing oxidation of fatty acids, and an increase in blood lactate reflects the anaerobic metabolism of glucose. The cytochrome oxidative mechanisms are essential in both aerobic and anaerobic muscle metabolism; these mechanisms are considered in Chap. 37, in relation to the mitochondrial diseases, and are referred to here only briefly.

It follows from these observations that the efficiency and endurance of muscle depend on a constant supply of glycogen, glucose, and fatty acids and the enzymes committed to their metabolism. Biochemical derangements in their metabolism give rise to a large number of muscle disorders, the most important of which are elaborated in the following pages.

Glycogen Storage Myopathies

An abnormal accumulation of glycogen in the liver and kidneys was described by von Gierke in 1929; shortly thereafter, Pompe (1932) reported a similar disorder involving cardiac and skeletal muscle. Major contributions to our understanding of glycogen metabolism were made by McAndie, by Cori and Cori, and by Hers, who discovered the deficiency of acid maltase in Pompe disease and enunciated the concept of inborn lysosomal diseases (see Chap. 37). Since then, many nonlysosomal enzyme deficiencies have been identified and have become the basis of the classification presented in Table 51-1. These enzymatic deficiencies alter the metabolism of many cells but most strikingly those of the liver, heart, and skeletal muscle. In about half of the affected individuals, a chronically progressive or intermittent myopathic syndrome is the major manifestation of the disease. With the exception of the rare phosphoglycerate kinase deficiency (X-linked recessive inheritance), all the glycogenoses are inherited as autosomal recessive traits. The most impressive and common of these glycogen storage diseases from the standpoint of the clinical neurologist are α-1,4-glucosidase (acid maltase) and myophosphorylase deficiencies.

Table 51-1 The glycogenoses affecting skeletal muscle

Acid Maltase Deficiency (Glycogenosis Type II) The gene encoding acid maltase has been mapped to the distal portion of the long arm of chromosome 17 (17q23). A deficiency of this enzyme takes three forms, of which the first (Pompe disease) is the most malignant. The latter develops in infancy, between 2 and 6 months; dyspnea and cyanosis call attention to enlargement of the heart, and the liver may be enlarged as well. The skeletal muscles are found to be weak and hypotonic, though their bulk may be increased. The tongue may be enlarged, giving the infant a cretinoid appearance. Hepatomegaly, often present, is not pronounced. Exceptionally, the heart is relatively normal in size, and the central nervous system and muscles bear the brunt of the disorder. The clinical picture then resembles infantile muscular atrophy (Werdnig-Hoffmann disease) and, to add to difficulty in differential diagnosis, occasionally there are fasciculations. The disease is rapidly progressive and ends fatally in a few months. The electromyogram (EMG) is myopathic, but there are fibrillation potentials, heightened insertional activity, and pseudomyotonia as well. Large amounts of glycogen accumulate in muscle, heart, liver, and neurons of the spinal cord and brain. All tissues lack alpha
glucosidase (acid maltase).

In the second (childhood) form, onset is during the second year, with delay in walking and slowly progressive weakness of shoulder, pelvic girdle, and trunk muscles. The toe walking, waddling gait, enlargement of calf muscles, and lumbar lordosis resemble those of Duchenne dystrophy. Cardiomyopathy is exceptional. Hepatomegaly is less common than in the infantile form, and mental retardation was present in only 2 of 18 cases reported by DiMauro et al. Death occurs between 3 and 24 years of age, usually from ventilatory insufficiency.

In the third, or adult, form there is a more benign truncal and proximal limb myopathy. The weakness is slowly progressive over years, and death is usually the result of respiratory complications. At times there is considerable variation in the degree of weakness, some patients being able to remain relatively independent for long periods of time. Death is usually due to respiratory failure. The liver and heart are not enlarged. Creatine kinase (CK) values are increased, as they are in all forms of the disease. The EMG discloses a number of abnormalities—brief motor unit potentials, fibrillation potentials, positive waves, bizarre high-frequency discharges, and occasional myotonic discharges (without clinical evidence of myotonia). The disease is inherited as an autosomal dominant trait, with variable expressivity. The primary abnormality in adult McArdle disease is a deficiency of muscle phosphorylase, which prevents the conversion of glycogen to glucose-6-phosphate. Phosphofructokinase deficiency (Tarui disease) interferes with the conversion of glucose-6-phosphate to glucose-1-phosphate; the defect in the latter condition is also present in red blood cells (Layzer et al.). The gene for myophosphorylase has been localized to the long arm of chromosome 11 (11q13), and analysis of DNA from the patient's leukocytes can be used for diagnosis. The muscle (M) subunit of the phosphofructokinase protein localizes to a gene defect on chromosome 1. This defect predominates in Ashkenazi Jewish men.

Clinical variants of these disorders are known. Some patients, with no previous symptoms of cramps or myoglobinuria, develop progressive weakness of limb muscles in the second decade of life, with proximal limb weakness predominating. This neuroskeletal disorder is similar to the disease of infancy and early childhood, characterized by cirrhosis and chronic hepatic failure, usually with death in the second or third year. Hepatomegaly due to the presence of glycogen and mental retardation was present in only 2 of 18 cases reported by DiMauro et al. Death occurs between 3 and 24 years of age, usually from ventilatory insufficiency.

Carnitine (beta-hydroxy-gamma-N-trimethylamino-butyrate), derived from lysine and methionine, plays a central role in the metabolism of fatty acids. About 75 percent of carnitine comes from dietary sources (red meat and dairy products); the remainder is synthesized in the liver and kidneys. Practically all of the body carnitine is stored in muscle, where it has two main functions: (1) transporting long-chain fatty acyl-CoAs from the cytosolic compartment of the muscle fiber into the mitochondria, where they undergo b-oxidation, and (2) preventing the intramitochondrial accumulation of acetyl-CoAs, thus protecting the cell from the membrane-destructing effects of these substances.

In order to be oxidized, the long-chain fatty acids undergo a series of biochemical transformations. First they are activated to corresponding acyl-CoA esters by acyl-CoA synthetase, located on the outer mitochondrial membrane. Since the inner mitochondrial membrane is impermeable to acyl-CoA esters, they are transferred into the mitochondria as acylcarnitines. This is accomplished by carnitine palmitoyl transferase I (CPT I), also located on the outer mitochondrial membrane. A second carnitine palmitoyl transferase (CPT II), bound to the inner face of the inner mitochondrial membrane, reconverts the acyl-carnitines to fatty acyl-CoAs, which are translocated into the mitochondria matrix. The steps in the transport of long-chain fatty acids into the mitochondrial matrix (the carnitine cycle) are described in detail in the reviews of DiMauro et al, DiDonato, and Roe and Coates, listed in the References. Isoforms of carnitine palmitoyltransferase are critically involved in this process at the inner and outer membranes of the mitochondria.

**Clinical Features of Disordered Fatty Acid Metabolism**

Despite the many biochemical abnormalities that have been defined in the fatty acid metabolic pathways, there are essentially three clinical patterns by which these defects are expressed:

1. One constellation of symptoms referred to as the encephalopathic syndrome has its onset in infancy or early childhood. Its very first manifestation may be sudden death (sudden infant death syndrome, or SIDS), or there may be vomiting, lethargy and coma, hepatomegaly, cardiomegaly, muscular weakness, and hypoketotic hypoglycemia, with hyperammonemia, i.e., a Reye-like syndrome. Undoubtedly, instances of this syndrome have not been recognized as abnormalities of fatty acid metabolism but have been designated incorrectly as the Reye syndrome or as SIDS. They are discussed in Chap. 37.

2. A second (myopathic) syndrome appears in late infancy, childhood, or adult life and takes the form of a progressive myopathy, with or without cardiomyopathy. The myopathy may follow upon episodes of hypoketotic hypoglycemia or may develop de novo.

3. The third syndrome is one that usually begins in the second decade of life. It is induced by a sustained period of physical activity or fasting and is characterized by repeated episodes of rhabdomyolysis with or without myoglobinuria.

Summarized below are the disorders of fatty acid metabolism that affect skeletal muscle:

**Primary Systemic Carnitine Deficiency**

To date, this is the only form of carnitine deficiency that can be considered primary. Its main clinical features are progressive lipid storage myopathy and cardiomyopathy, sometimes associated with the signs of hypoketotic hypoglycemia. There is no dicarboxylic aciduria, in distinction to the secondary b-oxidation defects, in all of which dicarboxylic aciduria is present. The cardiomyopathy, which is fatal if untreated, responds dramatically to oral administration of L-carnitine, 2 to 6 g/day. This disorder is inherited as an autosomal recessive trait. In these families there is frequently a history of sudden unexplained death in siblings, so that early identification of affected children is essential.

**Carnitine Palmitoyltransferase (CPT) Deficiency**

This disease is also inherited as an autosomal recessive trait. The gene encoding CPT has been mapped to chromosome 1q12. There are three types of CPT deficiency, referred to as types I, IIA, and IIB. Type I is the most common. It affects males predominantly, beginning in the second decade of life. Attacks of myalgia, cramps, and muscle weakness, “tightness,” and stiffness are precipitated by sustained (though not necessarily intense) exercise and less often by a prolonged period of fasting. Fever, anesthesia, drugs, emotional stress, and cold are rare precipitating events. The attacks vary greatly in frequency. They are usually accompanied by myoglobinuria, and renal failure occurs in about one-fourth of cases (DiMauro et al). The attacks are not aborted by rest and, once initiated, there is no second-wind phenomenon. There are no warning signs of an impending attack. Any muscle group may be affected.

Persistence of weakness after an attack is uncommon. Serum CK rises to high levels not only during attacks of myoglobinuria but also after vigorous exercise without myoglobinuria. A mild form is more likely to occur in females.

In type I deficiency, necrosis of muscle fibers, particularly type I fibers, occurs during attacks, followed by regeneration. Between attacks, muscle is normal. In type IIA, lipid bodies accumulate in the liver, and in type IIB, excess lipid is detected in heart, liver, kidneys, and skeletal muscle.

During attacks, CPT is either undetectable or greatly reduced in muscle. Dicarboxylic aciduria is absent. Assays are available for the measurement of CPT I and II in circulating lymphocytes and cultured fibroblasts.

There is no specific therapy except that directed at the myoglobinuria and its renal complications. A high-carbohydrate, low-fat diet, ingestion of frequent meals, and additional carbohydrate before and during exercise appear to reduce the number of attacks. Patients need to be instructed about the risks of prolonged exercise and skipped meals.

**Secondary Systemic Carnitine Deficiency**

This is occasionally the result of severe dietary deprivation or impaired hepatic and renal function. Such instances have been observed in patients with alcoholic-nutritional diseases and kwashiorkor, in premature infants receiving parenteral nutrition, in patients with chronic renal failure undergoing dialysis, and rarely as a complication of valproate therapy. However, most cases of systemic carnitine deficiency are due to defects of b-oxidation, described below.

**Other Rare Lipid Myopathies**

**Defects of b-Oxidation**

Rarely do these defects affect muscle alone or predominantly. Practically always, other features of disordered fatty acid metabolism—liver disease, hypoketotic hypoglycemia, Reye-like syndrome, SIDS, and so on—are present in some combination. All of the b-oxidative defects are characterized by dicarboxylic aciduria. The abnormal organic acid(s) in each case are determined by analysis of blood and urine; identification of the specific enzyme deficiency requires tissue analysis (liver and muscle homogenates, cultured fibroblasts). At the time of this writing, no less than eight specific defects of b-oxidation affecting muscle have been described; they are tabulated below.

**Carnitine Acylcarnitine Translocase Deficiency**

This condition causes muscular weakness, cardiomyopathy, hypoketotic hypoglycemia, and hyperammonemia, which develop in early infancy, with death in the first month of life.

**Long-Chain Acyl-CoA Dehydrogenase Deficiency (LCAD)**

The presentation is in infancy, with recurrent episodes of fasting hypoglycemic coma, muscle weakness, and myoglobinuria, and sometimes sudden death. Survivors may develop a progressive myopathy. Administration of carnitine improves the cardiac disorder and prevents metabolic attacks.

**Medium-Chain Acyl-CoA Dehydrogenase Deficiency (MCAD)**

This is a cause of SIDS and a Reye-like syndrome. About half of survivors develop a lipid-storage myopathy in childhood or adult life. The abnormal gene has been mapped to chromosome 1p31. Oral L-carnitine may be of therapeutic value.

**Short-Chain Acyl-CoA Dehydrogenase Deficiency (SCADD)**

This myopathy in a limb-girdle distribution may appear initially in older children and adults, or it may follow episodic metabolic disorders in infancy.

**Long-Chain Hydroxyacyl-CoA Dehydrogenase Deficiency (HAD)**

This is a disease of infancy marked by episodes of Reye-like syndrome, hypoketotic hypoglycemia, lipid storage myopathy, cardiomyopathy, and sometimes sudden death.

**Short-Chain Hydroxyacyl-CoA Dehydrogenase Deficiency (SCHAD)**

This presents as an episodic disorder like the one described above (HAD), but having its onset in adolescence. Recurrent attacks may be associated with myoglobinuria.

**Multiple Acyl-CoA Dehydrogenase Deficiency (MADD); Glutaric Aciduria Type II (GA II)**

Some cases are caused by a deficiency of electron transfer flavoprotein
In the severest form of MADD, infants are born prematurely and many die within the first week of life; added to the common metabolic abnormalities are multiple congenital defects and a characteristic “swueet feet” odor. In less severe cases, the congenital anomalies are absent. In the least severe form, the onset may be in late infancy (with episodic metabolic disturbances) or in childhood or adult life (with a lipid storage myopathy and a deficiency of serum and muscle carnitine). The prenatal diagnosis of GA II is suggested by the finding of large amounts of glutaric acid in the amniotic fluid. In the milder forms of the disease, oral riboflavin (100 to 300 mg/day) may be helpful.

**Muscle Coenzyme Q10 Deficiency**

This condition presents as a slowly progressive lipid storage myopathy from early childhood. The basic defect is in coenzyme Q10 in the respiratory chain of muscle mitochondria. The feeding of coenzyme Q10 has improved the myopathy.

**Multisystem Triglyceride Storage Disease (Chanarin Disease)**

The abnormality of lipid metabolism is distinct from the b-oxidation defects. A progressive myopathy is combined with ophthalmologic manifestations, such as developmental delay, alexia, neurosensory hearing loss, and microeyopia. The lipid material is stored in muscle as triglyceride droplets that are nonlysosomal and non-membrane-bound.

**Mitochondrial Myopathies**

The genetic aspects of mitochondrial diseases and the diverse and overlapping clinical syndromes that constitute this category—including the myopathies—are discussed in Chap. 37.

**THE ENDOCRINE MYOPATHIES**

**Thyroid Myopathies**

Several myopathic diseases are related to alterations in thyroid hormone: (1) chronic thyrototoxic myopathy, (2) exophthalmic opthalmoplegia (infiltrative ophthalmopathy), (3) myasthenia gravis associated with diffuse toxic goiter or with hypothyroidism, (4) periodic paralysis associated with toxic goiter, and (5) muscle hypertrophy and slow muscle contraction and relaxation associated with myxedema and cretinism. Although they are not common, we have encountered several examples of these diseases in a single year in a large general hospital.

**Chronic Thyrotoxic Myopathy**

This disorder, first noted by Graves and Basedow in the early nineteenth century, is characterized by progressive weakness and wasting of the skeletal muscle, occurring in cases without overt hyperthyroidism. The muscle disease is usually myopathic and is different from the nodular than the diffuse type. Exophthalmos and other classic signs of hyperthyroidism are often present but need not be. This complication of hyperthyroidism is most frequent in middle age, and men are more susceptible than women. Some degree of myopathy has been found in more than 50 percent of these patients. The onset is insidious and the weakness progresses over weeks and months. The muscular disorder is most often mild to moderate in degree, but it may be so severe as to suggest progressive spinal muscular atrophy (motor system disease). Muscles of the pelvic girdle and thighs are weakened more than others (Basedow paraplegia), although all are affected to some extent, even the bulbar muscles and rarely the ocular ones. However, the shoulder and hand muscles show the most conspicuous atrophy. Tremor and twitching during contraction may occur, but we have not seen fasciculations. The tendon reflexes are of average briskness, possibly more lively than normal. Both the contraction and relaxation phases of the tendon reflexes are shortened, but usually this cannot be detected by the clinician. Serum concentrations of muscle enzymes are not increased and may be reduced. Usually the EMG is normal, without fibrillations or polyphasic. Biopsies of muscle, except for slight atrophy of both type 1 and 2 fibers and an occasional degenerating fiber, have been normal. Administration of neostigmine has no effect. Muscle power and bulk are gradually restored when thyroid activity is reduced to normal levels.

**Exophthalmic Ophthalmoplegia (Graves Ophthalmopathy)**

These terms refer to the concurrence of weakness of the external ocular muscles and exophthalmos in patients with Graves disease (pulmonary and clini muscles are also involved). The exophtalmos or variies with the stage of the disease, and the muscle weakness is not in itself responsible for the weakness. Often there is orbital pain. Both the exophthalmos and the weakness of the ocular muscles may be preceded by signs of hyperthyroidism or may follow effective treatment of the disorder. The extraocular muscle palsies (and exophthalmos) may occasionally be unilateral, especially at the onset of the illness. Any of the external muscles may be affected, usually one more than others, accounting for strabismus and diplopia; the inferior and medial recti are the most frequently affected, but upward movements are usually limited as well. The typical but not invariable sign of lid retraction imparts a staring appearance. Subtle exophthalmos can be appreciated by standing above and behind the seated patient and observing the relative positions of the lids and the eyelashes. Conjunctival edema and vascular engorgement over the insertions of the medial and lateral rectus muscles can be appreciated by inspecting the globe in its extreme lateral positions. In advanced cases, the enlarged muscle insertions themselves can be appreciated. These swollen muscles are visible on orbital ultrasound, CT, and MRI.

Examination of the eye muscles in biopsy and autopsy material has shown prominent fibrotic tissue, many degenerated fibers, and infiltrations of lymphocytes, mononuclear leukocytes, and lipocytes; hence the term infiltrative ophthalmopathy. These histopathologic findings are suggestive of a specific autoimmune disease—a hypothesis supported by the finding of specific antibodies that react with extracts of eye muscles (Kodama et al). Possibly the antibodies target glycans of the ocular fibers. b-Adrenergic sensitivity of muscle fibers caused by excessive thyroid hormone has been also postulated. Other factors may be involved, such as the small size of reactivity or the reactivity of the abnormal muscle, and the rich mitochondrial content of these specialized muscles. The condition often runs a self-limited course, as does the exophthalmos, and therapy is difficult to evaluate. Certainly the maintenance of a euthyroid state is desirable.

If the exophthalmos is slight, topical applications of adrenergic blocking agents (guanethidine eye drops, 5%) and ophthalmic ointment to prevent corneal drying are adequate. Severe exophthalmos, marked by periorbital and conjunctival edema, and the extraocular muscle weakness may be partially controlled by high doses of corticosteroids (about 80 mg prednisone per day). Because of the hazards of protracted corticosteroid therapy, it should be reserved for patients who would otherwise require surgical intervention. In a number of such cases it has been possible for the patient treated with corticosteroids to weather the crisis and avoid the damaging effects of extreme exophthalmos and risks of surgery. Exophthalmos of a degree that threatens to injure the cornea or cause blindness requires more thorough or by removal of the roof of the bony orbit.

**Thyrotropic Periodic Paralysis**

This disorder resembles familial periodic paralysis (page 1562) and consists of attacks of mild to severe weakness of the muscles of the trunk and limbs; usually the cranial muscles are spared. The weakness develops over a period of a few minutes or hours and lasts for part of a day or longer. In some series of patients with periodic paralysis, as many as half have had hyperthyroidism and many of them have been Asian males. Unlike the typical hypokalemic form, thyrotoxic periodic paralysis is not a familial disorder, and its onset is usually in early adult life. Nevertheless, in most of the thyrotoxic cases, the serum potassium is normal; during the attacks of weakness, and the administration of 100 to 200 mg of potassium chloride has terminated the attacks. Propranolol in doses of 160 mg daily in divided doses is helpful in preventing the attacks. Effective treatment of the hyperthyroidism abolishes the periodic attacks of weakness in more than 90 percent of cases. Other aspects of periodic paralysis are discussed in Chap. 54.

**Myasthenia Gravis with Hyperthyroidism**

Myasthenia is discussed fully in Chap. 37. Here only a few remarks are made on its special relationship to thyrotoxicosis. Myasthenia gravis, in its typical autoimmune, anticholinesterase-responsive form, may accompany hyper- and, rarely, hypothyroidism, which are also considered to be autoimmune diseases. Approximately 5 percent of myasthenic patients have hyperthyroidism, and the frequency of myasthenia gravis in hyperthyroid patients is 20 to 30 times that in the general population. Either condition may appear first, or they may coincide. The weakness and atrophy of chronic thyrotoxic myopathy may be added to the myasthenia without appearing to affect the requirement for or response to neostigmine. By contrast, hypothyroidism, even of mild degree, seems to aggravate the myasthenia gravis, greatly increasing the need for pyridostigmine and at times inducing a myasthenic crisis. Also, in the latter case, thyroxine is beneficial to myasthenia, restored the patient to the status that existed before the onset of thyroid insufficiency. The myasthenia should be regarded as an autoimmune disease independent of the thyroid disease, and each must be treated separately.

**Hypothyroid Myopathy**

Abnormalities of skeletal muscle—consisting of diffuse myalgia and increased volume, stiffness, and slowness of contraction and relaxation—are common manifestations of hypothyroidism. The weakness and atrophy are more marked in the tongue and dysarthria that one observes in myxedema. The presence of action myospasm and myokymia (both of which are rare) and of percussion myoedema and slowness of movement are characteristic of the thyroid myopathies. In the severest form, thyrotoxic periodic paralysis is not a familial disorder, and its onset is usually in early adult life. Nevertheless, in most of the thyrotoxic cases, the serum potassium is normal; during the attacks of weakness, and the administration of 100 to 200 mg of potassium chloride has terminated the attacks. Propranolol in doses of 160 mg daily in divided doses is helpful in preventing the attacks. Effective treatment of the hyperthyroidism abolishes the periodic attacks of weakness in more than 90 percent of cases. Other aspects of periodic paralysis are discussed in Chap. 54.

**Myasthenia Gravis**

Myasthenia is discussed fully in Chap. 54. Here only a few remarks are made on its special relationship to thyrotoxicosis. Myasthenia gravis, in its typical autoimmune, anticholinesterase-responsive form, may accompany hyper- or, rarely, hypothyroidism, which are also considered to be autoimmune diseases. Approximately 5 percent of myasthenic patients have hyperthyroidism, and the frequency of myasthenia gravis in hyperthyroid patients is 20 to 30 times that in the general population. Either condition may appear first, or they may coincide. The weakness and atrophy of chronic thyrotoxic myopathy may be added to the myasthenia without appearing to affect the requirement for or response to neostigmine. By contrast, hypothyroidism, even of mild degree, seems to aggravate the myasthenia gravis, greatly increasing the need for pyridostigmine and at times inducing a myasthenic crisis. Also, in the latter case, thyroxine is beneficial to myasthenia, restored the patient to the status that existed before the onset of thyroid insufficiency. The myasthenia should be regarded as an autoimmune disease independent of the thyroid disease, and each must be treated separately.

**Hypothyroid Myopathy**

Abnormalities of skeletal muscle—consisting of diffuse myalgia and increased volume, stiffness, and slowness of contraction and relaxation—are common manifestations of hypothyroidism. The weakness and atrophy are more marked in the tongue and dysarthria that one observes in myxedema. The presence of action myospasm and myokymia (both of which are rare) and of percussion myoedema and slowness of movement are characteristic of the thyroid myopathies.
but CK levels are usually elevated, often markedly so. Serum globulin may also be increased. Muscle biopsies have disclosed only the presence of large fibers or an increase in the proportion of small fibers (either type 1 or 2) and slight distention of the sarcoplasmic reticulum and subsarcolemmal glycogen (probably all due to disuse atrophy).

The administration of thyroxine corrects the muscle disturbance.

Pathogenesis of the Thyroid Myopathies How thyroid hormone affects the muscle fiber is still a matter of conjecture. Clinical data indicate that thyroxine influences the contractile process in some manner but does not interfere with the transmission of impulses in the peripheral nerve, across the myoneural junction, or along the sarcoclemma. In hypothyroidism this functional disorder enhances the speed of the contractile process and reduces its duration, the net effect being fatigability, weakness, and loss of endurance of muscle action. In hypothyroidism, muscle contraction is slowed, as is relaxation, and its duration is prolonged.

The speed of the contractile process is thought to be related to the quantity of myosin adenosine triphosphatase (ATPase), which is increased in hyperthyroid muscle and decreased in hypothyroid muscle. The speed of relaxation depends on the rate of release and reaccumulation of calcium in the endoplasmic reticulum. This is slowed in hypothyroidism and increased in hyperthyroidism (Ianuzzo et al). The myopathic effects of hypothyroidism need always to be distinguished from those of a neuromyopathy, which may rarely complicate hypothyroidism (page 1414).

Corticosteroid Polyneuropathies

The widespread use of adrenal corticosteroids has created a class of muscle diseases similar to the one that occurs in the Cushing syndrome (Müller and Kugelberg). A deficiency of corticosteroids, as occurs in Addison disease, also causes generalized weakness, but without an identifiable muscle disease.

Corticosteroid Myopathy The prolonged use of corticosteroids causes the proximal limb and girdle musculature to become weak, to the point where the patient has difficulty in elevating the arms and arising from a sitting, squatting, or kneeling position; walking, particularly up stairs, may also be hampered. The EMG is either normal or mildly myopathic, with small and abundant action potentials but no fibrillations. Biopsies disclose only a slight variation in fiber size, with atrophic fibers, mainly of type 2b, but little or no fiber necrosis and no inflammatory cells. Electron microscopically, there are aggregates of mitochondria, accumulations of glycogen and lipid, and slight myofibrillar loss (disuse atrophy). The serum CK and aldolase are usually normal. These changes are the same as those that characterize Cushing disease and may suggest that diagnosis (page 715).

There is only a poor correlation between the total dose of corticosteroid and the severity of muscle weakness. Nevertheless, in patients who develop this type of myopathy, the corticosteroid dosage has usually been high and sustained over a period of months or years. All corticosteroids may produce the disorder, although fluocinonide and the fluorinated ones are said to be more culpable than others. Discontinuation or reduction of corticosteroid administration leads to gradual improvement and recovery. The mechanism by which corticosteroids cause muscle weakness is not known. In corticosteroid-treated animals, there is a measurable decrease in amino acid uptake and protein synthesis.

Acute Steroid Myopathy (Critical Illness Myopathy; Acute Quadriplegic Myopathy) In addition to the well-known proximal myopathy induced by the long-term use of steroids, an acute and severe myopathy has been recognized. It is seen most often in critical care units, typically among patients with severe intratable asthma but also among others with numerous systemic diseases who are being treated with high doses of corticosteroids—and rarely in those with sepsis and shock alone. The use of neuromuscular blocking agents plays an important complementary role in the genesis of this myopathy, being a factor in over 80 percent of reported cases, but it is uncertain whether they alone can produce a similar process (see reviews by Gorson and Ropper, by Lacomis et al, and by Barohn et al).

The severe muscle weakness becomes evident when the systemic illness subsides, and it greatly slows weaning from the ventilator. The tendon reflexes are normal or diminished, and there may be confounding features of a polyneuropathy, which can also be induced by critical illness and sepsis (page 1388). Most of our patients have recovered over a period of many weeks after the offending agent has been withdrawn, but a few have remained weak for as long as a year. Patients who acquire this problem have generally been exposed to high doses of corticosteroids, albeit for brief periods in some cases. Exceptional instances have been reported in which the myopathy was induced by drugs as low as 60 mg prednisone administered for 5 days, but we have not encountered cases such as these. Likewise, the amount of simultaneous exposure to neuromuscular blocking agents, when they have been implicated, has varied, the total dose falling in the range of 500 to 4000 mg of pancuronium or its equivalent.

Some patients have recovered almost completely, at least early in the process. The EMG discloses the characteristic features of a myopathy; often there are fibrillations as well, attributable to separation of the motor end-plate region from intact segments of muscle fibers. Polyneuropathy and residual neuromuscular blockade can be excluded by appropriate electrophysiologic studies. Muscle biopsy shows varying degrees of necrosis and vacuolation affecting mainly type 2 fibers. There is a striking loss of thick (myosin) filaments that is thought by some to be due to an increase in the amount of myosin (myosin filaments) but is more likely due to denervation. The most severe degrees of muscle necrosis have been accompanied by massively elevated CK levels and by myoglobinuria and renal failure.

Several experimental observations explain the apparent additive effect on muscle of steroids and neuromuscular blocking agents. Animals exposed to high doses of steroids after muscle denervation display a selective loss of myosin, which is characteristic of this disease. The depletion of myosin is reversed by reinnervation but not by the withdrawal of the corticosteroids. Furthermore, denervation of muscle has been found to induce an increase in glucocorticoid receptors in the muscle. Dubois and Almon have postulated that exposure to neuromuscular blocking agents creates a functional denervation, rendering the muscle fiber vulnerable to the damaging effects of steroids. It is curious that this myopathy has not been seen with high-dose corticosteroid administration for neurologic diseases such as multiple sclerosis, and the observation of Panegyres and colleagues of a myasthenic patient who developed a severe, myosin-depleted myopathy following high doses of methylprednisolone supports a dual action of denervation (at the postsynaptic membrane) and glucocorticoids.

Adrenocortical Insufficiency

Generalized weakness and fatigueability are characteristic of adrenocortical insufficiency, whether it be primary in type, i.e., due to Addison disease (infectious, neoplastic, or autoimmune destruction of the adrenal glands or adrenal hemorrhage) or secondary to a pituitary deficiency of adrenocorticotropic hormone (ACTH). The weakness and fatigueability are related to the water and electrolyte disturbances and hypotension. Rarely, a permanent contracture of hamstring muscles develops, producing pseudoparalysis. Death (or sterility) is the common end result. Biopsy has not disclosed any abnormalities of muscle, and postmortem examination of the muscle in one such case showed no changes.

The EMG is normal, and the tendon reflexes are retained. Addisonian weakness (and hypokalemic paralysis) respond to glucocorticoid and mineralocorticoid replacement.

Primary Aldosteronism Production of an excess of aldosterone by adrenal adenomas has been the subject of many articles, one of the earliest and most notable was that of Conn. Muscle weakness has been observed in three-quarters of the reported cases, and in nearly half of them there was either hypokalemic periodic paralysis or tetany. Chronic potassium deficiency may express itself either by periodic weakness or by a chronic myopathic weakness. An associated alkalosis causes the tetany.

Diseases of Parathyroid Glands and Vitamin D Deficiency

A small proportion of patients with parathyroid adenomas complain of weakness and fatigability. Vicedo described the first example of this disorder and remarked on the muscular atrophy and weakness and the pain on passive or active movement. The tendon reflexes were retained. A few scattered muscle fibers had undergone degeneration. Claims for a denervative process are disputed. We have not been impressed with either a myopathy or neuropathy in this disease.

In hypoparathyroidism, muscle cramping is prominent but there are no other neuromuscular manifestations. In both hypoparathyroidism and pseudohypoparathyroidism—the latter with characteristic skeletal abnormalities and, in some instances, mental backwardness—the most important muscle abnormality is tetany. This is due to low ionized serum calcium, which depolarizes axons more than any muscle fibers (see page 1465).

In osteomalacia, due to vitamin D deficiency and disorders of renal tubular absorption, muscle weakness and pain have been common complaints, similar to those in patients with primary hyperparathyroidism and uremia (see Layzer for further comment).

More striking than any of the foregoing disturbances, in our view, has been a chronic proximal myopathy in conjunction with hypophosphatemia and solitary bone cysts. In two of our patients, removal of the cyst restored serum phosphorus levels and cured the muscle weakness. Hypophosphatemic myopathic weakness has also
been noted in a number of our patients in a critical care unit. The onset can be so abrupt when precipitated by hyperalimentation solutions as to simulate the Guillain-Barré syndrome. The oral administration of phosphates to raise the serum phosphorus has been beneficial in the nonneoplastic cases. Some of the latter are accompanied by pain and stiffness. Presumably the phosphorus depletion in these disorders had limited the phosphorylation reactions and the synthesis of ATP.

Diseases of the Pituitary Gland

Proximal muscle weakness and atrophy have been recorded as late developments in many acromegalic patients. Formerly thought to be due to neuropathy, these symptoms have been convincingly shown by Mastaglia and colleagues to be the result of a chronic polyneuropathy. The serum CK is slightly elevated in some cases, and myopathic potentials are observed in the EMG. Biopsy specimens have shown atrophy and reduced numbers of type 2 fibers and necrosis of only a few fibers. Treatment of the pituitary adenoma and correction of the hormonal changes restores strength. A mild peripheral neuropathy of sensorimotor type has also been reported in a few acromegalic patients but is less frequent than the carpal tunnel syndrome.

MYOPATHIES DUE TO DRUGS AND TOXINS

A vast number of drugs and other chemical agents have been identified as myotoxic. Curry and colleagues, in 1989, found reports (in the English literature alone) of about a hundred drugs that had caused rhabdomyolysis and myoglobinuria. The list continues to grow, and additional myotoxic agents can be expected to appear as new drugs are introduced. It is not practical to describe the myotoxins individually; they are categorized and their main features are listed in Table 51-2.

Table 51-2 Features of toxin-induced myopathies

| Toxic agents produce myopathic changes in several ways. They may act directly on muscle cells, either diffusely or locally, as occurs with intramuscular injections, or the muscle damage can be secondary to a diverse number of factors—electrolyte disturbances (hypokalemia), renal failure, excessive energy requirements of muscle (as occur with drug-induced seizures and malignant hyperthermia), or inadequate delivery of oxygen and nutrients (drug-induced coma with compressive-ischemic injury of muscle). |
| Several clinical features mark a myopathy as toxic in nature: lack of pre-existing muscular symptoms; delay in onset of symptoms after exposure to a putative toxin; lack of any other cause for the myopathy; and often complete or partial resolution of symptoms after withdrawal of the toxic agent. Pathologically, this group of disorders is characterized by nonspecific myopathic changes, which in severe degrees take the form of myonecrosis (rhabdomyolysis) and myoglobinuria; the latter is the most frequent and serious myotoxic syndrome and is discussed below, along with its more important causes. |
| Necrotizing Polymyopathy (Rhabdomyolysis) with Myoglobinuria | In any disease that results in rapid destruction of striated muscle fibers (rhabdomyolysis), myoglobin and other muscle proteins may enter the bloodstream and appear in the urine. The latter is “ cola”-colored (burgundy red or brown), much like the urine in hemoglobinuria. In hemoglobinuria, however, the serum is initially pink, because hemoglobin (but not myoglobin) is bound to haptoglobin, and this complex is not excreted in the urine as readily as myoglobin (also, the hemoglobin molecule is three times as large as the myoglobin molecule). The hemoglobin-haptoglobin complex is removed from the blood plasma over a period of hours, and if hemolysis continues, the haptoglobin may be depleted, so that hemoglobinuria is present without grossly evident hemoglobinemia. Differentiation of the two pigments in urine is difficult; both are guaiac-positive and may be detected by a “ dipstick.” Only very small differences are seen on spectroscopic examination. The most sensitive means of detecting myoglobin is by radioimmunoassay. |
| Many of the causes of myonecrosis and myoglobinuria have already been mentioned. Myoglobinuria may be detected in cases of acute inflammatory myopathy, in several types of glycogenosis (Table 51-1), in carnitine palmitoyltransferase deficiency, and as a result of poisoning or therapeutic use of a vast array of drugs (including the combination of steroids and pancuronium, discussed above), toxins, and venoms (see Table 51-2). Myoglobinuria is an important feature of many other conditions: crush injury; extensive infarction of muscle; excessive use or repeated injury of muscles (as occurs in status epilepticus, generalized tetanus, malignant neuroleptic syndrome, agitated delirium, prolonged marching, conga drumming, or simply excessive exercise—although the latter always suggests an underlying metabolic disease of muscle); electrical and lightning injuries; etc. Two noteworthy conditions that are characterized by myonecrosis and myoglobinuria are acute alcoholic intoxication and malignant hyperthermia. The former is described below and the latter in Chap. 54, with the membrane channel disorders. |
| Regardless of the cause of the rhabdomyolysis, the affected muscles become painful and tender within a few hours. Power of contraction is diminished. Sometimes the skin and subcutaneous tissues overlying the affected muscles (nearly always of the limbs and sometimes of the trunk) are swollen and congested. There may be a low-grade fever. Apart from the discoloration of the urine, albumin excretion rises, and there is a leukocytosis. If myoglobinuria is mild, recovery occurs within a few days and there is only a residual albuminuria. When myoglobinuria is severe, renal damage may ensue and lead to anuria. The mechanism of the renal damage is not clear; probably it is not simply a mechanical obstruction of tubules by precipitated myoglobin. It is more likely to occur with massive rhabdomyolysis and very high CK levels in the serum. Alkalization of the urine by ingestion or infusion of sodium bicarbonate is said to protect the kidneys by preventing myoglobin casts, but in severe cases it is of doubtful value, and the sodium may actually be harmful if anuria has already developed. Therapy is the same as for the anuria that follows shock (see Harrison’s Principles of Internal Medicine). |

Alcoholic Myopathy

Several forms of muscle weakness have been ascribed to alcoholism. In one type, a painless and predominantly proximal weakness develops over a period of several days or weeks in the course of a prolonged drinking bout and is associated with severe degrees of hypokalemia (serum levels <2 meq/L). The urinary excretion of potassium is not significantly increased; depletion is probably the result of vomiting and diarrhea, which usually precede the onset of muscular weakness. In addition, serum levels of liver and muscle enzymes are markedly elevated. Biopsies from severely weakened muscles show single-fiber necrosis and vacuolization. Treatment consists of the administration of potassium chloride intravenously (about 120 meq daily for several days), after which oral administration suffices. Strength returns gradually in 7 to 14 days, and enzyme levels return to normal concomitantly.

Another type of myopathic syndrome, occurring acutely at the height of a prolonged drinking bout, is manifest by severe pain, tenderness, and edema of the muscles of the limbs and trunk, accompanied in severe cases by renal damage and hyperpotassemia (Hed et al). The muscle affection is generalized in some patients and remarkably focal in others. A swollen, painful, tender limb or part of a limb may give the appearance of a deep phlebothrombosis or lymphatic obstruction. Myonecrosis is reflected by high serum levels of CK and aldolase and the appearance of myoglobin in the urine, leading in some cases to fatal myoglobinuric nephrosis. In a general hospital, alcoholism is the commonest cause of rhabdomyolysis and myoglobinuria. Some patients recover within a few weeks, but others require several months, and relapse during another drinking spree occurs frequently. Restoration of motor power is attendant upon regeneration but may be complicated by polyneuropathy and other syndromes of neuromuscular disability associated with alcoholism. Haller and Drachman have produced rhabdomyolysis (with elevated CK and myoglobinuria) in rats by subjecting the animals to a brief fast following a 2- to 4-week exposure to alcohol, suggesting that a similar mechanism may be operative in alcoholic individuals.

Perkoff and his associates described what is presumably another form of acute muscular disorder in alcoholics, characterized by severe muscular cramps and diffuse weakness, occurring in the course of a sustained drinking bout. They noted a number of biochemical abnormalities in these patients as well as in asymptomatic alcoholics who had been drinking heavily for a sustained period prior to admission to the hospital—elevated serum levels of CK, myoglobinuria, and a diminished rise in blood lactic acid in response to ischemic exercise, as occurs in McArdle disease. In distinction to the latter, however, myophosphorylase levels were not
consistently reduced in the alcoholic patients. How these biochemical abnormalities are related to muscle cramps and weakness is a matter of speculation.

From time to time one observes in alcoholics the subacute or chronic evolution of painless weakness and atrophy of the proximal muscles of the limbs, especially of the legs, with only minimal signs of neuropathy in the distal segments of the legs and feet. Cases such as these have been referred to as chronic alcoholic myopathy, implying a direct toxic effect of alcohol on muscle, but the data are insufficient to warrant such an assumption. Some of these cases have shown necrosis of individual muscle fibers and other signs of polymyositis; most cases seen by the authors have proved to be neuropathic in nature. This has been the experience of others as well (Farris and Reyes; Rossouw et al.). Treatment follows along the lines indicated for nutritional-alcoholic neuropathy (page 1214), and complete recovery can be expected if the patient abstains from alcohol and maintains a regimen of good nutrition.

Chapter 52
THE CONGENITAL NEUROMUSCULAR DISORDERS

The Development and Aging of Muscle

The commonly accepted view of the embryogenesis of muscle is that muscle fibers form originally by fusion of myoblasts soon after the latter differentiate from somatic mesodermal cells. Muscle connective tissue derives from somatopleural mesoderm. The myoblasts, which are postmitotic, are spindly-shaped mononuclear cells that fuse to form muscle fiber. After fusion, a series of transcriptional cellular events leads to myofibril formation. The newly formed fibers are thin, centrally nucleated tubes (appropriately called myotubes) in which myofilaments begin to be produced from polyribosomes. As myofilaments become organized into myofibrils, the nuclei of the muscle fiber are displaced peripherally to a subsarcolemmal position. Once the nuclei assume a peripheral position, the myofiber is formed. The detailed mechanisms whereby myoblasts seek one another, the manner in which each of a series of fused nuclei contribute to the myotube, the formation of actin and myosin filaments, and the differentiation of a small residue of satellite cells on the surface of the fibers are reviewed by Franzini-Armstrong and Fischman.

The mechanisms that determine the number and arrangement of fibers in each muscle are not as well understood. Presumably the myoblasts themselves possess the genetic information that controls the program of development, but within any given species there are wide familial and individual variations, which account for obvious differences in the size of muscles and their power of contraction.

The number of fibers assigned to each muscle is probably attained by birth, and growth of muscle thereafter depends mainly on the enlargement of fibers. Although the nervous system and musculature develop independently, muscle fibers continue to grow after birth only when they are active and under the influence of nerve. Measurements of muscle fiber diameters from birth to old age show the growth curve ascending rapidly in the early postnatal years and less rapidly in adolescence, reaching a peak during the third decade. After puberty, growth of muscle is less in females than in males, and such differences are greater in the arm, shoulder, thigh, and pelvic muscles than in those of the leg; growth in ocular muscles is about equal in the two sexes. At all ages, disuse of muscle decreases fiber size by as much as 30 percent (at the expense of myofibril), and overuse increases the size by about the same amount (work hyperthrophy). Normally, type 1 (oxidative enzyme-rich) fibers are slightly smaller than type 2 (phosphorylative enzyme-rich) fibers; the proportions of the two fiber types vary in different muscles in accordance with their natural functions.

During late adult life and the senium, the number of muscle fibers diminishes and variation in fiber size increases. The variations are of two types: group atrophy, in which clusters of 20 to 30 fibers are all reduced in diameter to about the same extent, and random single-fiber atrophy. Also, there is enlargement of other fibers. The exercising of young animal muscle causes a hypertrophy of high-oxidative type 1 fibers and an increase in the proportion of low-oxidative type 2 fibers; aging muscle lacks this capacity—exercise produces only an increase in the proportion of type 2 fibers (Silbernang et al.). No such data are available in humans, but clinical observation informs us that with aging, the capacity of muscle to respond to intense, sustained exercise is diminished. Also, muscle cells, like other cells of postmitotic type, are subject to aging changes (lipofuscin accumulation, autophagic vacuolization, enzyme loss) and to death. Group atrophy, present in 90 percent of gastrocnemius in individuals more than 60 years of age, represents denervation effect from loss of lumbar motor neurons and peripheral nerve fibers.

Derangements of the Life Cycle of Muscle Fibers

These have not been fully ascertained, but one can envision the following possibilities: (1) failure of myoblasts to differentiate in a given region, manifest by a congenital absence of muscle; (2) congenital hypoplasia, local or universal; (3) congenital hyperplasia, local or universal; (4) faulty intrinsic development, leading to certain disfigurations of fibers (improper arrangement of nuclei, myofibrils, and other organelles, particularly mitochondria; this conceivably could reduce viability, i.e., cause atrophy); and (5) denervation effect of aging, as noted above.

Denervation from spinal or nerve disease at every age has roughly the same effect—namely, atrophy of muscle fibers (first in random distribution, then in groups) and later degeneration. Segmental necrosis at all ages excites a regenerative response from sarcolemmal and satellite cells in the intact parts of the fibers. Presumably, if this occurs repeatedly, the regenerative potential wanes, with ultimate death of the fiber—leading to permanent depopulation of fibers and muscle weakness.

CONGENITAL DEFORMITIES INVOLVING MUSCLE

Congenital Fibrous Contractures of Muscle and Joint Deformities

Arthrogryposis Multiplex Congenita

Multiple congenital contractures, multiple congenital articular rigidities, and amyoplasia congenita are some of the names that have been applied to congenital deformity and rigidity of many joints. This disorder, now generally referred to as arthrogryposis (literally, curved joints), has been estimated to occur once in 3000 births. The joint deformities result from a lack of movement during fetal development and can therefore be produced by any disorder that immobilizes the developing embryo—whether it be of anterior horn cells, peripheral nerves, the motor end plate (as in an infant born to a myasthenic mother), or muscle. Often there are associated developmental defects of the nervous system and somatic structures—low-set ears, wide and flat nose, micrognathia, and high-arched palate; less often, there is a short neck, congenital heart disease, hypoplasia of the lungs, and cryptorchidism.

Of the many conditions that underlie arthrogryposis, developmental abnormalities of the anterior horn cells (mainly Werdnig-Hoffman disease, as discussed in Chap. 39) are by far the most common. A failure in development of anterior horn cells results in an uneven smallness and paresis of limb muscles. The unopposed contraction of relatively normally innervated muscles sets the fixed deformities. In the less common myopathic form, the nervous system is intact and the disease is that of a polymyopathy or congenital muscular dystrophy. It is of interest that in the myopathic variety, the limbs are fixed in a position of flexion at the hips and knees and adduction of the legs, in contrast to the variable postures of the myelopathic (anterior horn cell) form. Also, the latter type is more frequently conjoined with multiple anomalies than the myopathic type. In addition to these two well-recognized types, occasional cases of arthrogryposis are attributable to a neonatal neuropathy, neonatal myasthenia gravis, and the Prader-Willi syndrome (intrauterine hypotonia).

An infant with arthrogryposis should be evaluated with an electromyogram (EMG), interpreted by an experienced electromyographer for the presence of denervation or myopathic potentials, and particularly with a biopsy of muscle to detect group atrophy or one of the characteristic congenital polymyopathies described further on in this chapter. These tests may be difficult to interpret in the premature and term infant; in many circumstances, there is value in delaying them until several weeks of post-term development. If the initial evaluation is unrevealing, an imaging study of the brain, to detect malformations that may portend malformations, and this chapter. These tests may be difficult to interpret in the premature and term infant; in many circumstances, there is value in delaying them until several weeks of post-term development. If the initial evaluation is unrevealing, an imaging study of the brain, to detect malformations that may portend malformations, and
the absence of a countervailing antagonist. Trauma to a muscle during intrauterine life or at birth leads to fibrosis and to fibrous contracture in some cases.

Congenital Clubfoot
Here the deformity may be one of planter flexion of the foot and ankle (talipes equinus), inversion (talipes varus or clubfoot), eversion (talipes valgus or splayfoot), or dorsiflexion of foot and ankle (talipes calcaneus). About 75 percent of all cases are equinovarus. Usually both feet are affected. Multiple inciencence in one family may occur. Several explanations of cause and pathogenesis have been offered: fetal malposition, an embryonic abnormality of tarsal and metatarsal bones, a primary defect in nerves or anterior horn cells of the spinal cord, or a congenital dystrophy of muscle. No one theory explains all cases; available pathologic data exclude a single cause and pathogenesis, but more often it occurs as a manifestation of generalized arthropathy (see below) and is an indicator of a more widespread involvement of the central nervous system. (See Kakulas and Adams and also Banker for pertinent literature on the subject.)

Congenital Torticollis (Wryneck)
This disorder begins during the first months of life and, unlike the dystonic torticollis of adults, is due to shortening of the sternomastoid muscle, which is firm and taut. The head is inclined to one side and the occiput slightly rotated to the side of the affected muscle. This disorder is nonfamilial and is usually ascribed to injury of the sternomastoid at birth. Whether the injury is a purely mechanical one to the muscle itself or is due to ischemia stemming from arterial or occlusive causes is not entirely clear. It gives rise to a sternomastoid tumor (actually a pseudotumor) that appears, on exploration, as a pale, spindle-shaped swelling of the muscle belly. The histologic findings are similar to those of Volkmann contracture, i.e., replacement of the muscle fibers by relatively acellular connective tissue, so that an ischemic mechanism appears most likely.

Congenital Absence of Muscles
It is well known that some individuals are born without certain muscles. This pertains not only to certain inconstant and functionally unimportant muscles, such as the palmaris longus, but also to more constant and important ones as well. The muscles found to be absent most frequently are the pectoralis, trapezius, serratus anterior, and quadriceps femoris, but many others are found to be missing in isolated cases.

Congenital absence of muscle is usually associated with congenital anomalies of neighboring nonmuscular tissues. For example, congenital absence of the pectoral muscle is often accompanied by aplasia or hypoplasia of the mammary gland as well as syndactyly and microdactyly. Agenesis of the pectoral muscle may also be associated with scoliosis, webbed fingers, and underdevelopment of the ipsilateral arm and hand (Poland syndrome). Another unusual syndrome consists of congenital absence of portions of the abdominal muscles (“prune belly”) in association with arthrogryposis and a defect of ureters, bladder, and genital organs.

Restricted Nuclear Amyotrophies
In another group of restricted palsies, the essential abnormality appears to lie in the nervous system (nuclear amyotrophies). One of the most frequent is congenital ptosis, due to an innervatory defect of the levator palpebrae muscles. Complete paralysis of all muscles supplied by the oculomotor nerve, due apparently to hypoplasia of the third nerve, may be observed in several members of a family and occasionally in only one member. A congenital Horner syndrome is well known and may be familial; it is associated with depigmentation of the iris (heterochromia iridis). Bilateral abducens palsy is often associated with bilateral ptosis in the newborn and is known as the Möbius syndrome; this usually nonfamilial anomaly, the cause of which is thought to be a nuclear hypoplasia or aplasia, is discussed with the developmental disorders (page 1079). In these familial nuclear amyotrophies the muscles develop independently of the nervous system but have no prospect of attaining their normal growth and function—and indeed of surviving—because of failure of innervation. It is a kind of congenital denervation hypotrophy. Of course, a primary muscle defect may also give rise to ptotic weakness, as in fasciocapulohumeral muscular dystrophy.

RELATIVELY NONPROGRESSIVE CONGENITAL POLYMYOPATHIES
Beginning in 1956, with the account by Shy and Magee of a patient whose muscle fibers showed a peculiar central densification of sarcoplasm (“cores”), a new class of hereditary diseases of muscle has been delineated. The more common and better-defined members of this group are the central core, nemaline (rod-body), and centronuclear myopathies and myopathy with tubular aggregates. As the names imply, in each of these diseases there is a distinctive morphologic abnormality that expresses itself early in life by a lack of muscle bulk, hypotonia, weakness of the limbs, and often mild dysmorphic features of other parts of the body. A variety of other names have been descriptive of the lesions, but each of these latter types are mentioned only briefly. A detailed account can be found in the chapter by Fardeau and Tomé in Myology. Further study has revealed that the diseases of this group are not confined to infancy and early childhood and some of them, especially those present at birth, are not as benign as their early descriptions implied.

Each of the entities mentioned above has been observed to be present at a later age, even in middle adult life; if the disease is mild, there is often no way of deciding whether it had been present since birth. Lack of progression or extremely slow progression characterizes most of the congenital myopathies, in contrast to the more rapid pace of many muscular dystrophies, Werdnig-Hoffmann disease, and other forms of hereditary motor system disease of childhood and adolescence. Exceptionally, an example of more rapid progression of a congenital myopathy has been reported, and, prior to the use of histochemical and electron microscopic techniques, such patients were usually considered to have a benign muscular dystrophy. Familial occurrence has also been established, so the clinical line of separation between this group of diseases and some of the more slowly progressive muscular dystrophies remains ambiguous. There is no specific treatment for any of the congenital myopathies.

As mentioned earlier, the lesions in the congenital myopathies are revealed most clearly by the systematic application of histochemical stains to frozen sections and by phase and electron microscopy. Some of the abnormalities are also disclosed by the conventional stains used in light microscopy, but as a group their identification has been the product of newer histologic techniques.

A word of caution about the specificity of some of the morphologic changes and the classifications of the congenital myopathies based upon them. It is treacherous to assume that a change in a single organelle or a subtle change in the sarcoplasm of a muscle fiber can be relied upon to characterize a pathologic process. Indeed, as more careful studies were made of this class of disease, the specificity of the lesions came to be questioned. Central cores are sometimes found in the same muscle as nemaline bodies, and so on, and each of the denotative lesions has been reported in association with other conditions. Nevertheless, the prominence of the morphologic change in any individual case, along with certain characteristic clinical features, permits an accurate diagnosis to be made.

Central Core Myopathy
In the original family described by Shy and Magee, 5 members (4 males) in three successive generations were affected, suggesting an autosomal dominant pattern of inheritance. The youngest was 2 years old; the oldest, 65 years. In each, there was weakness and hypotonia (“floppy infant”) and a general delay in motor development, particularly in walking, which was not achieved until the age of 4 to 5 years; always the patient had had difficulty in rising from a chair, climbing stairs, and running. The weakness was greater in proximal than in distal muscles, though the latter did not escape, and shoulder-girdle muscles were adversely affected. The lower limbs were normal, as was the plantar flexion of the feet. A few of the patients had a narrow chest and were described as having a “barrel chest.” The tendon reflexes were hypoactive and symmetrical. Muscle atrophy was a prominent feature, though poor muscular development was present in one patient and has since been reported in others. There were no fasciculations, cramps, or myotonia, but cramps following exercise have been described in other families. The electrocardiograms were normal.

The disease is rare, but as additional cases were discovered, milder forms of the disease came to be recognized, and in some of them the symptoms first appeared in adult life. Originally some of these patients were thought to have limb-girdle dystrophy because of the disproportionate involvement of proximal muscles. In other families, such as the one reported by Patterson and colleagues, the disease was first recognized in middle adult life, with the rapid evolution of a proximal myopathy. This represents the two extremes of the clinical state. Dislocation of the hips, pes cavus or pes planus, and kyphoscoliosis have been found in a few children. In the majority of cases the progress of the disease is extremely slow, with slight worsening over many years.

The EMG reveals only brief, small-amplitude motor unit potentials with a normal interference pattern. Serum concentration of CK is normal or only slightly elevated, as in facioscapulohumeral muscular dystrophy.

Pathologically, the majority of the fibers appear in size or enlarged, and no focal destruction or loss of fibers can be found. The unique feature of the disease is the presence in the central portion of each muscle fiber of a dense, amorphous condensation of myofilaments or myofilibril material. This altered zone characteristically lacks mitochondria and other organelles and gives a positive periodic acid–Schiff (PAS) reaction and a dark blue color with the Gomori trichrome stain, contrasting
with the normal blue-green color of the peripheral fibrils. Within the core, there is a lack of phosphorylase and oxidative enzymes. Most of the cores are in type 1 fibers, which predominate. These cores run the length of the muscle fiber, thus differing from the multiple cores or minicores that are seen in occlulopharyngeal and other forms of muscular dystrophy.

**Nemaline Myopathy**

This disorder also expresses itself by hypotonia and impaired motility in infancy and early childhood, but—unlike the case in central core disease—the muscles of the trunk and limbs (proximal greater than distal) as well as the facial, lingual, and pharyngeal muscles are strikingly thin and hypoplastic. Several forms have been observed. One is congenital, with generalized weakness in early childhood, making breathing and feeding difficult. The limbs are flaccid and areafehic. Pneumonia and death occur within weeks to months. In forms that permit survival, the weakness is less severe, involving mainly the proximal muscles. Tendon reflexes are diminished or absent. The young child with this disease usually suffers from anorexia and frequent respiratory infections, which may shorten life. Strength slowly improves with growth, the latter process evidently overcoming the advance of the disease. A slender appearance, narrow face, open mouth, narrow, arched palate, and kyphoscoliosis are regular but not invariable accompaniments of nemaline myopathy. Pes cavus or clubfoot may be added. Some of the milder cases may reach adulthood, at which time a cardiomyopathy may threaten life. A. G. Engel as well as W. K. Engel and Reznick have observed individuals who first showed signs of the disease in middle age; the weakness was mainly in proximal muscles, and the dysmorphic and skeletal abnormalities of the childhood form were lacking. The EMG is “myopathic,” and serum enzymes are normal or only slightly elevated.

Nemaline myopathy appears to be genetically heterogeneous. The pattern of inheritance is most often autosomal dominant, with variable penetrance. In a few families an autosomal recessive or an X-linked pattern of inheritance has been suggested. The localization of the gene (in the autosomal dominant type) to chromosome 1q21–23 should clarify the uncertainties about inheritance and perhaps explain the relationships between the different forms of the disease. More recently, the allop LLPomyosinogen gene (TPM3) has been reassigned to the same locus.

A Gomori trichrome–stained section of frozen muscle discloses the characteristic lesion, which can be seen under the light microscope. Myriads of bacillus-like rods, singly and in small packets, are seen beneath the plasma membrane of the muscle fiber. They are composed of material that resembles that of Z bands under the electron microscope, and often actin filaments are attached, just as they are to Z bands. The type 1 fibers, which usually predominate, are smaller than normal, as in central core disease. The size of the motor neurons is said to be reduced. The cause of the disease is unknown, but probably the weakness is related to a smallness and reduction in the number of muscle fibers and possibly to focal interruption of their cross striations, particularly the Z bands.

**Centronuclear or Myotubular Myopathy**

In this familial disease, hypotonia and weakness become manifest soon after birth or in infancy or early childhood. Rarely, in the mildest form, the diagnosis does not become evident until adult years. All the striated skeletal muscles are involved to some degree. Ptosis and ocular palsies are combined with weakness of facial, masticatory, lingual, pharyngeal, laryngeal, and cervical muscles in most of the infants with this disease, but not in the adults. In the child, muscle weakness increases in pace with proximal weakness. The limbs remain thin and areafehic throughout life. Motor development is necessarily retarded, though some improvement with maturation can occur; later, however, motor functions that had been acquired may be lost as the disease slowly advances. Several patients have shown signs of cerebral abnormality, with seizures and an abnormal electroencephalogram (EEG), but this may not be part of the disease. Needle EMG examination shows the usual myopathic pattern, as well as positive sharp waves and fibrillation potentials in some cases. Abundant spontaneous activity should suggest the diagnosis of centronuclear myopathy (Griggs et al.). Beckmann and colleagues have classified this disorder into three types, based on severity, mode of presentation, and genetic pattern: (1) a severe neonatal X-linked recessive type; (2) a less severe early-infantile, late-infantile, or childhood autosomal recessive type; and (3) a still milder late childhood–adult autosomal dominant type. The gene for the X-linked form has been localized to chromosome Xq28, making possible the identification of carriers.

The outstanding pathologic features of the disease are the smallness of muscles and their constituent fibers and central nuclei. In one group of centronuclear myopathies, there is hypotrophy of type 1 fibers (Battelli et al., Karnats et al.). Surrounding most of the centrally placed nuclei is a clear zone, in which there is a lack of organization of contractile elements. Because of central nucleation, the disease has incorrectly been referred to as myotubular myopathy, implying an arrest in development of muscle at the myotubular stage. Actually, the nature of the pathologic process is obscure. The small, centrally nucleated fibers do not really resemble typical myotubes. Also, there is evidence, from electron microscopic studies, of changes in the central parts of the fibers (lack of enzymatic activity in the clear zones surrounding the nuclei), leading in all probability to fiber loss. Such changes argue against a purely developmental abnormality.

**Myopathy with Tubular Aggregates**

The accumulation of tubular aggregates in the subsarcolemmal or more interior regions of muscle fibers was first observed in patients with hypokalemic periodic paralysis and myotonia congenita and later with a number of diverse conditions, such as chronic drug intoxication, hypoxia, and congenital myasthenic syndromes. However, tubular aggregates are also the defining feature of several purely myopathic syndromes: (1) a slowly progressive muscular weakness, in a limb-girdle distribution, with onset in childhood or early adult life; inheritance is either autosomal dominant or recessive in type. (2) A more benign childhood onset of proximal weakness, easy fatigability, and myasthenic features; heredity is autosomal recessive. This syndrome may respond to pyridostigmine. (3) Muscle pain, cramps, and stiffness induced by exercise; the cases to date have been sporadic.

The histologic changes are readily overlooked in paraffin sections. Cryostat sections show masses of material that is basophilic with hematoxylin and eosin and bright red with Gomori trichrome and shows an intense reaction with NADH dehydrogenase. By electron microscopy, the bundles of tubular aggregates are sharply demarcated from myofibrils.

**Other Congenital Myopathies**

The foregoing congenital myopathies—central core, nemaline, centronuclear, and tubular aggregate types—are well-defined clinical-pathologic entities. In addition, other far less common types have been described, each named according to a distinctive dysmorphic alteration of organelles in myofibrils. These histochemical and electron microscopic observations have led to the following three additional types that have been identified: (1) myopathy with lysis in type 1 fibers, (2) myopathy with characteristic sarcoplasmic bodies and skeleton (desmin) filaments; (3) myopathy with Malory-body-like inclusions; and familial cardiomyopathy with subsarcolemmal veriform deposits. Implied by these reports was the notion that each of these structural abnormalities represented a new and distinctive myopathy.

More recently, in a careful light microscopic evaluation of both published reports and their own cases, Nakano and Engel and their colleagues convincingly demonstrated that the many reported structural changes were the consequence of a single pathologic process—a focal dissolution of myofibrils, followed by an accumulation of the products of the degradation process. These authors proposed the term myofibrillar myopathy to encompass the entire spectrum of pathologic changes.

The diagnosis of myofibrillar myopathy (by biopsy) is usually made in adult life. Men and women are equally affected. Slowly progressive weakness of the muscles of limbs and trunk is the main clinical feature. Both proximal and distal muscles are affected, more in the legs than in the arms. Hyporeflexia is usual. Cardiac involvement, although at times severe, is usually not present. Other than the involvement of skeletal muscles, however, about one-half of the patients. The pattern of inheritance is most often autosomal dominant, but autosomal recessive and X-linked inheritance is well known.

Genetically there is considerable heterogeneity. At the time of writing, no fewer than five chromosomal loci for myofibrillar myopathy have been documented, and more are likely to exist (Engel). Predictably, therefore, a more sharply defined disease or diseases will emerge with further study of the category of myofibrillar myopathy.

**The Spinal Muscular Atrophies of Infancy and Childhood**

Obviously this important group of diseases, appearing as they do in the same periods of life as the congenital polymyopathies described above and certain of the congenital muscular dystrophies, must figure in the differential diagnosis of early-onset muscular weakness. Indeed, they represent the main problems faced by the
clinical myologist. Their hereditary nature, their progressivity to fatal issue or delayed motor attainments, and their tendency in certain instances to produce disabling contractures are shared with the primary muscle diseases. Fortunately the proper application of current laboratory techniques sets them apart in most instances. In deference to their neuronal origin, the authors have decided to place them with the other degenerative diseases (see pages 1158–1162).

MYASTHENIA GRAVIS AND RELATED DISORDERS OF THE NEUROMUSCULAR JUNCTION

Mayasthenia Gravis

Clinical Manifestations

Other Disorders of Neuromuscular Transmission

Chapter References

Included under this title is a group of diseases affecting the neuromuscular junction, the most important of which is myasthenia gravis. As a group, these disorders exhibit several striking features, the essential one being fluctuatioS in strength of muscle. There is usually some degree of weakness at all times, but it is made worse by activity. The weakness and fatigability reflect physiologic abnormalities of the neuromuscular junction that are demonstrated by clinical signs and special electrophysiologic testing.

MYASTHENIA GRAVIS

The main feature of myasthenia gravis, usually referred to as simply myasthenia, is a fluctuating weakness of certain voluntary muscles, particularly those innervated by motor nuclei of the brainstem, i.e., ocular, masticatory, facial, deglutitional, and lingual. Manifest weakening during continued activity, quick restoration of power with rest, and dramatic improvement in strength following the administration of anticholinesterase drugs such as neostigmine are the other notable clinical features.

Historical Note

Several students of medical history affirm that Willis, in 1672, gave an account of a disease that could be none other than myasthenia gravis. Others give credit to Wilks (1877) for the first description and for having noted that the medulla was free of disease, in distinction to other types of bulbar paralysis. The first reasonably complete accounts were those of Erb (1878), who characterized the disease as a bulbar palsy without an anatomic lesion, and of Goldflam (1893); for many years thereafter, the disorder was referred to as the Erb-Goldflam syndrome. Jolly (1895) was the first to use the name myasthenia gravis, to which he added the term pseudoparalytica to indicate the lack of structural changes at autopsy. Also it was Jolly who originally demonstrated that myasthenic weakness could be reproduced by repeated faradic stimulation of the relevant motor nerve and that the “fatigued” muscle would still respond to galvanic stimulation. Interestingly, he suggested the use of physostigmine as a form of treatment, but there it remained until R. R. and Walker, in 1934, demonstrated the therapeutic value of the drug.

Campbell and Bramwell (1900) and Oppenheim (1901) each analyzed over 60 cases and crystallized the clinical concept of the disease. The relationship between myasthenia gravis and tumors of the thymus gland was first noted by Laquer and Weigert in 1901, and in 1949 Castelman and Norris gave the first detailed description of the pathologic changes in the gland.

In 1905 Buzzard published a careful clinicopathologic analysis of the disease, commenting on both the thymic abnormalities and the infiltrations of lymphocytes (called lymphorrhages) in muscle. He postulated that an “autoxic agent” caused the muscle weakness, the lymphorrhages, and the thymic lesions. He also commented on the close relation of myasthenia gravis to Graves disease and Addison disease, which are also now considered to have an autoimmune basis. In 1960, Simpson and, independently, Nastuk and coworkers theorized that an autoimmune mechanism must be operative in myasthenia gravis. Finally, in 1973 and subsequently, the autoimmune nature of myasthenia gravis was established through a series of investigations by Patrick and Lindstrom, Fambrough, Lennon, and Engel and their colleagues (see further on, under "Etiology and Pathogenesis").

These and other references to the early historical features of the disease are to be found in the reviews by Viets and by Kakulas and Adams; Engel's monograph (1999) is an excellent modern reference.

Clinical Manifestations

Myasthenia gravis, as the name implies, is a muscular weakness with a (formerly) grave prognosis. Repeated or persistent activity of a muscle group exhausts its contractile power, leading to a progressive paresis, and rest restores strength, at least partially. These are the identifying attributes of the disease; their demonstration, assuming that the patient cooperates fully, is sometimes enough to establish the diagnosis.

The onset is usually insidious, but there are instances of fairly rapid development, sometimes initiated by an emotional upset or infection (usually respiratory). In most patients, however, a precipitating event cannot be identified. Symptoms may first appear during pregnancy or, more commonly, in the puerperium or in response to drugs used during anesthesia. Thymic abnormalities of several types are closely connected with the disease, as elaborated further on, and weakness may begin months or years after removal of a thymoma. Once the disease has begun, a slow progression follows. Usually the muscles of the eyes—and somewhat less often of the face, jaws, throat, and neck—are the first to be affected, but in rare cases the initial complaint may be referable to the limbs. However, as the disease advances, it often spreads to other muscles.

The special vulnerability of certain muscles is another characteristic of myasthenia gravis, accounting for its common modes of clinical presentation. Weakness of the levator palpebrae or extracranial muscles is the initial manifestation of the disease in about half the cases, and these muscles are involved eventually in more than 90 percent. Ocular palsies and ptosis (weakness of eyelid opening) are usually accompanied by weakness of eye closure, a combination observed regularly only in this disease and in muscular dystrophy. Certain ocular signs are characteristic of myasthenia. Usually the diplopia that is demonstrated by red-glass testing (pages 282 to 286) does not correspond to a particular innervation but is the result instead of weakness that randomly involves several muscles in both eyes. Sustained upgaze will usually induce or exaggerate ptosis. Cogan has described a twitching of the upper eyelid that appears a moment after the patient moves his eyes from a downward to the primary position. Or, after sustained upward gaze, one or more twitches may be observed with closure of the eyelids or during horizontal movements of the eyes. Repeated ocular versions induced by tracking a target or by an optokinetic stimulus will cause progressive paresis of the muscles utilized for these movements. Unilateral painless ptosis without ophthalmoplegia or paresis abnormality in an adult will most often prove to be due to myasthenia. Attempts to overcome the ptosis may impart a staring expression of the opposite eye. Bright sunlight is said to aggravate the ocular signs and cold, to improve them.

Muscules of facial expression, mastication, swallowing, and speech are frequently affected (80 percent), and in 5 to 10 percent they are the first or only muscles to be involved. Even less frequent is the initial or early involvement of the flexors and extensors of the neck, muscles of the shoulder girdle, and flexors of the hips. Of the trunk muscles, the erector spinae are the most frequently affected. In the most advanced cases, all muscles are weakened, including the diaphragmatic, abdominal, and intercostal muscles and even the external sphincters of the bladder and bowel. The incidence of involvement of any group of muscles closely parallels the likelihood of their having been initially affected by the disease. Clinically, myasthenia gravis may be conceived as a fluctuating oculofaciobulbar palsy. In patients with weakness of the trunk and limbs, the clinical rule holds firm that the proximal muscles are far more vulnerable than distal ones, as they are in almost all other forms of myopathy.

To reiterate the topographic attributes of the illness, drooping of the eyelids and intermittent diplopia are the most common complaints. In fact, the presence of normal pupillary responses to light and accommodation in the face of weakness of the extraocular muscles, levators, and orbicularis oculi is virtually diagnostic of myasthenia gravis. For this reason, patients are advised to avoid activities that may normally result in eye strain, such as reading or watching television. Drowsiness and lassitude may be the first symptoms of myasthenia gravis, but the patient often experiences occasional episodes of fatigue that are relatively mild in comparison to the more severe weakness of the muscles of the neck, shoulder, and upper arm. The first signs of weakness are often noticed in the morning, followed by some recovery later in the day. This pattern of muscle weakness is characteristic of myasthenia gravis and is particularly evident in the muscular facies of the eyelids and in the eyelid ptosis. In some patients, the ptosis is so severe that they are unable to open their eyes at all. In other patients, the ptosis is accompanied by miosis (constriction of the pupil), and in still others, it is associated with mydriasis (dilation of the pupil). In some cases, the ptosis is intermittent, with episodes of weakness lasting for a few seconds or minutes. In other cases, the ptosis is constant and cannot be reversed by ptosis exercises or by the patient closing the eyelids. In still other cases, the ptosis is associated with ptosis of the upper lip and the eyelids of the opposite eye. Bright sunlight is said to aggravate the ocular signs and cold, to improve them.

Muscules of facial expression, mastication, swallowing, and speech are frequently affected (80 percent), and in 5 to 10 percent they are the first or only muscles to be involved. Even less frequent is the initial or early involvement of the flexors and extensors of the neck, muscles of the shoulder girdle, and flexors of the hips. Of the trunk muscles, the erector spinae are the most frequently affected. In the most advanced cases, all muscles are weakened, including the diaphragmatic, abdominal, and intercostal muscles and even the external sphincters of the bladder and bowel. The incidence of involvement of any group of muscles closely parallels the likelihood of their having been initially affected by the disease. Clinically, myasthenia gravis may be conceived as a fluctuating oculofaciobulbar palsy. In patients with weakness of the trunk and limbs, the clinical rule holds firm that the proximal muscles are far more vulnerable than distal ones, as they are in almost all other forms of myopathy.

To reiterate the topographic attributes of the illness, drooping of the eyelids and intermittent diplopia are the most common complaints. In fact, the presence of normal pupillary responses to light and accommodation in the face of weakness of the extracranial muscles, levators, and orbicularis oculi is virtually diagnostic of myasthenia gravis, except if strength is restored after a period of rest. Facial mobility and expression are altered. The natural smile becomes transformed into a snarl. The jaw may sag, so that it must be propped up by the patient’s hand. Chewing tough food may be difficult, and the patient may have to terminate a meal because of inability to masticate and swallow. It may be more difficult to eat after talking, and the voice fades and becomes nasal after sustained conversation. Women may complain of inability to fix their hair because of fatigue of the shoulders, or of difficulty in applying lipstick because they are unable to purse and roll their lips. Weakness of the neck muscles causes fatigue in holding up the head. Another characteristic feature of myasthenic weakness is its tendency to increase as the day wears on or with repeated use of an affected muscle, but patients seldom volunteer this information. A few are worse on awakening, especially if they have not received medication during the night. A temporary increase in weakness has reportedly followed vaccination, menstruation, and exposure to extremes of temperature. A peculiarity of myasthenic muscle contraction is a sudden lapse of sustained posture or interruption of movement resulting in a kind of irregular tremor, similar to that of normal muscle near the point of exhaustion. A dynamometer demonstrates the rapidly waning power of contraction of a series of hand grips, and repetitive stimulation of a motor nerve at slow rates while recording muscle action potentials reveals the same decremental disorder in a more quantitative fashion (see Fig. 286).
Weakened muscles in myasthenia gravis undergo atrophy to only a minimal degree or not at all. Tendon reflexes are seldom altered. Even repeated tapping of a tendon does not usually tax muscles to the point where contraction fails. Smooth and cardiac muscles are not involved.

Other neural functions are preserved. The weakened muscles, especially those of the eyes and back of the neck, may ache, but pain is seldom an important complaint. Paresthesias of the face, hands, and thighs are reported very infrequently and are not accompanied by demonstrable sensory loss. Anoxia and ageusia have been mentioned as rare findings, but whether they are coincidental has not been decided. The tongue may display one central and two lateral longitudinal furrows (trident tongue), as pointed out originally by Buzzard.

Certain statistical features of the disease are of clinical significance. Its prevalence is variously estimated to be from 43 to 84 per million of the population and the annual incidence rate, approximately one per 300,000. The disease may begin at any age, but onset in the first decade is relatively rare (only 10 percent of cases confined to the medulla of the thymus, peak age of occurrence is between 30 and 40 years). The peak age of onset of myasthenia gravis is between 30 and 60 years in men. Under the age of 40, females are affected two to three times as often as males, whereas in later life, the incidence in males is higher (3:2). Of patients with thymomas, the majority are older (50 to 60 years), and males predominate.

The course of the illness is extremely variable. Rapid spread from one muscle group to another occurs in some, but in others the disease remains unchanged for months before remissions. Remissions may take place without explanation, but these happen in less than half the cases and seldom last longer than a month or two. If the disease remits for a year or longer and then recurs, it tends to be progressive. Remission is more likely to occur in the early years of the disease than later. Remission is more often prolonged by the same events that preceded the onset of the illness. In Simpson's opinion, and this coincides with our observations, the danger of death from myasthenia gravis is greatest in the first year after onset of the disease. A second period of danger in progressive cases is from 4 to 7 years after onset. After this time the disease tends to stabilize and the risk of severe relapse diminishes. Fatalities then relate mainly to respiratory complications (infection, aspiration). The mortality rate in the first years of illness, formerly in excess of 30 percent, is now less than 5 percent, and with appropriate therapy, most patients are able to lead productive lives. The course is altered by thymectomy (see further on).

To facilitate clinical staging of therapy and prognosis, the following classification, introduced by Osserman, has been widely adopted (the relative incidence of each type is indicated):

I. Ocular myasthenia (15 to 20 percent)
II. A Mild generalized myasthenia with slow progression; no crises; drug-responsive (30 percent)
III. Severe generalized myasthenia; severe skeletal and bulbar involvement but no crises; drug response less than satisfactory (25 percent)
IV. Acute fulminating myasthenia; rapid progression of severe symptoms with respiratory crises and poor drug response; high incidence of thymoma; high mortality (15 percent)
V. Late severe myasthenia; symptoms same as III, but resulting from steady progression over 2 years from class I to class II (10 percent)

Other authors (Compston et al) have classified the disease according to age of onset, presence or absence of thymoma, antibody level against acetylcholine receptors (AChR), and association with HLA haplotypes: (1) myasthenia gravis with thymoma—no sex or HLA association, high ACHR antibody titer; (2) onset before age 40, thymectomy mandatory; (3) onset after age 40, no thymoma, moderate weakness—female preponderance, increased association with HLA A3, B7, and DRW2 antigens, low ACHR antibody titer. The latter group includes a proportion of older men with purely ocular symptoms (Osserman type I).

The prognosis and response to treatment vary with the pattern of muscle involvement and severity, though it remains difficult to predict the outcome in an individual case. According to Bever and coworkers, an increasing duration of purely ocular myasthenia is associated with a decreasing risk of late generalization of weakness. These authors found, in a retrospective study of 108 such patients, that only 15 percent of the observed generalizations occurred after 2 years of ocular manifestations alone. They also found that a higher age at onset was associated with a higher incidence of fatal respiratory crises; in general, patients with a younger age at onset are at a much lower risk (1 percent) of developing fatal respiratory complications than are older patients. Grob and colleagues, who observed the course of 1036 benign cases for a mean duration of 12 years, found that the clinical manifestations remained confined to the extracranial muscles and orbicularis oculi in 16 percent. Their data indicated further that if localized ocular myasthenia had been present for only a month, there was a 60 percent likelihood that the disease would become generalized. If the ocular myasthenia remained localized for a year, there was only a 16 percent likelihood that it would eventually become generalized. These authors found that in two-thirds of 750 patients with generalized myasthenia gravis, the disease attained its maximum severity within a year of onset, and in 83 percent of patients, within 3 years. By contrast, in our experience, 17 of 37 ocular cases became generalized within a period of 6 years (Weinberg et al). As a rule, the progression of symptoms was more rapid in male than in female patients.

It is not widely recognized that isolated muscle groups may occasionally remain permanently weak even when the ocular and generalized weakness has resolved. The muscles most often affected in this way are the anterior tibials, triceps, and portions of the face.

The long-term outlook for myasthenic children is generally good, and their life expectancy is only slightly reduced. Rodriguez and colleagues followed a group of 149 children for an average of 17 years; 85 of them had thymectomies. Approximately 30 percent of the nonthymectomized and 40 percent of the thymectomized patients underwent remission and were free of symptoms. The remission usually occurred in the first 3 years. Those with bulbary symptoms and no ocular or generalized weakness had the most favorable outcome.

Thymic and Other Associated Disorders

Thymic tumors occur in 10 to 15 percent of patients with myasthenia gravis, and lymphofollicular hyperplasia of the thymic medulla in 65 percent. Thymomas with malignant characteristics may spread locally in the mediastinum and to regional lymph nodes, but rarely metastasize. (N.B.: types are common in our material. Thymic tumors may be unattended by myasthenia, though myasthenia eventually developed in all of our cases, sometimes 15 to 20 years after the tumor was first recognized and removed surgically. According to Brill et al, the severity of myasthenic symptoms is no different in patients with thymic tumors as compared to those having myasthenia without thymoma. The significance of thymic disorders are discussed below and in page 1545.

A biologic trait of interest is the coexistence of myasthenia gravis and other autoimmune diseases. Thyrotoxicosis (5 percent of myasthenic patients—page 1520), lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, mixed connective tissue disease, antinuclear antibody, and polymyositis are all associated with myasthenia more often than can be explained by chance. Aplastic anemia of autoimmune type has also been reported, particularly with thymoma. In the series of patients reported by Kerzin-Storrer and associates, 30 percent had a maternal relative with one of these other disorders of autoimmune nature, suggesting that myasthenia gravis patients inherit a susceptibility to autoimmune disease.

There have been numerous case reports of the concurrence of myasthenia and multiple sclerosis, again suggesting a common autoimmune basis, but the statistical association is not certain. A large proportion of young women with myasthenia have moderately elevated titers of antinuclear antibody without the clinical manifestations of lupus. Antibody against striated muscle has been found in almost half the patients with onset of myasthenia after age 40 (without thymoma) and in 84 percent of myasthenics with thymoma (Compston et al).

Familial occurrence is known but rare. Many of these cases prove to have a genetically determined myasthenic syndrome and not the acquired autoimmune form of myasthenia gravis (see further on).

Pathologic Features Reference has already been made to the involvement of the thymus gland in myasthenia gravis. True neoplasms of the gland are found in about 10 to 15 percent of patients, and fully 65 percent of the remaining patients show a striking degree of hyperplasia of lymphoid follicles, with active germinal centers confined to the medulla of the thymus. The proportion with hyperplasia is even higher in younger patients. The cells in the centers of the follicles are histiococytes; they are surrounded by helper T lymphocytes, B lymphocytes, and plasma cells; IgG is elaborated in the germinal follicles. The changes in the thymus gland resemble the reaction in the thyroid in Hashimoto thyroiditis. Since the latter has been reproduced in animals by injecting extracts of thyroid with Freund adjuvants, it is probable that the so-called thymitis of myasthenia gravis is of similar autoimmune nature. Immunosuppression with steroids causes involution of the thymus.

Aside from lymphoid hyperplasia, two forms of thymic tumors have been described: one is composed of reticular (histiocytic) cells like those in the center of the follicles, and the other is predominantly lymphocytic and specified as lymphosarcomatous. Some of the tumors are composed of spindle-shaped cells. Overlapping types are common in our material. Thymic tumors may be unattended by myasthenia, though myasthenia eventually developed in all of our cases, sometimes 15 to 20 years after the tumor was first recognized and removed surgically. According to Brill et al, the severity of myasthenic symptoms is no different in patients with thymic tumors as compared to those having myasthenia without thymoma.
thymoma from that in patients without a tumor.

As regards the nervous system, all current studies, including 40 autopsies at our hospitals, confirm Erb's original contention that myasthenia gravis is a disease without a central nervous system lesion. The brain and spinal cord are normal unless damaged by hypoxia and hypotension from cardiorespiratory failure. The muscle fibers are generally intact, although in fatal cases with extensive paralysis, isolated fibers of esophageal, diaphragmatic, and eye muscles may undergo segmental necrosis with variable regeneration (Russell). Scattered aggregates of lymphocytes (lymphorrhages) are also observed, as originally noted by Buzzard, but none of these changes in muscle explain the widespread and severe weakness. The lymphorrhages, which are found more frequently in the tumor cases, are not confined to the vicinity of the motor end plates.

Of central importance are the ultrastructural alterations of the motor end plate. These changes, elegantly demonstrated by A. G. Engel and associates, consist of a reduction in the area of the nerve terminal, a simplification of the postsynaptic region (sparse, shallow, abnormally wide or absent secondary synaptic clefts), and a widening of the primary synaptic cleft (Fig. 53-1). The number and size of the presynaptic vesicles and their quanta of ACh are within the normal range. The observation of regenerating axons near the junction, the many simplified junctions, and the absence of nerve terminals supplying some postsynaptic regions suggested to Engel and coworkers that there is a process of degeneration and repair of the neuromuscular junction in myasthenia gravis.

The present view of the disease is that the myasthenic weakness and fatigue are due to the failure of effective neuromuscular transmission. Normally, binding of ACh to the ACh receptor produces a localized electrical end-plate potential of sufficient amplitude to generate a muscle action potential and trigger contraction of the muscle fiber. At myasthenic junctions, because of the greatly reduced number of receptors and the competitive activity of anti-AChR antibodies (see below), the end-plate potentials are of insufficient amplitude to generate action potentials in some fibers (page 1347). Blocked transmission at many end plates results in a reduction in the contractile power of the whole muscle. This deficiency is reflected first in the ocular and cranial muscles, the most continuously active muscles, whose motor units have the fewest ACh receptors. Fatigue is understandable as the result of the normal decline in the amount of ACh released with each successive impulse.

Antibodies to ACh receptor protein have been found to be present in approximately 85 percent of patients with generalized myasthenia and in 60 percent of those with ocular myasthenia (Newsom-Davis). Antibodies are also present in infants with neonatal myasthenia gravis and in animal species known to have a naturally occurring myasthenia. The presence of receptor antibodies has proved to be a sensitive and reliable test of the disease, as discussed further on, under "Measurement of Receptor Antibodies in Blood."

How the antibodies act at the receptor surface of the end plate has also been investigated, but the matter is not entirely settled. Neuromuscular transmission can be impaired in several ways: (1) The antibodies may block the binding of ACh to the ACh receptors. (2) Serum IgG from myasthenic patients has been shown to induce a two- to threefold increase in the degradation rate of ACh receptors. This may be the result of the capacity of antibodies to cross-link the receptors, which are gathered into clusters in the muscle membrane, internalized by a process of endocytosis, and degraded. (3) Antibodies may cause a complement-mediated destruction of the postsynaptic folds (Engel and Katsura). The latter two mechanisms would be expected to reduce the number of ACh receptors at the synapse.

Although the evidence that an autoimmune mechanism is responsible for the functional disorder of muscle in myasthenia gravis appears to be incontrovertible, the source of the autoimmune response has not been established. Because most patients with myasthenia gravis have thymic abnormalities and a salutary response to thymectomy, it is logical to implicate this gland in the pathogenesis of the disease. Both T and B cells from the myasthenic thymus are particularly responsive to the ACh receptor, more so than analogous cells from peripheral blood. Moreover, the thymus contains "myoid cells" (resembling striated muscle) that bear surface ACh receptors. That thymic myoid cells are the foci of immunologic stimulation in myasthenia gravis is unlikely for several reasons, the most obvious being that such cells are even more abundant in the normal than in the myasthenic thymus (Schluep et al). Another suggestion, unconfirmed, is that a virus with a tropism for thymic cells that have ACh receptors might injure such cells and induce antibody formation. It might at the same time have a potential for oncogenesis, accounting for the 10 percent or more of myasthenic patients with thymic cancers. Scadding and associates have suggested a somewhat different mode of thymic involvement; they have shown that thymic lymphocytes from patients with myasthenia gravis can synthesize anti-ACh receptor antibody, both in culture and spontaneously.

Diagnosis in patients who present with a changeable diplopia and the typical myasthenic facies—unequally drooping eyelids, relatively immobile mouth turned down at the corners, a smile that looks more like a snarl, a hanging jaw supported by the hand—the diagnosis can hardly be overlooked. However, only a minority of patients present in this stage of the disease, and seldom is there a clear recognition, even by the patient, that the muscles tire during activity. Ptosis, diplopia, difficulty in speaking or swallowing, or weakness of the limbs are at first mild and inconstant. However, the finding that sustained activity of small cranial muscles is impaired in several ways: (1) The antibodies may block the binding of ACh to the ACh receptors. (2) Serum IgG from myasthenic patients has been shown to induce a two- to threefold increase in the degradation rate of ACh receptors. This may be the result of the capacity of antibodies to cross-link the receptors, which are gathered into clusters in the muscle membrane, internalized by a process of endocytosis, and degraded. (3) Antibodies may cause a complement-mediated destruction of the postsynaptic folds (Engel and Katsura). The latter two mechanisms would be expected to reduce the number of ACh receptors at the synapse.

Etiology and Pathogenesis The establishment of an immunologic mechanism, operative at the neuromuscular junction, has been the most significant development in our understanding of myasthenia gravis. Almost accidentally, it was discovered by Patrick and Lindstrom that repeated immunization of rabbits with ACh receptor protein obtained from the electric eel caused a muscular weakness, which Lennon and colleagues recognized as being similar to that of myasthenia gravis. Soon thereafter Fambrough and coworkers demonstrated the basic defect in myasthenia gravis—a marked reduction in the number of ACh receptors on the postsynaptic membrane of the neuromuscular junction. These observations were followed by the creation of an experimental model of the disease and the demonstration that experimentally induced myasthenia had clinical, pharmacologic, and electrophysiologic properties identical with those of human myasthenia gravis—i.e., decreased miniature end-plate potentials (MEPPs), decremental response on neuromuscular stimulation at 3 Hz, and correlation of weakness with the number of labeled antibodies attached to the receptor sites. It was also shown that humoral antibodies to receptor protein could transverse the neuromuscular junction to normal animals and that the weakness as well as the physiologic abnormalities could be reversed by the administration of anticholinesterase drugs. Thus, the accumulated evidence satisfied the criteria for the diagnosis of an autoimmune-mediated disorder (Drachman).

Electrophysiologic Testing The rapid reduction in the amplitude of compound muscle action potentials evoked during repetitive stimulation of a peripheral nerve at a rate of 3 per second (Fig. 45-5A) and the decremental response by neonigare or edrophonium has been a reliable confirmatory finding in the majority of cases; it can be obtained from the facial, hand, or proximal limb muscles, which may or may not be clinically weak. During a progressive phase of the disease or during steroid therapy, a slight initial incrementing response may be obtained, not to be confused with the marked incrementing response after voluntary contraction that characterizes the Lambert-Eaton syndrome (see further on).

Single-fiber electromyography (EMG) represents an even more sensitive method of detecting the defect in neuromuscular transmission by demonstrating increased variability of the interpotential interval ("jitter"—see page 1366) or blocking of successive discharges from single muscle fibers belonging to the same motor unit. This test requires a great deal of cooperation from the patient in sustaining contraction of a muscle at just the right amplitude in order to isolate single muscle fibers from...
the same unit. With patience on the part of the electromyographer, it is also possible to detect such pairs by electrically stimulating a nerve. Also characteristic of the myasthenic syndrome is the postactivation potentiation of single evoked action potentials, followed by exhaustion. Since the eye muscles exert a pull on the globe, which is reflected in intraocular tension, the increase of the latter in response to edrophonium can also be measured, although this test is rarely performed. Nerve conduction velocities and distal latencies are usually normal.

Equally valuable at this point are the edrophonium (Tensilon) and neostigmine tests, which are performed in the following manner.

Edrophonium (Tensilon) and Neostigmine Tests After the strength of certain cranial muscles (usually the levator palpebrae or an extraocular muscle) or limb muscles (by dynamometry) or vital capacity has been measured, 10 mg (1 mL) of edrophonium is injected intravenously. Initially 1 mg (0.1 mL) is given, if this dose is tolerated and no definite improvement in strength occurs after 45 s, another 3 to 6 mg is injected. If there is no response after another 45 s, the remaining amount is given over approximately 1 min. Most patients who respond do so after 5 mg has been administered. The clinical effect persists for no more than 4 to 5 min. The mild muscular effects of edrophonium (nausea, vomiting, bowel activation, sweating, salivation) can be blocked by pretreatment with atropine 0.8 mg subcutaneously. A positive test consists of visible (objective) improvement in muscle contractility, complete fusion of diplopia, or total resolution of fatigable ptosis. The report of subjective improvement alone is not dependable, and one must also be distrustful of equivocal test results, which may occur with ocular palsies due to tumors, thyroid disease, Guillain-Barré syndrome, progressive supranuclear palsy, or carotid aneurysms (pseudo-ocular myasthenia). In some patients who later prove to have myasthenia gravis, the edrophonium test (or AChR antibody measurements) may be entirely normal during the first episode or even after several episodes of ocular myasthenia. Only later, for inexplicable reasons, do these tests become positive. Finally, it should be noted that the drug carries a rare risk of ventricular fibrillation and cardiac arrest, so that testing is preferably carried out in a hospital setting, where emergency respiratory support is available.

The use of the edrophonium test in the diagnosis of so-called cholinergic crisis is discussed further on.

Neostigmine is sometimes preferable to edrophonium because the longer duration of its effect allows more deliberate and repeated testing. Neostigmine methylsulfate is injected intramuscularly in a dose of 1.5 mg. Atropine sulfate (0.8 mg) should be given several minutes in advance to counteract muscarinic effects. Neostigmine may be given intravenously in a dose of 0.5 mg but again should always be preceded by atropine sulfate to obviate the annoying muscarinic side effects and the danger of cardiac arrhythmia. Objective and subjective improvement occurs in 10 to 15 min, reaches its peak at 20 min, and lasts 2 or 3 h, allowing for careful testing of neuromuscular function. A negative test does not exclude myasthenia gravis but is a strong point against the diagnosis (see below). A trial of oral pyridostigmine, 15 mg every 4 h during the day, is sometimes recommended in doubtful cases, but we have been misled more often than helped by it.

Measurement of Receptor Antibodies in Blood As stated earlier, this is in general a sensitive and highly specific test. The radioimmunoassay method has been the most accurate and widely used. Serum antibody against ACh receptor can be found in 80 to 90 percent of patients with generalized myasthenia gravis and about 60 percent of those whose symptoms are restricted to the ocular muscles (Vincent and Newsom-Davis). Adult myasthenics whose serum is persistently negative for AChR antibodies do not differ clinically or electromyographically from patients with serum antibodies. In general, persistently negative AChR antibody tests are more frequently found in ocular myasthenia than in patients with generalized weakness. Patients with thymoma and severe generalized myasthenia are practically always seropositive. Interestingly, the antibody titers remain elevated during clinical remissions. The reason for persistent seronegativity in some patients is not well understood. Some instances are due to antibody production against unusual epitopes on or near the acetylcholine receptor; their detection requires a special panel of tests.

Each of the commonly used diagnostic tests proves to be about equally reliable. Kelly and coworkers obtained positive results with single-muscle-fiber recording in 79 percent, with the antireceptor antibody test in 71 percent, and with the edrophonium test in 81 percent. Combined, they confirmed the diagnosis in 95 percent of clinically suspected cases.

In keeping with the observation by some myasthenic patients that their weakness improves in the cold, a test has been devised in which an ice pack is placed over the potted eyelid. Sethi and colleagues found that the ptosis was diminished in 8 of 10 patients, but we have been unsuccessful in demonstrating this effect with consistency.

Other diagnostic tests performed routinely in all patients thought to have myasthenia gravis include CT of the chest (for thymus enlargement or thymoma), tests of thyroid function, and, in selected patients, magnetic resonance imaging of the cranium and orbits (to rule out compressive and inflammatory lesions of the cranial nerves and ocular muscles).

Special Diagnostic Problems We have sometimes been puzzled by the following clinical problems.

1. The concurrence of myasthenia gravis and thyrotoxicosis. As indicated on page 1520, thyrotoxicosis may produce its own type of myopathy. There is no certain evidence that thyrotoxicosis aggravates myasthenia gravis; some have even observed a seesaw relationship which we have not confirmed. Hypothyroidism, however, does worsen myasthenia gravis. The ophthalmoplegia of thyrotoxicosis can usually be distinguished by the presence of an associated opthalmalmas (early in the disease, ophthalmalmos may be absent) and the lack of response to neostigmine. Lupus erythematosus and polymyositis are distinguished by lack of involvement of extracranial muscles. Finding the signs of these diseases in combination with those of myasthenia usually indicates the concurrence of two independent autoimmune diseases.

2. The neurothentic patient who complains of weakness when actually referring to fatigability. There is no ptosis, strabismus, or dysphagia, though a neuromuscular individual may complain of diplopia (usually of momentary duration, when drowsy) and also of tightness in the throat (globus hystericus). A number of such patients claim improvement with neostigmine, but objective weakness and reversal thereof is always uncertain. Conversely, myasthenia may be mistaken for hysteria or other emotional illness, mainly because the physician is unfamiliar with myasthenia (or with hysteria) and has been overly impressed with the precipitation of the illness by an emotional crisis.

3. Progressive external ophthalmoplegia and other restricted myopathies, including the congenital myasthenic states. These may be mistaken for myasthenia gravis. It should be emphasized that the extracranial muscles and levator palpebrae may be permanently damaged by myasthenia and cease to respond to neostigmine. Another possibility is that restricted ocular myasthenia may not respond to anticholinesterase drugs from the beginning and the diagnosis of myasthenia is erroneously excluded. One must then turn to other muscles for clinical and electromyographic confirmation of the diagnosis.

4. Illnesses with dystarhria and dysphagia, but without ptosis or obvious strabismus. These may be mistaken for multiple sclerosis, polymyositis, inclusion body myositis, stroke, motor neuron disease, or some other neurologic disease.

5. The initial manifestations of botulism—blurred vision, diplopia, ptosis, strabismus, and ophthalmoparesis—may be mistaken for myasthenia gravis of acute onset. In botulism, however, the pupils are usually large and unreactive, and the eye signs are followed in rapid succession by bulbar and limb muscles.

6. The oculopharyngeal-brachial and Fisher variants of the Guillain-Barré syndrome (GBS), in their early stages, have many of the features of myasthenia gravis, including ptosis that may be partially responsive to anticholinesterase drugs. The loss of tendon reflexes or the rapid development of ataxia in GBS and detailed electrophysiologic testing distinguishes the two conditions.

7. Intoxication with organophosphate insecticides, because of their ability to induce a cholinergic crisis, may be confused with a myasthenic crisis (see further on).

Treatment The treatment of this disease involves the careful use of two groups of drugs—anticholinesterases and immunosuppressants—thymectomy, and, in special circumstances, plasma exchange and intravenous immune globulin.

Anticholinesterase Drugs The two drugs that have given the best results in ameliorating myasthenic weakness are neostigmine (Prostigmin) and pyridostigmine (Mestinon), the latter being preferred by most clinicians and patients. The usual dose of pyridostigmine is 30 to 90 mg q6h (typically a 60-mg pill is tried first); the oral dose of neostigmine ranges from 7.5 to 45 mg given every 2 to 6 h. Delayed-action forms of both drugs are available but should be given at bedtime only to patients who complain of weakness during the night or early morning hours. The dosage of these drugs and their frequency of administration vary considerably from patient to patient, but we agree with Drachman that the maximal useful dosage of pyridostigmine rarely exceeds 120 mg q3h.

For mild cases without thymic tumor and for purely ocular myasthenia, the use of anticholinesterase drugs may be adequate and the only form of therapy necessary.
for some period of time. Although these drugs seldom relieve symptoms completely (the response of ocular symptoms is incomplete), most such patients are able to remain functional. Small doses of corticosteroids are often necessary for complete relief of diplopia (see further on).

If the response to anticholinesterase drugs is poor and progressively larger doses are not relieving symptoms, there is always the danger of a so-called cholinergic crisis. This consists of a relatively rapid increase in muscular weakness, usually coupled with the muscarinic effects of the anticholinesterase drug (nausea, vomiting, pallor, sweating, salivation, colic, diarrhea, miosis, bradycardia). An impending cholinergic effect is betrayed by constriction of pupils (they should not be allowed to contract to less than 2 mm). If the blood pressure falls, 0.6 mg atropine sulfate should be given slowly by the intravenous route. Edrophonium may be used to determine whether weakness is due to an excess of anticholinesterase medications or whether little change signifies a cholinergic excess. This test has been made more specific by having contributed to an overestimation in the frequency and importance of the cholinergic crisis. In our own experience with more than 60 cases of severe myasthenia in an intensive care unit, we have been persuaded of the occurrence of a cholinergic crisis only rarely. Infusion or the natural course of the disease (myasthenic crisis as discussed below) has been a far more common cause of severe weakness and respiratory failure.

Thymectomy Thymectomy, first introduced by Blalock, is advisable as an elective procedure in practically all patients with uncomplicated myasthenia gravis between puberty and approximately 55 years of age who, after a period of treatment with anticholinesterase drugs, are responding poorly and require increasing doses of medication. The remission rate after thymectomy in nontumor patients is approximately 35 percent provided that the procedure is done in the first year or two after onset of the disease, and another 50 percent will improve progressively lower if operation is postponed beyond this time. The response to thymectomy is usually not evident for several months and is maximal by 3 years. In favorably responding cases, levels of circulating receptor antibody are reduced or disappear entirely. If possible, thymectomy should be postponed until puberty because of the importance of the gland in the development of the immune system, but juvenile myasthenia is also quite responsive.

A supralinear approach has been developed and results in less postoperative pain and morbidity; however, the transternal approach is preferable because it assures a more complete removal of thymic tissue. In patients with myasthenia restricted to the ocular muscles for a year or longer, the prognosis is so good that thymectomy is unnecessary. The operation is best performed in a hospital where there is close collaboration between the thoracic surgeon and the neurologist. If the patient is very weak preoperatively, a course of plasma exchange or immune globulin should precede the surgical procedure. After operation, respiratory assistance may be needed. Neostigmine may be given every 3 to 6 h. Usually the dose requirement is about 75 percent of that taken before surgery. As improvement occurs, the dosage of neostigmine can be reduced.

The benefit of thymectomy in children has already been described under “Clinical Manifestations.” Thymectomy is also a safe and effective treatment in nontumorous patients with late-onset myasthenia. In 12 such patients, Olanow and associates reported complete remission in 9 and clinical improvement in the remainder. Evidence of benefit in older patients is less convincing than in the younger group, in part because the thymus is atrophic, but some of our patients over age 60 have benefited.

Removal of the thymus gland is also indicated in practically all patients in whom thymoma is detected by CT scanning of the chest. The tumor can be locally invasive but rarely metastasizes. The operative approach is through the anterior thorax, with adequate exposure to remove all the tumor tissue. If the tumor cannot be removed completely, the remaining tissue should be treated with focused radiation. Local spread and lymph node invasion has been treated with combinations of chemotherapy including cisplatin. Park and colleagues have concluded from a large retrospective study that chemotherapy offers some benefit in terms of survival, but this remains a controversial area.

Corticosteroids For the myasthenic patient with moderate to severe generalized weakness in whom a remission has not been induced by thymectomy or who is responding inadequately to anticholinesterase drugs, the long-term administration of corticosteroids is the most consistently effective form of treatment (Pascuzzi et al). The usual dose is 1 mg/kg daily with the side effects of long-term corticosteroid therapy, and we hesitate to undertake such a program in children or patients with severe diabetes or other diseases that are likely to be aggravated by this form of immunosuppression. Corticosteroids alone or in combination with azathioprine (see below) are often adequate to control ocular myasthenia.

The usual form of corticosteroid therapy is prednisone (or corresponding doses of prednisolone), beginning with 15 to 20 mg/day and increasing the dose gradually until a satisfactory clinical response or a daily dose of 50 to 60 mg is reached. With higher doses or more rapid elevations of the doses, worsening in the first week is common, and hospitalization and careful observation for respiratory difficulty is advisable. Improvement occurs in the following few weeks. Once the maximal effect from prednisone has been attained, the dosage can be reduced slowly over months to the lowest point at which it is still effective. The usual practice is then to institute an alternate-day schedule, which diminishes the side effects. Our patients have done better with a modest difference in dose from one day to the next, rather than omitting an alternate-day dose entirely. Potassium supplements and antacids should be prescribed liberally, as with any chronic corticosteroid regime. At the outset of steroid therapy, anticholinesterase drugs are given simultaneously; as the patient improves, the dosage may be adjusted downward.

Azathioprine (Imuran) and Cyclosporine Azathioprine is a useful drug as an adjunct to steroids and in patients who cannot tolerate or fail to respond to prednisone. It has been able to manage the disease effectively with azathioprine alone. Treatment begins with 50 mg (1 tablet) daily for a few days; if this is well tolerated, the dose is raised to 2 to 3 mg/kg per day (150 to 250 mg daily). The number of positive responses is much the same as with prednisone. However, improvement occurs much more slowly with azathioprine, and a significant response may not be evident for many months to a year (Wilt et al). The Myasthenia Gravis Clinical Study Group has found that the most severe forms of the disease, often resistant to prednisone or azathioprine alone, benefit from the combination of the two medications. Liver function and the white blood cell count should be monitored regularly.

The clinical effects of the immunosuppressive agent cyclosporine are much like those of azathioprine but become evident more rapidly, in a matter of a month or two (Tindall et al). It is given in two divided doses daily, to a total of about 6 mg/kg. The use of this drug is restricted by its serious side effects (hypertension, nephrotoxicity) and its high cost.

Plasma Exchange and Intravenous Immune Globulin For the patient with severe myasthenia that is refractory to treatment with anticholinesterase drugs, thymectomy, and prednisone, one must resort to other measures. Striking temporary remissions (2 to 8 weeks) may be obtained by the use of plasma exchange. This form of treatment may be lifesaving during a myasthenic crisis, as noted below. It is also useful before and after thymectomy and at the start of immunosuppressive drug therapy. The number and volume of exchanges required in these circumstances is somewhat arbitrary, but they tend to be less than those required for Guillain-Barré syndrome; several exchanges of 2 to 3.5 L each (totaling approximately 125 mL/kg), performed over a week, usually suffice. The removed plasma is replaced with albumin and saline. It has been estimated that a 2-L exchange will remove 80 percent of circulating antibodies and that this will be reflected in reduced ACh antibody levels in 3 to 5 days. However, there is only a rough correlation between a reduction in the titer of circulating antibody and the degree of clinical improvement. In a crisis requiring plasma exchange and mechanical ventilation, it has been our practice to discontinue or curtail the use of anticholinesterase drugs and resume them as the patient is being weaned from the ventilator. Also, it appears that sensitivity to these drugs may be enhanced in the hours after an exchange, so that their dosages must be adjusted accordingly. Plasma exchange also reduces the weakness that is often induced by the institution of high-dose corticosteroids.

A few patients respond so well to plasma exchange and find the side effects of steroids so intolerable that they choose to be maintained with two to three exchanges every few months. Immunadsorption, a technique that removes antibodies and immune complexes by running blood over a tephrophan column, is less cumbersome than conventional plasma exchange, but experience with this procedure is as yet limited.

Intravenous immune globulin is also a useful measure in the short-term control of acutely worsening myasthenia. The usual dose is 2 g/kg given in divided doses over 3 to 5 days. However, neither plasma exchange nor immune globulin has been subjected to systematic study or comparison, and it should be re-emphasized that while these measures are invaluable in deteriorated patients or those in crisis, they offer only short-term benefit and are not used regularly in the treatment of most patients.

Myasthenic Crisis A rapid deterioration of the myasthenia itself, termed myasthenic crisis, can bring the patient to the brink of respiratory failure and quadriparesis in a matter of hours, with the infective or excessive use of sedative drugs or drugs with a potential for blocking neuromuscular transmission may precipitate the myasthenic crisis. We have encountered numerous cases in which oropharyngeal weakness has led to aspiration pneumonia and precipitated a rapid deterioration of power in the limbs and diaphragm. Just as frequently, a precipitating event is not evident. Rarely, a respiratory arrest is the first manifestation of crisis. Such events may occur at any time after the diagnosis of myasthenia, but about half of them are evident within 18 months. In experience with 53 patients in myasthenia crisis seen over a period of 12 years at the Columbia-Presbyterian Medical Center, infection, usually pneumonia, was the most frequent precipitating event, but no cause could be determined in almost one-third of the patients (Thomas et al).
Incontinent respiratory failure is marked usually by a reduction of vital capacity, often accompanied by restlessness, anxiety, diaphoresis, or tremor. Once the diaphragm fails, movements of the chest wall and abdomen become paradoxical (the abdomen moves inward during inspiration) or there may be shallow excursions of the chest, alternating with paradoxical movements. In an emergency, after clearing of the airway, such a patient can be supported briefly by a tight-fitting face mask and manual bag breathing.

Management of the crisis entails timely and careful intubation followed by mechanical ventilation in a critical care unit that is prepared to attend to the medical and neurologic needs of such a patient. One must cope with both the oropharyngeal weakness that endangers the airway and the diaphragmatic weakness.

Anticholinergic drugs are best withdrawn at this point. The use of plasma exchange appears to hasten improvement and weaning from the ventilator. Intravenous gamma globulin may be a useful alternative but has not been studied extensively. Some of our colleagues have used high-dose corticosteroid infusions, but this measure has not been particularly successful in our hands and, in the short run, carries the risk of inducing widespread worsening of the weakness (Panagiotakos et al.). Patients may respond to plasma exchange or immunoglobulin infusions in 1 or 2 days, but more often a week or more is required for recovery. It is generally best to wait 2 or 3 weeks before attempting such a patient to tracheostomy.

When weaning from the ventilator is anticipated, anticholinesterase agents are reintroduced slowly, and treatment with corticosteroids can be instituted if necessary. Oral doses of 60 mg pyridostigmine or 15 mg neostigmine are roughly equivalent to 0.5 to 1 mg neostigmine intravenously and 1.5 to 2 mg intramuscularly. The management of the critically ill myasthenic patient has been reviewed by Fink.

Most patients with myasthenic crisis will take several weeks to recover, and a few of our patients have remained ventilator-dependent for months. Again, in the euthyroid, dehydrated, and older patient, the condition may persist for months to years (by a month or two). During the acute stage, there may be within 2 days to a week 7 deaths among 53 patients, reflecting the gravity of this syndrome; this mortality accords with our experience. Atlelectasis, severe anemia, congestive heart failure, and clostridial diarrhea (associated with antibiotic use) portend a prolonged period of intubation. From time to time one encounters a patient in whom respiration and ambulation do not improve for months after a myasthenic crisis. In our experience these have been middle-aged or older patients, usually women, in whom an element of hyperthyroidism or hypothyroidism may have been added. They became wasted as the proximal limb and axial muscles, including the diaphragm, failed to recover their power, even though the oropharyngeal and oculomotor muscles had improved. The role of corticosteroids in producing a concomitant proximal myopathy is a frequent problem that can be solved by careful EMG examination.

Management of Anesthesia and Pregnancy in the Myasthenic Patient These special problems should be mentioned here. Surgical procedures of any type are often sufficiently stressful to produce decompensation of the disease. If the patient is unable to take medications orally, anticholinesterase agents may be given intramuscularly (one-thirtieth of the oral dose of pyridostigmine and one-tenth the oral dose of neostigmine). If corticosteroids were being used, they should be continued and the dose generally kept unchanged; large “stress” doses are generally not necessary. Neuromuscular blocking agents of the noncompetitive type may have a very prolonged effect and should be avoided as part of the anesthetic regimen if possible. If they are necessary for some reason, a period of mechanical ventilation should be anticipated. In contrast, the dose of succinylcholine (which is not recommended) required to produce muscle relaxation may be larger than usual. Any drug whose use is contemplated in the anesthetic and postsurgical management of the myasthenic patient should be checked against the list of drugs that might exaggerate myasthenic weakness (see below).

Pregnancy is usually uncomplicated in myasthenic patients. However, the use of intravenous cholinesterase inhibitors is contraindicated because of the possibility of inducing uterine contractions, and cytotoxic drugs are generally not used because of the potential for causing fetal abnormalities. Also, magnesium is not recommended for the treatment of eclampsia because of its neuromuscular blocking effects. Delivery usually proceeds normally, and breast-feeding is not thought to be a problem with regard to the transmission of AChR antibodies. The issues of neonatal myasthenia and reduced intrauterine movements are considered below.

Other Disorders of Neuromuscular Transmission

Considered here are several disorders of neuromuscular transmission characterized clinically by muscular weakness and fatigability but differing in causation and mechanism from acquired autoimmune myasthenia gravis. The Lambert-Eaton myasthenic syndrome, neonatal myasthenia, the congenital myasthenic syndromes, and botulism are typical of diseases characterized by disorders induced by drugs and toxins as the main representatives of this group of disorders. Two important members of this group—botulism and organophosphate poisoning—are described elsewhere (pages 1274 and 1281, respectively).

The Lambert-Eaton Myasthenic Syndrome of Lambert and Eaton This special form of myasthenia, observed most often with oat-cell carcinoma of the lung, was first described by Lambert, Eaton, and Rooke in 1956 and by Eaton and Lambert in 1957. Unlike the case in myasthenia gravis, the muscles of the trunk, shoulder girdle, pelvic girdle, and lower extremities are the ones that most frequently become weak and fatigable; the EMG findings and poor response to anticholinesterase drugs also serve to differentiate it from myasthenia gravis. Often the first symptoms are arising in a case, a climbing stairs, and walking: the shoulder muscles are affected later. While ptosis, diplopia, dysarthria, and dysphagia may occur, presentation with these symptoms is distinctly unusual. Increasing weakness after exertion stamps the condition as myasthenic, but as originally pointed out, there may be a temporary increase in muscle power during the first few contractions. The tendon reflexes are often diminished, but abolition of the reflexes should raise the question of an associated carcinomatous polynuropathy. Fasciculations are not seen, but there are signs of paresthesias, ataxias, and a number of other symptoms (such as dizziness of the mouth, constipation, difficult micturition, and impotence). There may be other neurologic manifestations of neoplasia (polyneuropathy, polyneuritis or dermatomyositis, focal leukoencephalopathy, cerebellar degeneration, as discussed on pages 721–728).

The onset is usually subacute and the course variably progressive. The myasthenia may precede discovery of the tumor by months or years. About 60 percent of patients have an associated small-cell lung cancer, but the syndrome has also occurred with carcinoma of the breast, prostate, stomach, and rectum and with lymphomas. Males are affected more often than females (5:1). In about one-third of patients, no tumor is found; most of these cases are associated with other autoimmune diseases. The condition may occur in children, usually without relation to tumor. In the cases reported, death usually occurs in a few months or years from the effect of the tumor itself.

As mentioned above, the response to neostigmine and pyridostigmine is poor and unpredictable. On the other hand, d-tubocurarine, suxamethonium chloride, gallamine, and other muscle relaxants have a deleterious effect; when given during anesthesia, they may increase the weakness dramatically and even lead to fatality.

Electrodiagnostic studies have shown no abnormality in the peripheral nerves. A single stimulus of nerve may yield a low-amplitude muscle action potential (in contrast to myasthenia gravis, in which it is normal or nearly so), whereas at fast rates of stimulation (50 per second) as shown in Fig. 45–5E and with strong voluntary contraction (for 15 s or longer), there is a marked increase in the amplitude of action potentials (incrementing response). Single-fiber recordings show an increase in “jitter,” as in myasthenia gravis (page 1366).

In patients with the Lambert-Eaton syndrome, there is an increased incidence of HLA-DR and -DQ haplotypes, as may occur in other autoimmune diseases. Elmquist and Lambert, from a series of studies of excised muscle, deduced that there is a defect in the release of ACh quanta from the presynaptic nerve terminals, akin to that in myasthenia gravis (page 1366). Streib and others have suggested that the Lambert-Eaton myasthenic syndrome is a deficit in ACh release, with diminished sensitivity of the ACh receptors.

In patients with the Lambert-Eaton syndrome, there is an increased incidence of HLA-DR and -DQ haplotypes, as may occur in other autoimmune diseases. Elmquist and Lambert, from a series of studies of excised muscle, deduced that there is a defect in the release of ACh quanta from the presynaptic nerve terminals, akin to that in myasthenia gravis (page 1366). Streib and others have suggested that the Lambert-Eaton myasthenic syndrome is a deficit in ACh release, with diminished sensitivity of the ACh receptors.

Recognition of the Lambert-Eaton syndrome should lead to a search for occult tumor, especially of the lung. If found, it should of course be treated; this alone may result in improvement in the neurologic syndrome. If none is found, the search should be repeated at regular intervals, since the tumors tend to be small and may be inapparent until autopsy.

Treatment Guanidine hydrochloride (20 to 30 mg/kg/day in divided doses) has proved to be more effective in increasing strength than neostigmine or pyridostigmine. Subsequently, guanidine was largely replaced by 3,4-diaminopyridine, 20 mg orally five times daily, in conjunction with pyridostigmine (Lunenfeld et al.). Streib and Rothner were able to achieve long-term improvement with prednisone. Dau and Denys obtained the best results in nontumor cases with repeated courses of plasmapheresis in combination with prednisone and azathioprine. Intravenous immune globulin has also been effective in a few cases. Because of the unpredictable...
side effects of dipyridamole (seizures, confusion, state, paresthesias), some clinicians prefer alternate-day administration of prednisone and azathioprine—prednisone 25 to 60 mg/day, and azathioprine 2.3 to 2.9 mg/kg body weight daily—supplemented by intravenous immune globulin. The response to treatment tends to be slow, over a period of months to a year. Some patients recover fully; in others, restoration of power is incomplete.

**Diagnosis** A syndrome of symmetrical weakness and fatigability of proximal muscles—coupled with dry mouth, sphincter disturbances, aching muscles, and diminished reflexes—should be diagnostic. The only illnesses with which it might be confused are polymyositis and hysterical paralysis, where the patient may do better with encouragement on successive voluntary contractions, and arthritides, where pain hampers the first movements more than successive ones. Then the electrodiagnostic tests are of value.

**Neonatal Myasthenia Gravis** An estimated 12 to 20 percent of babies born to myasthenic mothers show signs of myasthenia (hypotonia, weak cry and suck). This is a transient phenomenon with a mean duration of 18 days, and recovery is usually complete within 2 months of birth (rarely longer), without later relapse. Uncommonly, the myasthenic mother experiences reduced intrauterine movements, suggesting a dangerous degree of myasthenia in the fetus. A few of these children will be born with atrophy, the result of a sustained period of intrauterine immobility, and this complication tends to recur in subsequent births. It has long been assumed that this neonatal myasthenia is due to the passive transplacental transfer of anti-AChR antibodies. This explanation seems unlikely, insofar as maternal AChR antibodies are transferred from mother to fetus in all AChR antibody–positive pregnancies. Moreover, the severity of the neonatal myasthenia gravis does not correlate with the severity or duration of the mother’s illness or with the serum level of the maternal AChR antibody. In fact, neonatal myasthenia may occur when the mother is in remission.

The use of plasma exchange and anticholinesterase drugs may be useful in hastening recovery from neonatal myasthenia.

**Congenital Myasthenic Syndromes** Sporadically in the medical literature, there have appeared reports of a benign congenital myopathy in which myasthenic features could be recognized in the neonatal period or soon thereafter. The affected infants had been born to nonmyasthenic mothers and were described under headings such as “Myasthenia Gravis in the Newborn” and “Familial Infantile Myasthenia” (Greer and Schotland; Robertson et al.).

In the 1970s and 1980s, when the autoimmune basis of myasthenia gravis was established and its morphologic and physiologic features were defined, the differences between this disease and the familial infantile forms became evident. Since then, at least six distinct and rare congenital myasthenic syndromes have been delineated on the basis of their electrophysiologic and ultrastructural features, and a number of others have been partially characterized. Each of these new forms of congenital myasthenia is featured by a unique synaptic or pre- or postsynaptic defect, involving the resynthesis or packaging of ACh or a paucity of synaptic vesicles (presynaptic defect); a deficiency of end-plate ACh esterase (synaptic defect); or a kinetic abnormality of the ACh receptor channels, with or without AChR deficiency (postsynaptic defects). In three-fourths of the cases the defect is postsynaptic, in 13 percent it is synaptic, and in 8 percent it is presynaptic. Mainly this has been the accomplishment of A. G. Engle, who has systematically defined and classified these disorders in a series of extensive investigations of more than 100 cases of congenital myasthenia. A detailed and current account of this work can be found in Engle's chapter on the subject in his monograph Myasthenia Gravis and Myasthenic Disorders. The following clinical features are more or less applicable to all of the congenital myasthenic syndromes.

In the neonate, the most important clue to the disease is an increase in ptosis and in bulbar and respiratory weakness with crying. Later in infancy these symptoms, as well as fluctuating ocular palsies and abnormal fatigability, are brought out by one or more symptoms of sustained activity. Motor milestones may be delayed. In some cases, the myasthenic weakness and fatigability become evident only in the second and third decades of life. The intravenous edrophonium test is consistently positive in a few forms of congenital myasthenia but is usually negative. There is usually a decremental EMG response at low-frequency stimulation (2 Hz). A positive ACh receptor antibody test excludes the diagnosis of a congenital myasthenic syndrome. Some forms of the syndromes respond to treatment with anticholinesterase drugs; others do not. All congenital myasthenic syndromes are inherited as an autosomal recessive trait.

**Myasthenic Weakness due to Antibiotics and Other Drugs and to Natural Environmental Toxins** Many drugs may cause a myasthenic syndrome or a worsening of myasthenia gravis by their action on pre- or postsynaptic structures. This is most likely to happen in patients who are already receiving some other drug or drugs for a variety of illnesses and have hepatic or renal disease. The myasthenic state in these conditions is acute and lasts hours or days, with full recovery provided that the patient is promptly taken off the offending drug. The treatment in all instances is to provide respiratory support, discontinue the offending drug, and attempt to reverse the block at the end plate by infusions of calcium gluconate, potassium supplements, and the administration of anticholinesterases along the lines suggested by Argov and Mastaglia.

There are more than 30 drugs in current clinical use (other than anesthetic agents) that may interfere with neuromuscular transmission in otherwise normal individuals. Of these, the most important are the aminglycylide antibiotics. Myasthenic weakness has been reported with 18 antibiotics in addition to penicillin but particularly with neomycin, kanamycin (less so with gentamicin), colistin, streptomycin, polymyxin B, and certain tetracyclines (McQuillen et al.; Pittinger et al.). It has been shown that these drugs impair transmitter release by interfering with calcium-ion fluxes at nerve terminals. They are especially dangerous when given to myasthenic patients, but they may be used to reverse the effects of muscle relaxants in emergency situations. Also advented in situations in which ACh is needed are the antihistaminic hormone (ACTH), prednisone, and possibly azathioprine—worsen myasthenia temporarily by depolarizing nerve terminals or impairing release of ACh.

Other drugs—such as anticholinesterase agents, particularly insecticides and nerve gases—cause paralysis by binding to cholinesterase and blocking the hydrolysis of ACh. The end plate remains depolarized and is refractory to neural stimuli. As mentioned, the most notable of these drugs or toxins are botulinum toxin, which binds to cholinergic motor endings, blocking quantal release of ACh; black widow spider venom, which causes a massive release of ACh, resulting in muscular contraction and then paralysis from a lack of ACh; d-tubocurarine, which binds to ACh receptors; suxamethonium and decamethonium, which also bind to ACh receptors; organophosphates, which bind irreversibly to ACh esterases; and malathion and parathion, which inhibit ACh esterase. The actions of all these agents except for the organophosphate “nerve gases” are too toxic.

The administration of d-penicillamine has also caused a type of myasthenia. The weakness is typical in that rest increases strength—as do neostigmine and edrophonium—and the electrophysiologic findings are also the same. In such cases, Vincent and others found anti-ACh receptor antibodies in the serum; hence, one must assume that this is due to idiopathic autoimmune myasthenia gravis. In these respects it differs from the weakness caused by aminglycylide (see review of Swift). Rarely, typical autoimmune myasthenia gravis develops as part of a chronic graft-versus-host disease in long-term (2- to 3-year) survivors of allogeneic marrow transplant.

A large group of naturally occurring environmental neurotoxins are known to act at the neuromuscular junction and to induce muscle paralysis with a distribution like that of myasthenia gravis. Venom of snakes, spiders, and ticks are common and well-known animal poisons, as are ciguatera and related toxins (from fish that have ingested the poisoned gastropods, Coshridium botulinum—all of which are discussed in other parts of this book (see Ch. 43). Poisoning by these natural neurotoxins constitutes an important public health hazard in many parts of the world but particularly in the tropics. This class of disorders of the following clinical features are more or less applicable to all of the congenital myasthenic syndromes.

Chapter 54

THE HEREDITARY MYOTONIAS AND PERIODIC PARALYSES (THE CHANNELOPATHIES)

Chloride Channel Diseases
- Myotonia Congenita (Thomsen Disease)
- Generalized Myotonia (Becker Disease)
- Sodium Channel Diseases
  - Primary Hypokalemic Periodic Paralya
  - Paramyotonia Congenita (Erb-Dudenheffer)
- Calcium Channel Disease
  - Hypocalcemic Periodic Paralya
  - Secondary Hyperkalemic Periodic Paralya
- Malignant Hyperthermia
- Malignant Neuropathic Syndrome

Clinical Features

Grouping the hereditary myotonias with the periodic paralyses is a relatively new development in the classification of muscle diseases. In the medical literature, until quite recently, the myotonias stood alone or were thought to be related in some undefined way to the muscular dystrophies. In a similar vein, the periodic paralyses (better called episodic paralyses) have usually been considered with other types of metabolic myopathy. Recent molecular genetic studies, notably those of Rüdel, Lehmann- Horn, and Ricker and their associates, have identified the fundamental defects in the myotonias and episodic paralyses and clarified their relationships, and several new forms of nondystrophic myotonia have been defined. It is now known that all these diseases are caused by mutations in genes that code for chloride, sodium, or calcium channels in muscle fiber membranes, and all are now referred to as ion channel diseases, or, colloquially, as “channeopathies.” The main features of the ion channel diseases are summarized in Table 54-1. Individual members of the group are described below.

Table 54-1 Inherited myotonia and periodic paralyses (the channelpathies)

CHLORIDE CHANNEL DISEASES

Myotonia Congenita (Thomsen Disease)

This is an uncommon disease of skeletal muscle that begins in early life and is characterized by myotonia, muscular hypertrophy, a nonprogressive course, and dominant inheritance. It is set apart from myotonic dystrophy, which has a different genetic basis and is characterized by a progressive degeneration of muscle fibers (see page 1503).

History

This disorder was first brought to the attention of the medical profession in 1876 by Julius Thomsen, a Danish physician who himself suffered from the disease, as did 20 other members of his family over four generations. His designation of ataxia muscularis was not apt, but his description left no doubt as to the nature of the condition, which featured “tonic cramps in voluntary muscles associated with an inherited psychical indisposition.” The association of the latter condition was not borne out by subsequent studies and is now thought to be fortuitous. Strumpell in 1881 assigned the name myotonia congenita to the disease, and Westphal in 1883 referred to it as Thomsen's disease. Erb provided the first description of its pathology and called attention to two additional unique features, muscular hyperexcitability and hypertrophy. In 1923, Nissen, Thomsen's great-nephew, extended the original genealogy to 35 cases in seven generations. In 1948, Thomasen updated the subject in a monograph that is still a useful clinical reference.

Clinical Features

Tonic spasm of muscle after forceful voluntary contraction stands as the cardinal feature of the disease and is most pronounced after a period of inactivity. Repeated contractions “wear it out,” so to speak, and later movements in a series become more swift and effective. Rarely the converse is observed—where only the later movements of a series induce myotonia (myotonia paradoxica); but usually this is a feature of cold-induced paramyotonia congenita (see further on). Unlike cramp, the spasm is painless, but after prolonged activity, nocturnal myalgia—a pinching-aching sensation in the overactive muscles—may develop and prove distressing. Close observation reveals a softness of the muscles during rest, and the initial contraction appears not to be significantly slowed unless there is pre-existent myotonia.

The congenital nature of the dominant form of the disease may be evident even in the crib, where the infant's eyes are noted to open slowly after it has been crying or sneezing, and its legs are conspicuously stiff as the child tries to take its first steps. In other cases, the myotonia becomes evident only later in the first or second decade. The muscles are generously proportioned and may become hypertrophied, but seldom to the degree observed in the recessive form of the disease, described further on. Despite their muscular appearance, these patients are inept in athletic pursuits.

When severe, the myotonia tends to affect all skeletal muscles but is especially prominent in the lower limbs. Attempts to walk and run are sometimes impeded to the extent that the patient stumbles and falls. Other limb and trunk muscles are also thrown into spasm, as are those of the face and upper limbs. Occasionally a sudden noise or fright may cause generalized stiffness and falling. Small, gentle movements such as blinking or elicitation of a tendon reflex do not initiate myotonia, whereas only the later movements of a series induce myotonia (myotonia paradoxica); but usually this is a feature of cold-induced paramyotonia congenita (see further on).

Myotonia can be induced in most cases by tapping a muscle belly with a percussion hammer (percussion myotonia). Unlike the lump or ridge produced in hypothyroid or cachectic muscle (myoedema), the myotonic contraction involves an entire fasciculus or an entire muscle and, unlike the phenomenon of idiomuscular irritability, it persists for several seconds. If tapped, the tongue shows a similar reaction. An electrical stimulus delivered to the motor point in a muscle also induces a prolonged contraction (Erb's myotonic reaction).

Biopsy reveals no abnormality other than enlargement of muscle fibers, and this change occurs only in hypertrophied muscles. As often happens in fibers of increased...
volume, central nucleation is somewhat more frequent than in normal muscle. The large fibers contain increased numbers of normally structured myofilaments. In well-fixed biopsy material examined under the electron microscope, Schroeder and Adams were unable to discern any significant morphologic changes. There are no changes in the peripheral or central nervous system.

Pathogenesis In view of the absence of morphologic changes and the prominence of the myotonic phenomenon in individual muscle fibers, one must assume the existence of a physiologic change in the sarcolemma or some other part of the conducting apparatus of the muscle fibers. It persists after the administration of curare. Electromyography (EMG) shows that the tension in contracting muscle fibers is slow to diminish, due to persistence of very fine electrical potentials (Fig. 45-8). Some of the latter are the same size as fibrillation potentials, but others are larger (normal motor unit potentials). The small potentials indicate independent, incoordinate and repetitive activity. Their activity continues after the volley of nerve impulses that initiated the contraction has ceased. Denny-Brown and Foley, stimulating single muscle fibers directly, obtained this myotonic afterdischarge only by a volley of stimuli, never by a single stimulus, and the series of myotonic fibrillation potentials progressively diminished in size—these physiologic findings matching the clinical ones. Perfusion elicits myotonia because it, too, provides a brief but relatively intense repetitive excitation. Thus myotonia can be distinguished electrophysiologically from conditions (e.g., that produced by perfusion of muscle with Veratrum alkaloids). In addition, Denny-Brown and Nevin noted that strong myotonia in one group of muscles may evoke reflex afterspasm in antagonist and synergist muscles—a reaction that depends on the operation of spinal mechanisms. This impairs efficiency and power of movement.

The biophysical basis of myotonia is now reasonably well understood. Intrinsic proteins, embedded in the lipid bilayer of the muscle membrane, function as gates or filters for the passage of particular ions—sodium (Na⁺), calcium (Ca²⁺), chloride (Cl⁻)—each of which flows through its separate channel. Bryant, on the basis of in vitro studies of myotonic goat muscle, attributed the myotonic excitability (repetitive firing and afterdischarge) to a reduced chloride conductance in the transverse tubular system. Subsequent studies of human myotonic muscle, by Lipicky and Bryant, demonstrated a similar low chloride conductance. Abnormal sodium channel rearrangements are also implicated in the membrane hyperexcitability of the myotonic muscle fibers. As indicated earlier, the genes encoding these muscle ion channels and the gene protein products have now been identified (see Table 54.1).

Myotonia Levior This is the name applied by De Jong to a dominantly inherited form of myotonia congenita in which the symptoms are of milder expression and later onset than those of Thomsen disease. In two patients of a myotonia levior family, Lehmann-Horn and coworkers have identified a mutation of the chloride ion channel (CLCN1)—that is, the same genetic defect that characterizes Thomsen disease. Thus it appears that myotonia levior is simply a mild form of Thomsen disease.

Diagnosis In patients who complain of spasms, cramping, and stiffness, myotonia must be distinguished from several of the disorders described in Chap. 55—myokymia, persistent muscle activity and the crampfasciculation syndromes, periodic hyperkalemic paralysis, the Schwartz-Jampel syndrome, the pathologic cramp syndrome, the “stiff-man” syndrome—as well as the contracture of phosphorylase or phosphofructose kinase deficiency. In none of these disorders is there percussion myotonia or the usual EMG abnormality. The only exception is the Schwartz-Jampel syndrome of hereditary stiffness combined with short stature and muscle hypertrophy. This is probably a form of myotonia and should be set apart from myokymia and the syndrome of continuous muscle activity (page 1568).

Diagnostic uncertainty may arise in those patients who later prove to have myotonic dystrophy when only myotonia is noted in early life. The myotonia in these latter cases is usually mild, and in several families that we have followed, some degree of weakness and a typical facies could be perceived even in early childhood. Also, in paramyotonia congenita (see further on) there is myotonia of early onset, but again it tends to mild, involving mainly the orbicularis oculi, levator palpebrae, and tongue; the diagnosis is seldom in doubt because of the cold-induced episodes of paralysis.

Also to be differentiated is the myotonia induced by certain drugs—occasionally by beta-blocking agents or diuretics (especially during pregnancy) and more regularly by depolarizing, relaxing, and anesthetic drugs and used in the treatment of hypercholesterolemia. Their effects are usually short-lived.

In patients with very large muscles, one must consider not only myotonia congenita but also familial hyperdevelopment of hypothyroid polymyopathy, hypertrophic polymyopathy (hypothyroid muscular vitamin), and the Bruck-De Lange syndrome (mental retardation, and extrapyramidal movement disorder). The demonstration of myotonia by percussion and EMG study usually resolves the problem, although it should be noted that in exceptional cases of Thomsen disease, the persistence of contraction may be difficult to demonstrate. In hypothyroidism, the EMG may show bizarre high-frequency (pseudomyotonic) discharges (page 1364). However, true myotonia does not occur, myoedema is prominent, and—along with other signs of thyroid deficiency—there is slowing of contraction and relaxation of tendon reflexes not seen in myotonia congenita.

Treatment Quinidine sulfate, 0.3 to 0.6 g, procainamide, 250 to 500 mg qid, and mexiletine, 100 to 300 mg tid, are clearly beneficial in myotonia congenita. Phenytion, 100 mg tid, has also been useful in some cases. The cardiac antiarrhythmic drug tocaide (1200 mg daily) has also proved to be beneficial, but it sometimes causes agranulocytosis and is no longer recommended.

Generalized Myotonia (Becker Disease) This is the name applied by Gamstorp described two additional families with this disorder and named it adynamia episodica hereditaria. As further examples were reported, it was noted that in many of them there were minor degrees of myotonia, which brought the condition into relation with paramyotonia congenita (see further on).

There are three distinct variants of hyperkalemic periodic paralysis: (1) without myotonia, (2) with myotonia, and (3) with paramyotonia. The three clinical variants, which are elaborated below, are found to breed true. Presumably in all three, rises in extracellular potassium (K) fail to inactivate the aberrant sodium (Na) channel.

Included in this category are the following hereditary muscle disorders: hyperkalemic periodic paralysis, normokalemic periodic paralysis, paramyotonia congenita, myotonia adynamia episodica hereditaria, the “stiff-man” syndrome—and as well as the contracture of phosphorylase or phosphofructose kinase deficiency. There are many myotonic disorders in muscles, central nucleation, and extrapyramidal movement disorder.

This is a second form of myotonia congenita, inherited as an autosomal recessive trait. Like the dominant form, it is caused by an allelic mutation of the gene encoding the chloride ion channel of the muscle fiber membrane. The clinical features of the dominant and recessive types are similar except that myotonia in the recessive type does not become manifest until 10 to 14 years of age or even later and tends to be more severe than the myotonia of the dominant type. The myotonia appears and spreads to the trunk, arms, and face. Hyperthermia and fever are invariably present. There may be a related mild distal weakness and atrophy; this was found in the forearms in 28 percent of Becker’s 148 patients and in the sternomastoids in 19 percent. Dorsiflexion of the feet was limited and fibrous contracture of the muscle became prominent. The course of the illness thereafter remains unchanged. The creatine kinase (CK) may be elevated. Testicular atrophy, cardiac abnormality, frontal baldness, and cataracts—the features that characterize myotonic dystrophy—are conspicuously absent.

SODIUM CHANNEL DISEASES Included in this category are the following hereditary muscle disorders: hyperkalemic periodic paralysis, normokalemic periodic paralysis, paramyotonia congenita, myotonia fluctuans, myotonia permanens, and acetazolamide-responsive myotonia. All of them have been mapped to chromosome 17q23 and are due to mutations in the gene encoding the α subunit of the sodium channel in skeletal muscle (SCN4A). The first three are the better-known members of the group: the three later disorders have been included only in recent years and are included on the basis of shared clinical abnormalities and molecular defects.

Primary Hyperkalemic Periodic Paralysis This type of periodic paralysis was first described and distinguished from the more common (hypokalemic) form by Tyrer and colleagues, in 1951. Five years later, Gamstorp described two additional families with this disorder and named it myokymia. As further examples were reported, it was noted that in many of them there were minor degrees of myotonia, which brought the condition into relation with paramyotonia congenita (see further on).

There are three distinct variants of hyperkalemic periodic paralysis: (1) without myotonia, (2) with myotonia, and (3) with paramyotonia. The three clinical variants, which are elaborated below, are found to breed true. Presumably in all three, rises in extracellular potassium (K) fail to inactivate the aberrant sodium (Na) channel.

Clinical Manifestations The pattern of inheritance is autosomal dominant. Onset is usually in infancy and childhood. Characteristically, the attacks of weakness occur before breakfast and later in the day, when the patient is resting in a chair about 20 to 30 min after exercise. The paresis begins in the legs, thighs, and lower back and spreads to the hands, forearms, and shoulders. Only in the severest attacks are the neck and cranial muscles involved. Respiratory muscles are usually spared. As the muscles become inexcitable, tendon reflexes are diminished or lost. Attacks usually last 15 to 60 min, and recovery can be hastened by mild exercise. After an attack, mild weakness may persist for a day or two. In severe cases, the attacks may occur every day; during late adolescence and the adult years, when the patient becomes more sedentary, the attacks may diminish and cease. In certain muscle groups, if myotonia coexists, it is difficult to separate the effects of paresis from those of myotonia. Indeed, when an attack of paresis is prevented by continuous movement, firm, painful limbs may form in the calf muscles. Some patients with repeated attacks may be left with a permanent weakness and wasting of the proximal limb muscles.

During the attack of weakness, serum K rises, usually up to 5 to 6 mmoL. It is associated with an increased amplitude of T waves in the electrocardiogram (ECG), and there is a fall in the serum Na level (due to entry of Na into muscle). With increased urinary excretion of the K, the serum K falls and the attack terminates. Between attacks, serum K is normal. The attacks of paralysis are alike in the three clinical variants of the disease. Usually the presence of myotonia can only be detected
electromyographically. In the paramyotonic form, the attacks are associated with paradoxical myotonia—that is, myotonia induced by exercise and also by cold.

The provocative test, undertaken when the patient is functioning normally, consists of the oral administration of 2 g of KCl in a sugar-free liquid repeated every 2 h for four doses if that many are necessary to provoke an attack. The test is given in the fasting state, ideally just after exercise. The weakness typically has a latency of 1 to 2 h after the administration of K. The patient must be carefully monitored by ECG and frequent serum K estimations. The test should never be undertaken in the presence of an attack of weakness or reduced renal function or in diabetics requiring insulin.

The treatment of this syndrome is the same as that for paramyotonia congenita, described further on.

**Normokalemic Periodic Paralysis**

This is a rare form of episodic paralysis that resembles the hyperkalemic form in practically all respects except for the fact that serum potassium does not increase, even during the most severe attacks. However, some patients with normokalemic periodic paralysis are sensitive to potassium loading (Poskanzer and Kerr); other kindreds are not (Meyers et al). The disorder is also transmitted as an autosomal dominant trait, and the basic defect has proved to stem from the same mutation as that of hyperkalemic periodic hyperparalysis.

**Paramyotonia Congenita ( Von Eulenberg)**

In this disease, attacks of periodic paralysis are associated with myotonia, which may be paradoxical in type—that is, it develops during exercise and worsens as the exercise continues. Characteristically, a widespread myotonia, often coupled with weakness, is induced by exposure to cold. In some patients the myotonia can be elicited even in a warm environment. The weakness may be diffuse, as in hyperkalemic periodic paralysis, or limited to the part of the body that is cooled. Once started, the weakness persists for several hours, even after the body is warmed. Persuasion myotonia can be evoked in the tongue and thenar eminence. Immersion of the arm and hand in ice water elicits both myotonia and weakness after a period of about 30 min. According to Layzer and colleagues, myotonia that is constantly present in a warm environment diminishes with repeated contraction, whereas myotonia induced by cold increases with repeated contraction (paradoxical myotonia).

Like hyperkalemic periodic paralysis, paramyotonia congenita is transmitted as an autosomal dominant trait, and both diseases have been linked to the same gene (SCN4A), which encodes the alpha subunit of the muscle membrane sodium channel; the two diseases are caused by allelic mutations.

**Laboratory Findings**

In both hyperkalemic periodic paralysis and paramyotonia congenita, the serum K is usually above the normal range, but paralysis has been observed at levels of 5 meq/L, or even lower. Each patient appears to have a critical level of serum K, which, if exceeded, will be associated with weakness. The administration of KCl, raising serum K to above 7 meq/L but to a level that has no effect on normal individuals, invariably induces an attack in the patient. The EMG shows myotonic discharge in all muscles, even at normal temperatures. The CK may be elevated.

In vitro studies of muscle from patients with cold-induced stiffness and weakness have shown that as temperature is reduced, the muscle membrane is progressively depolarized, to the point where the fibers are inevitably (Lehmann-Horn et al). A sodium channel blocker (tetrodotoxin) prevents the cold-induced depolarization. In patients with paramyotonia—but not in those with hyperkalemic periodic paralysis—Subramony and colleagues have observed a diminution of the compound muscle action potential in response to the cooling of muscle, settling the argument as to whether the two syndromes (hyperkalemic paralysis and paramyotonia) are the same or different.

Some patients with paramyotonia, like those with other forms of periodic paralysis, may in later life slowly develop a mild myopathy that causes persistent weakness.

There are either no histologic changes or at most only a few vacuoles in some of the muscle fibers. By electron microscopy, aggregates of tubules are seen in the muscle fibers in this as well as in normokalemic periodic paralysis. Fiber necrosis occurs in long-standing cases with fixed weakness.

**Treatment**

Many attacks of primary hyperkalemic periodic paralysis and of paramyotonia congenita are too brief and mild to require treatment. If attacks are severe, intravenous calcium gluconate (1 to 2 g) often restores power. If, after a few minutes, this treatment is unsuccessful, intravenous glucose or glucose and insulin and hydrochlorothiazide should be tried.

The continuous use of diuretics such as hydrochlorothiazide (about 0.5 g daily), keeping the serum K below 5 meq/L, prevents attacks. When the myotonia is more troublesome than the weakness, procainamide or the lidocaine derivative tocainide, in doses of 400 to 1200 mg daily, is useful; as mentioned, the latter carries the risk of agranulocytosis. Acetazolamide has proved effective in treating myotonia but aggravates cold-induced weakness. Mexiletine 200 mg tid is perhaps the best alternative, since it prevents both cold- and exercise-induced myotonia.

**Other Sodium Channel Disorders**

Several other forms of hereditary periodic paralysis have been linked to mutations of the gene encoding the alpha subunit of the skeletal muscle sodium channel. One of these, first described by Ricker and colleagues, has been designated myotonia fluctuans, because the muscle stiffness fluctuates from day to day in affected family members. In other respects the clinical features resembled those of myotonia congenita, including provocation of attacks of myotonia by exercise. The muscle stiffness was only slightly sensitive to cold but was markedly aggravated by ingestion of potassium and, interestingly, never progressed to muscular weakness or paralysis.

Myotonia perennans is the name given to another sodium channel disorder, characterized by the presence of persistent myotonia and marked hypertrophy of muscles, particularly of the neck and shoulders. The EMG discloses continuous muscle activity. This disease was discovered in the course of genotyping a patient who earlier had been reported by Spaans and associates as an example of “myogenic” Schwartz-Jampel syndrome.

Trudell and colleagues, in 1987, studied 14 patients from a large kindred with autosomal dominant myotonia, the main feature of which was periodic worsening of myotonia accompanied by muscle pain and stiffness, most severe in the face and hands. The symptoms were enhanced by cold (suggesting paramyotonia), and severe stiffness and palpable rigidity followed within 15 min of K ingestion. Neither of these measures provoked muscle weakness. Muscle biopsy disclosed a normal ratio of types 1, 2A, and 2B fibers, further distinguishing this disorder from typical myotonia congenita, where 2B fibers may be reduced in number. All patients in this family who were treated with the carbonic anhydrase inhibitor acetazolamide (Diamox) had a dramatic resolution of symptoms within 24 h—hence the name acetazolamide-responsive myotonia. This disorder has now been linked to a specific molecular alteration of the sodium channel gene (Pth Ček et al).

Rosenfeld et al have described yet another form of painful congenital myotonia attributable to a novel mutation in the sodium channel a-subunit gene (SCN4A). Affected members of this family experienced debilitating pain, particularly severe in the intercostal muscles. Also, the pain was resistant to treatment with acetazolamide and other antmyotonic drugs (mexiletine and tocainamide) and could not be provoked by ingestion of potassium-rich foods—differing in these ways from the patients described by Trudell and Pth Ček and their associates.

Finally, in regard to the channelopathies, it should be mentioned that the marine toxins (ciguatoxin, tetrodotoxin, saxitoxin, etc.), as discussed in Chap. 43, produce their effects on the peripheral and central nerves by blocking sodium channels but have little obvious effect on muscle function.

**CALCIUM CHANNEL DISEASE**

**Hypokalemic Periodic Paralysis**

This is the best-known form of periodic paralysis. The history of the disease is difficult to trace, but the first unmistakable account was probably that of Hartwig in 1874, followed by the accounts of Westphal (1885) and Oppenheim (1891). Goldflam (in 1895) first called attention to the remarkable vacuolization of the muscle fibers, particularly of the neck and shoulders. The EMG discloses continuous muscle activity. This disease was discovered in the course of genotyping a patient who earlier had been reported by Spaans and associates as an example of “myogenic” Schwartz-Jampel syndrome.

Trudell and colleagues, in 1987, studied 14 patients from a large kindred with autosomal dominant myotonia, the main feature of which was periodic worsening of myotonia accompanied by muscle pain and stiffness, most severe in the face and hands. The symptoms were enhanced by cold (suggesting paramyotonia), and severe stiffness and palpable rigidity followed within 15 min of K ingestion. Neither of these measures provoked muscle weakness. Muscle biopsy disclosed a normal ratio of types 1, 2A, and 2B fibers, further distinguishing this disorder from typical myotonia congenita, where 2B fibers may be reduced in number. All patients in this family who were treated with the carbonic anhydrase inhibitor acetazolamide (Diamox) had a dramatic resolution of symptoms within 24 h—hence the name acetazolamide-responsive myotonia. This disorder has now been linked to a specific molecular alteration of the sodium channel gene (Pth Ček et al).

Rosenfeld et al have described yet another form of painful congenital myotonia attributable to a novel mutation in the sodium channel a-subunit gene (SCN4A). Affected members of this family experienced debilitating pain, particularly severe in the intercostal muscles. Also, the pain was resistant to treatment with acetazolamide and other antmyotonic drugs (mexiletine and tocainamide) and could not be provoked by ingestion of potassium-rich foods—differing in these ways from the patients described by Trudell and Pth Ček and their associates.

Finally, in regard to the channelopathies, it should be mentioned that the marine toxins (ciguatoxin, tetrodotoxin, saxitoxin, etc.), as discussed in Chap. 43, produce their effects on the peripheral and central nerves by blocking sodium channels but have little obvious effect on muscle function.
that controls calcium release from the sarcoplasmic reticulum, thus mediating muscle excitation-contraction coupling, and as a calcium-conducting pore. How the reduced calcium channel function relates to hypokalemia induced attacks of muscle weakness is not known.

**Clinical Manifestations** The disease may have its onset at any time from early childhood to the third decade of life. In Talbott's review of 152 cases, there were 40 in which symptoms began before the 10th year of life and 52 before the 16th year. The typical attack comes on during the second half of the night or the early morning hours, after a day of unusually strenuous exercise; a meal rich in carbohydrates favors its development. Excessive hunger or thirst, dry mouth, palpitation, sweating, diarrhea, nervousness, and a sense of weariness or fatigue are mentioned as prodromata but do not necessarily precede an attack. Usually the patient awakens to discover a mild or severe weakness of the limbs. However, diurnal attacks also occur, especially after a nap following a large meal. The attack evolves over minutes to several hours; at its peak, it may render the patient so helpless as to be unable to call for assistance. Once established, the weakness lasts a few hours if mild or several days if severe.

The distribution of the paralysis varies. Limbs are affected earlier and often more severely than trunk muscles, and proximal muscles are possibly more susceptible than distal ones. The legs are often weakened before the arms, but exceptionally the order is reversed. The muscles most likely to escape are those of the eyes, face, tongue, pharynx, larynx, diaphragm, and spinbunures, but on occasion even these may be involved. When the attack is at its peak, tendon reflexes are reduced or abolished and cutaneous reflexes may also disappear. Sensation is preserved. As the attack subsides, strength generally returns first to the muscles that were last to be affected. Headache, exhaustion, diuresis, and occasionally diarrhea may follow the attack. Myotonia is not seen; indeed, EMG evidence of myotonia excludes the diagnosis of hypokalemic periodic paralysis.

Attacks of paralysis tend to occur every few weeks and to lessen in frequency with advancing age. Rarely, death may occur from respiratory paralysis or derangements of the conducting system of the heart. Mainly, such cases were reported in the era before modern intensive care.

**Atypical forms** include weakness of one limb or certain groups of muscles, bifacial palsy (inability to lift one's arm or to comb one's hair), and transient weakness during accustomed activities. Earlier descriptions of daily brief attacks, some associated with exposure to cold or coupled with muscular hypertrophy or exophthalmic goiter, preceded recognition of the other types of periodic paralysis and cannot be evaluated. Some of our patients had a talipes deformity from early life. A number of patients developed a slowly progressive proximal myopathy, with vacuolated and degenerated fibers and myopathic action potentials, during middle adult life, in some instances long after attacks of periodic paralysis had ceased.

Andersen and coworkers first drew attention to a distinct form of periodic paralysis characterized by the triad of periodic potassium-sensitive weakness, ventricular dysrhythmias, and dysmorphic features (short stature, scapulophaehaly, hypertelorism, broad nose, low-set ears, short index fingers, and small mandible). More recently Samsone et al have described 11 additional patients with Andersen's syndrome from five kindreds. These authors have pointed out that attacks of paralysis come in the thyrotoxic type, normo-, or hyperkalemic. The latter is an integral feature, and that, and the myotonia of this type (or one of typical myotonia), is the only sign in an individual from a kindred. It is noteworthy that the fact that attacks of this type of periodic paralysis can be either hyperkalemic or hypokalemic periodic paralysis has not been established. Stevens has described a family, traced through five generations, with hypokalemic periodic paralysis as well as myotonia, peroneal muscle atrophy, impaired sensation, and ataxia. One cannot determine whether these are chance associations or two hereditary diseases.

**Laboratory Findings** The attacks are accompanied by reduction in serum K levels, as low as 1.8 meq/L, but usually at levels that would not be associated with paralysis. The episodes occur with near-normal levels of K, and weakness persists for a time after the serum level has been restored. The fall in serum K is associated with little or no increase in urinary K excretion. Presumably, large volumes of the K enter the muscle fibers during an attack. The K levels return to normal during recovery. Although the shifts in K are of undoubted importance in the pathogenesis of muscle weakness, the marked sensitivity to small reductions of serum K suggests that other factors are also operative and that the fall in K may be a secondary phenomenon.

**Pathogenic Changes** The nervous system is entirely normal. The muscle fibers are uniformly somewhat large, but the most striking change, particularly in the late degenerative phases of the disease, is vacuolization of the sarcoplasm. The myofibrils are separated by round or oval vacuoles containing clear fluid, presumably water, and their myofilaments are replaced by positive granules. These are characteristic changes in myofibrils and mitochondria as well, and focal increases in muscle glycogen. Isolated muscle fibers may undergo segmental degeneration. Electron microscopic studies have shown that the vacuoles arise as a result of proliferation and degeneration of membranous organelles within the sarcoplasmic reticulum and transverse tubules (A. G. Engel).

**Secondary Hypokalemic Periodic Paralyses** In addition to the hereditary periodic paralyses described above, transitory episodes of weakness are known to be associated with a number of acquired derangements of potassium metabolism (mainly hypokalemia), such as thyrotoxicosis, aldosteronism, 17a-hydroxylase deficiency (Yazaki et al), barium poisoning (Lewi and Bar-Khayim), glycineamic acid ingestion (a substance in licorice that has mineralocorticoid activity), and abuse of thyroid hormone (Layzer). Other forms of secondary hypokalemic weakness have been observed in patients suffering from chronic renal and adrenal insufficiency or disorders due to a loss of potassium, as occurs with excessive use of diuretics or laxatives (the commonest cause in practice). Renal failure with hyperkalaemia can also induce paralysis.

**Thyrotoxicosis with Periodic Paralysis** This, a form of secondary hypokalemic periodic paralysis, occurs mainly in young adult males (despite the higher incidence of thyrotoxicosis in women), with a predilection for those of Japanese and Chinese extraction. In Japan, Okinawa and associates found that 8.9 percent of males with thyrotoxicosis had periodic paralyses but only 0.4 percent of females; for the Chinese, the corresponding figures were 13.0 and 0.17 percent (McFadzean and Yeung). The paralytic disorder is unrelated to the severity of the thyrotoxicosis. In patients with the familial forms of periodic paralysis, the induction of hyperthyroidism (hyperthyroidism and hypothyroidism) may lead to severe attacks of periodic paralysis, Dalakas and Engel report a successful restoration of strength by the administration of the carbonic anhydrase inhibitor dichlorphenamide. Regular exercise (not too strenuous) to keep the patient fit is desirable. To prevent an attack, the drugs of choice are said to be imipramine or acetazolamide.

**Hypokalemic Weakness in Primary Aldosteronism** Hypokalemic weakness due to hypersecretion of the major adrenal mineralocorticoid aldosterone was first described by Conn and associates in 1955. In primary aldosteronism, the cause of the hypersecretion is in the adrenal gland itself—usually an adrenal cortical adenoma, less often adrenal cortical hyperplasia. The disorder is not common (occurring in about 1 percent of unselected hypertensive patients), but its recognition is essential, since it can be treated persistently. Persistent aldosteronism is frequently associated with hypernatremia, polyuria, and alkalosis, which predisposes the
patient to attacks of tetany as well as to hypokalemic weakness. Conn and associates (1964), in an analysis of 145 patients with primary aldosteronism, found that persistent muscular weakness was a major complaint in 73 percent; intermittent attacks of paralysis occurred in 21 percent and tetany in 21 percent. These manifestations were much more frequent in women than in men, in contrast to the preponderance of men among patients with hypokalemic periodic paralysis of familial type. Rarely, as already noted, primary aldosteronism is produced by the chronic ingestion of licorice; this is due to its content of glycyrrhizic acid, a potent mineralocorticoid (Conn et al 1968).

The muscle fibers of patients with primary aldosteronism show necrosis and vacuolation. Ultrastructurally, the necrotic areas are characterized by a dissolution of myofilaments with degenerative vacuoles; nonnecrotic fibers contain membrane-bound vacuoles and show dilatation of the sarcoplasmic reticulum and abnormalities of the transverse tubular system, suggesting that a vulnerability of the latter structures may be responsible for the muscle fiber necrosis (Atsumi et al).

Malignant Hyperthermia

This refers to a syndrome that is observed during general anesthesia, characterized, if not treated properly, by rapidly rising body temperature, muscular rigidity and a high mortality. Since the original report by Denborough and Lovell in 1960, as larger experience was gained with this entity, it proved to be a metabolic polymopathy inherited as a dominant trait, rendering the individual vulnerable to any potent volatile anesthetic agent, particularly halothane and to the muscle relaxant succinylcholine. Malignant hyperthermia occurs approximately once in the course of 50,000 instances of general anesthesia.

The clinical picture is dramatic. As halothane or a similar inhalational anesthesia is induced or suxamethonium is given for muscular relaxation, the jaw muscles unexpectedly become tense rather than relaxed, and soon the rigidity extends to all of the muscles. Thereafter the body temperature rises to 42 or 43° F—with coincidental tachycardia and tachycardia. Arterial CO₂ may exceed 100 mmHg, and blood pH may fall to 7.00 or below. There may be gross myoglobinuria, and serum CK often reaches extraordinarily high levels. Circulatory collapse and death may ensue (in approximately 10 percent of cases), or the patient may survive, with gradual recovery. In some cases there is the same sequence of events (increased temperature and acidosis) without muscular spasm. With the patient's early death, the muscle may appear normal by light microscopy. After the patient's survival for several days, samples of muscle reveal scattered segmental necrosis and phagocytosis of sarcoplasm without inflammation. Regenerative activity is in progress. Multifoci are frequently found in the muscle of patients who have had such episodes.

The pathogenesis of this reaction has been the subject of a number of investigations. During the rigor phase, oxygen consumption in muscle increases 3-fold and serum lactate, 15- to 20-fold. Muscle from affected individuals is abnormally sensitive to caffeine, which induces contracture in vitro. It has been postulated that halothane acts in a manner similar to caffeine—that is, to release calcium from the sarcoplasmic reticulum and prevent its reaccumulation, thus interfering with relaxation of the muscle. There is a breed of pigs, inbred for muscular development, in which muscle spasm (true contracture) and hyperthermia follow the administration of anesthetics. The latter increase O₂ consumption by 50 to 60 percent and deplete the adenosine triphosphate of muscle fibers. These swine have an inherited defect in the ryanodine receptor, a protein component of the calcium channel of the sarcoplasm that is sensitive to both caffeine and cyanide. One of several similar defects is found in only 10 percent of human cases. It has been proposed that other yet unidentified allelic mutations of this receptor or another that controls the structure of the calcium channel account for the remainder. The cause of the fever is not known; it is probably due to the muscle spasm, but an effect of the anesthetic on heat-regulating centers cannot be excluded.

Clues as to which patients are at risk come from several sources. Other members of the family may have collapsed or died during anesthesia. Some of the susceptible individuals exhibit certain myopathic and musculoskeletal abnormalities (Isaacs and Barlow). As to the latter, short stature, ptosis, strabismus, highly arched palate, dislocated patellae, and kyphoscoliosis have been noted in some families (King-Denborough syndrome). Duchenne-Becker muscular dystrophy may also be associated. Central core (multicore) myopathy (page 1533) is frequently complicated by malignant hyperthermia. This is understandable insofar as both disorders have been linked to the gene encoding the ryanodine receptor; the two diseases are allelic (Quane et al).

Treatment consists of discontinuation of anesthesia at the first hint of masseter spasm or rise of temperature. The intravenous administration of dantrolene, which inhibits the release of calcium from the sarcoplasmic reticulum, may be lifesaving. An infusion of 1 mg/kg is given initially and increased slowly until symptoms subside, the total dosage not to exceed 10 mg/kg. Other measures should include body cooling, intravenous hydration, sodium bicarbonate infusions to correct acidosis, and mechanical ventilation to decrease respiratory acidosis. Halothane and other volatile anesthetic agents and succinylcholine should thereafter be avoided in such individuals, and any surgical procedures, if necessary, should be done under nitrous oxide, fentanyl, thiopental (or other barbiturate), or local anesthesia. Intravenous dantrolene, 2.5 mg/kg given slowly 1 h prior to anesthesia, prevents the syndrome.

Malignant Neuroleptic Syndrome

This state, in which hyperthermia occurs as an idiosyncratic reaction to neuroleptic drugs, is also accompanied by widespread myonecrosis. It is discussed in Chap. 43.

Muscle Contractions: Pseudotetany, Tetany, and Related States

Localised Muscle Masses

Muscle Cramp

Quite apart from spasticity and rigidity, which are due to a disinhibition of spinal motor mechanisms, there are forms of muscular stiffness and spasm that can be traced to abnormalities of the lower motor neuron and its spinal inhibitory mechanisms or to the sarcoclemma of the muscle fiber and its intrinsic conducting apparatus. Thus, muscles may go into spasm because of an unstable depolarization of the motor axon, which sends volleys of impulses across neuromuscular junctions—as occurs in myokymia, hypocalcemic tetany, and pseudohypoparathyroidism. In other states, discussed in the preceding chapter, the innervation of muscle may be normal but contraction persists despite attempts at relaxation (myotonia). Or, after one or a series of contractions, the muscle may be slow in decontracting, as occurs in paradoxical myotonia and hypothyroidism; in the contracture of McKirdie phosphorylase deficiency and phosphofructokinase deficiency, muscle, once contracted, may lack the energy to relax.

Each of these conditions evokes the complaint of cramp or spasm, which is variably painful and interferes with free and effective voluntary activity. Each condition has its own identifying clinical and electromyographic (EMG) characteristics, and most of them respond favorably to therapy. A primary is therefore tied to the clinical differentiation of these phenomena.

Muscle Cramp

This subject has already been introduced in Chap. 48, where it was pointed out that everyone at some time or other has experienced muscle cramps. Usually they occur during the night, after a day of unusually strenuous activity; less often they occur during the day, either during a period of relaxation or occasionally after a strenuous, postural contraction or postural adjustment. A random restless or stretching movement will induce a hard contraction of a single muscle (most frequently of the foot or leg) that cannot be voluntarily relaxed. The muscle is visible and palpably taut and painful, and the condition is readily distinguished from an illusory cramp, in which the sensation of cramp is experienced with little or no contraction of the muscle. The latter phenomenon may occur in normal persons as well as in those with certain peripheral nerve diseases. Massage and vigorous stretch of the cramped muscle will cause the spasm to yield, though for a time the muscle remains excitable and subject to recurrent cramps. Visible fasciculations may precede and follow the cramp, indicating an excessive excitability of the terminal branches of motor neurons supplying the muscle. Sometimes the cramp is so strong that the muscle appears to have been injured; it remains sore to touch and painful upon use for a day or longer. Cramps of precordial chest muscles or diaphragm may arouse fear of heart or lung disease. In the EMG, the cramp is marked by bursts of high-frequency, high-voltage action potentials and the precram phase by runs of activity in motor units. Why cramps should be painful is not known; probably the demands of the overactive muscle exceed metabolic supply, causing a relative ischemia and accumulation of metabolites. Overwork of muscle with or without impairment of circulation is also painful. Between cramps, the muscles are normally clinical and electromyographically.

Cramps are known to increase in frequency under certain conditions and with certain diseases. They are frequent during pregnancy for reasons not fully understood. Dehydration and sweating predispose to cramping and are a constant threat to athletes, who try to prevent them by ingesting electrolyte solutions. Exertional cramps are frequent in motor system disease and hypothyroidism and less so in chronic polyneuropathies. Patients undergoing hemodialysis are subject to cramps, which can be suppressed by intravenous hypertonic saline or hypertonic glucose. Rapid rehydration after dehydration is another provocative factor. Focal cramping occurs after partial nerve or root injury and with diseases involving anterior horn cells.

The mechanism of muscle cramp is obscure. In a number of exercises-induced stiffness and muscle pain, sometimes progressing to cramp, below-normal levels of myoadenylate deaminase have been found. The significance of this observation is uncertain. This enzyme, which is present in high concentration in muscle, is thought to function primarily during aerobic exercise and facilitate the regeneration of adenosine triphosphate from adenosine diphosphate through the action of adenylate kinase. Others assert that low levels of this enzyme are not specific, occurring in such unrelated disorders as hypokalemic periodic paralysis and skeletal muscle atrophy (see Layzer for details).

Quinine sulfate, 300 mg at bedtime and repeated in 4 h if necessary, or 300 mg tid for diurnal cramping is an effective medication; diphenhydramine hydrochloride (Benadryl) 50 mg or procainamide 0.5 to 1.0 g can be substituted if quinine is not tolerated. Phenytoin, carbamazepine, propanoxyphene, and sometimes clonazepam are even more useful in alleviating repeated daytime cramping.

Tetany, Pseudotetany, and Related Cramp Syndromes

As pointed out on page 1352, a reduction in ionizable calcium and magnesium is associated with involuntary cramplike spasms; in their mildest form they appear as diaphoretic cramp spasms, but they may involve any of the muscles except the extracranial ones. Stimulation of a muscle through its nerve at certain frequencies (15 to 20 times per second) characteristically reproduces the spasms, and hyperventilation and ischemia increase the tendency. Indeed, the Trousseau sign—carpal spams with occlusion of the blood supply to the arm—takes advantage of the latter phenomenon. That hypocalcemic tetany is attributable to an unstable depolarization of the axonal membrane of the nerve fiber is shown by (1) the sensitivity of nerve to percussion (tapping over the facial nerve near its foramen of exit increases a facial twitch, or Chvostek sign), (2) the frequency of fast-frequency doublets and triplets of motor unit potentials in the EMG, (3) evocation of spasm by application of a tourniquet to proximal parts of a limb (causing ischemia of segments of nerve beneath the tourniquet), and (4) the regular association of tingling, prickling paresthesias from excitation of sensory nerve fibers. Hypocalcemia also causes a lesser change in the muscle fibers themselves; hence nerve block does not completely eradicate tetany.

A condition resembling tetany but without measurable hypocalcemia is the aforementioned benign cramp syndrome (pseudotetany). In the most severe forms, all skeletal muscles are intermittently locked in spasm, and almost any strong postural or voluntary movement leads to cramp. When this phenomenon is repeated again and again, the overtly active muscles begin to hypertrophy. In about half of the authors' cases, stimulation of nerve at 15 or more per second produced cramp discharges, as in tetany. Biopsies have disclosed no abnormalities of the muscle fibers except for a few ringbinden (circumferential bands of myofibrils encircling a normal core of longitudinally oriented myofibrils). Calcium and diazepam are of no therapeutic value, but some patients respond to phenytoin, carbamazepine, propoxyphene, and sometimes clonazepam.

Salgotoshi has described a group of such patients who, in addition to the widespread severe cramping of muscle, also showed universal alopecia, amenorrhea, intestinal malabsorption, and sometimes epilepsy and retarded growth; the serum calcium in these patients was normal, and the EMG showed only high-frequency discharges. A familial (autosomal dominant) form of the benign cramp syndrome has been reported by Juslin and coworkers, the cramps affected the distal limb muscles, began in childhood and adolescence, and persisted throughout life. Another such family with cramps beginning somewhat later in life and affecting the anterior neck, arm, and abdominal muscles as well as those of the thigh and calf has been described by Riker and Moxley. Also, as mentioned in Chap. 50, a familial myalgic-cramp syndrome has been associated with deletion of part of the dystrophin gene (but with little or no dystrophic weakness). A tendency to cramp and pain has also been noted in a number of the congenital myopathies and in some families with Duchenne and Becker dystrophies.

States of Persistent Fasciculation, Myokymia, Continuous Muscle Activity, Neuromyotonia, “Stiff-Man” Syndrome, and Schwartz-Jampel Syndrome

This is a confusing group of clinical states, all characterized by some degree of regional continuous muscular activity, that in some cases cannot be fully differentiated from one another.

Benign Fasciculations

As is well known, a few random fasciculations in the muscles of the calf or elsewhere are to be seen in most normal individuals. They are of
subacute myoclonic spinal neuronitis, described on page 1315. In both the stiff-man syndrome and myoclonic spinal neuronitis, the intense spasms and stiffness of muscles are rarely affected. Any noise or other sensory stimulus or attempted passive or voluntary movement precipitates severely painful spasms of all the involved muscles. Rapid eye closure may also occur. We have seen brief periods of cyanosis and respiratory arrest during episodes of intense spasm, and one of our patients died during such an episode. Eye muscles often twitch or show spontaneous rippling contractions; the eye occlusion may improve with sweating. Thus, myokymia, fasciculation, and cramping are closely related but not identical conditions.

Ricker and Burns and their associates have described a rare familial disorder (autosomal dominant) in which muscles display an unusual sensitivity to stretch, manifest by rippling waves of muscle contraction; percussion of muscles yields a pronounced and painful local mounding. The EMG discloses neither myotonic discharges nor the action potentials of cramp, indicating that the basic abnormality is in the muscle membrane.

Continuous Muscle Activity (Isaacs Syndrome) The relation of myokymia to the state called continuous muscle fiber activity is ambiguous. Sporadically, in the neurologic literature, there have been described patients whose muscles at some point begin to "work" continuously (see Isaacs). Terms such as neuromyotonia and widespread myokymia with delayed muscle relaxation are additional names that have been applied to what is essentially the same condition. At the moment, there is little reason to distinguish one from another except in gradations of severity. In each case the excessive and spontaneous activity can be attributed to hyperexcitability of terminal parts of motor nerve fiber, possibly as a result of a partial loss of motor innervation and compensatory collateral sprouting of surviving axons (Cifers et al., Vulli et al.). Twitching, spasms, and rippling of muscles (myokymia) are evident, the latter being the main clinical sign. In advanced cases there is generalized muscular stiffness and a sense of weakness. Complaints of muscle aching are usual, but severe myalgia is uncommon. The tendon reflexes may be reduced or abolished. Any movement of the involved limbs, however, is severely impaired.

Riber and Sautereau and colleagues have described a rare familial disorder (autosomal dominant) in which muscles display an unusual sensitivity to stretch, manifest by rippling waves of muscle contraction; percussion of muscles yields a pronounced and painful local mounding. The EMG discloses neither myotonic discharges nor the action potentials of cramp, indicating that the basic abnormality is in the muscle membrane.

General and spinal anesthesia do not always suppress the muscular activity, but curare does; nerve block usually has no effect or may reduce the activity, as in the case of Labsch and colleagues. The EMG findings are much the same as those described above.

This syndrome arises in childhood or adult life, in association either with a polyneuropathy or with an inherited type of episodic ataxia that is variably responsive to acetazolamide or remits spontaneously. An inherited form of continuous muscle activity has been traced to a gene mutation on chromosome 12 and is attributed to a peripheral nerve K channel abnormality (Gutmann and Gutmann). In addition to the association with polyneuropathy, continuous muscular activity has also been described in the case of lung cancer and thrombosis, with or without myasthenia, in which cases an immune mechanism has been inferred (see reviews by Thompson and by Newcom-Davis and Mills). An association of continuous muscle fiber activity with psychosis or a severe sleep disorder was first described by Morvan under the name chorea fibrillaris (see Serantice and Aslay). Most cases appear to be idiopathic, however.

Treatment with phenytoin or carbamazepine often abolishes the continuous muscular activity and causes a return of reflexes. Many of the idiopathic cases, as already noted, will improve spontaneously after several years, but plasma exchange may be tried if the symptoms are intractable.

“Stiff-Man” Syndrome This is a condition of persistent spasms, particularly of the lower limbs, forcing the patient eventually to lie helplessly in bed with the feet in equinus position and the legs extended. It was originally described by Moersch and Wolman in 1956 as “stiff-man” syndrome. Since then, many examples have been reported all over the world and the term “stiff-person” syndrome has been used to indicate its occurrence in women. The onset is insidious, usually in middle life, and men and women are affected equally. No genetic predisposition is known. At first the stiffness and spasms are intermittent; then, gradually, they become more or less continuously active in the proximal limb and axial trunk muscles and increasingly painful. The spasms impart a robotic appearance to walking and an exaggerated lumbar lordosis. Attempts to move an affected part passively yield an almost rock-like immobility, perceptibly different from spasticity, paraparesis, or extrapyramidal rigidity. Muscles of respiration and swallowing and those of the face may be involved in the more advanced cases, but tremor, a common feature of tetanus, does not occur. We have seen brief periods of cyanosis and respiratory arrest during episodes of intense spasm, and one of our patients died during such an episode. Eye muscles are rarely affected. Any noise or other sensory stimulus or attempted passive or voluntary movement precipitates severely painful spasms of all the involved muscles. The tendon reflexes are normal if they can be tested. A similar stiffness of one limb (“stiff limb” syndrome) has been differentiated from the generalized variety by Barker and colleagues, but it seems to us to be part of the same illness since most of the localized cases have antibodies to glutamic acid decarboxylase, as described below. This limited form of spasm is similar to localized tetanus.

A central origin of the muscle spasms is suggested by their disappearance during sleep, during general anesthesia, and with proximal nerve block. The electrophysiological features differ from those of myokymia and continuous muscle fiber activity syndrome in that the EMG in stiff-man syndrome consists entirely of normal motor units, with no evidence of distal motor nerve disturbance.

Of interest is the finding that more than half of the cases of stiff-man syndrome have circulating autoantibodies that are reactive with glutamic acid decarboxylase (GAD), the synthesizing enzyme for GABA (Barker and colleagues). An autoimmune mechanism is further suggested by the high incidence of insulin-dependent diabetes with detectable antibodies to islet cells; some patients have thyroiditis, pernicious anemia, or immune-mediated vitiligo.

In the stiff-man syndrome, diazepam in doses of 50 to 250 mg/day, increased gradually, is most effective; clonazepam or bacclofen are sometimes effective as well. In ketamine, the relieving effect of the administration of benzodiazepine may be offset by an increase in muscle tone, but the mixture of bacclofen and diazepam can be very effective. Some patients have required infusions of gamma globulin for several years at intervals of 2 to 6 weeks and became disabled if the dose of diazepam was reduced below 200 mg/day.

Clinically, the stiff-man syndrome must be distinguished from tetanus (page 1277 and further on), the Isaacs syndrome (see above), and the rare syndrome of subacute myoclonic spinal neuronitis, described on page 1315. In both the stiff-man syndrome and myoclonic spinal neuronitis, the intense spasms and stiffness of muscles are due to disinhibition of interneurons (possibly via GABAergic Renshaw cells) in the gray matter of the spinal cord. These syndromes of continuous muscle activity are not associated with polyneuropathy, as in myokymia. The cause of the stiff-limb” syndrome is unknown. A rare inherited syndrome of continuous muscle activity associated with skeletal abnormalities, the Schwartz-Jampel syndrome, has been described in families with muscle overgrowth and contractures, with areflexia of the lower extremities, and with a history of congenital deafness; the genetic basis of this condition is unknown. A state of persistent muscle spasm that is not associated with limb stiffness and with a history of congenital deafness; the genetic basis of this condition is unknown. A state of persistent muscle spasm that is not associated with limb stiffness and with a history of congenital deafness; the genetic basis of this condition is unknown. A state of persistent muscle spasm that is not associated with limb stiffness and with a history of congenital deafness; the genetic basis of this condition is unknown. A state of persistent muscle spasm that is not associated with limb stiffness and with a history of congenital deafness; the genetic basis of this condition is unknown.
activity, except perhaps the stiff-man syndrome, are, as a rule, usually distinguishable clinically and electromyographically from extrapyramidal and corticospinal abnormalities such as dystonia, dyskinesia, rigidity, and spasticity.

**Congenital Neonatal Rigidity** A "stiff-infant" syndrome, observed by Dudley and colleagues in four families of mixed heritage, should probably be included in this general category. The condition came to medical attention because of respiratory distress due to a generalized muscular rigidity beginning at about 2 months of age. The rigidity spread slowly from cervical muscles to those of the trunk and limbs, and, as it persisted, slight hypertrophy developed. The use of respiratory aid and a feeding gastrostomy enabled the infants to survive. The rigidity slowly disappeared in the second year of life. The clinical course was unlike that of tetanus. In fatal cases there were zones of fiber loss, with fibrosis in skeletal and cardiac muscles, and a greater than normal variation in fiber size. Altered Z lines were observed electronmicroscopically in some fibers.

**Schwartz-Jampel Syndrome** Blepharospasm, dwarfism, pinched face with low-set ears, blepharophimosis, high-arched palate, receding chin, diffuse myopathy and epiphyseal bone dysplasia with flattened vertebrae, and a generalized muscular disorder of stiffness and continuous muscle fiber activity were crystallized as a syndrome by Schwartz and Jampel in 1962. It has been referred to as myotonic dysostosis. Intelligence is usually preserved. There may be mental retardation. The stiff muscles are seen on radiographs. Muscle stiffness is the result of frequent, almost continuous muscle activity with a combination of normal motor units as well as high-frequency discharges and afterdischarges similar to those seen in Isaacs syndrome. Some of the discharges probably arise from muscle fibers themselves, whereas others are in block channels (analogous to block channels in muscle) that inhibit the discharges, just as they do in some other myotonic disorders. However, a few patients, and the most severe cases, have review the clinical, EMG, and histologic features of 30 cases of this syndrome, report a diminished chloride conductance by the sarcolemma, which can be suppressed by procainamide or even better by mexiletine. The disorder is usually inherited as an autosomal recessive trait. Electronmicroscopic studies of muscle have yielded inconsistent findings: dilated T system, Z-band streaming, and dilatation of mitochondria; in addition, in the patient reported by Fariello and colleagues, muscle biopsy disclosed signs of denervation (group atrophy). In the latter case, treatment with procainamide, phenytoin, diazepam, and barbiturates was ineffective.

The condition described by Aberfield and coworkers, of two siblings in whom myotonia was combined with dwarfism, diffuse bone disease, and unusual ocular and facial abnormalities and thought by them to represent a unique disorder, is probably a variant of the Schwartz-Jampel syndrome.

**Muscle Contracture, Pseudomyotonia, Tetanus, and Related States**

**Physiologic Contracture due to Phosphorylase Deficiency** (McArdle and Phosphofructokinase Deficiency (Tarui)) These are examples of an entirely different type of painful shortening and hardness of muscle. In both these diseases, an otherwise normal child, adolescent, or adult begins to complain of weakness and stiffness of the extremities, then those of the trunk, and finally those of the head, when the patient is in deep sleep. The stiffness is improved when the patient awakens, but it returns in the morning and under conditions of ischemia, causes the muscles to shorten gradually, due to failure of relaxation. The contracted muscles in these disorders—unlike muscles in cramp, continuous muscular activity syndromes, or myotonia and other involuntarv spasms—no longer use energy. During contraction, the muscles are more or less electrically silent in the EMG. This condition is spoken of as pharmacologic or physiologic contracture. McArdle and Tarui disease are discussed more fully beginning on page 1515.

**Pseudomyotonia** This phenomenon is observed in hypothyroidism, where the muscle fibers contract and relax slowly. This response is readily demonstrated in eliciting tendon reflexes, particularly the Achilles reflex. The muscles are large and subject to myotonia; when used, they may show waves of slow contraction. The basis of this disorder appears to be a slowing in the recumulation of calcium ions in the endoplasmic reticulum and in the disengagement of thin actin and thick myosin filaments. The EMG may show afterpotentials following voluntary contraction, but they do not resemble the typical waning discharges ("myotonic runs") of true myotonia.

A closely related syndrome, wherein painless contracture is induced by exercise, has been described by Lamb and Goldstein, and by Brody. Whereas muscle contraction is normal, the relaxation phase becomes increasingly slow during exercise. Lambert and coworkers referred to it as an unusual type of myotonia, and Brody, as a decrease of relaxing factor. The slow relaxation of muscles has also been attributed to a decreased uptake of calcium by the sarcoplasmic reticulum.

**Tetanus** This disorder is characterized by persistent spasms of skeletal muscles, owing to the effect of the tetanus toxin on spinal nerves (Renshaw and other cells), the natural function of which is to inhibit the motor neurons. As the condition develops, activities that normally excite the neurons (i.e., voluntary contraction and startle from visual and auditory stimulation) all evoke involuntary spasms. Sleep tends to quiet them, and they are suppressed by spinal anesthesia and curare. The EMG shows the expected interference pattern of action potentials. Once the muscle is involved in persistent contraction, it is said that the shortened state is not abolished by procaine block or severance of nerve (in animals), but this so-called myostatic contracture has not been demonstrated in humans.

The effect on the inhibitory neurons is analogous to that of strychnine (see page 1271 for a full description of tetanus and its treatment). There is also an action of the tetanus toxin at the neuromuscular junction, which has been more difficult to evaluate in the face of its powerful central action. Having injected this toxin locally in animals, Price and associates have demonstrated its localization at motor end plates. It binds with ganglioside in the axon membrane and is transported by retrograde flow to the spinal cord, where it induces local tetanus effects. Neurons that innervate slow-twitch type 1 muscle fibers are more sensitive than those supplying fast-twitch type 2 fibers. Presynaptic vesicles increase, acetylcholine (ACh) is blocked, and terminal axon injury may paralyze muscle fibers. Fibrillation potentials and axonal sprouting follow. The similarities to stiff-man syndrome have already been mentioned.

**Black Widow Spider Bite** The toxin produced by this spider, within a few minutes of the bite, leads to cramps and spasms and then a painful rigidity of abdominal, trunk, and leg muscles. The spasms are followed by weakness. There is also vasoostriction, hypertension, and autonomic hyperactivity. If death does not occur in the first 24 to 48 h, recovery is complete.

The spider venom has a presynaptic localization and rapidly releases quanta of ACh. The vesicles are depleted. There is some evidence that the venom prevents endocytosis of the vesicles by inserting itself into the presynaptic membranes, causing a disturbance of ionic conductance channels (Swift).

Treatment, which is more or less empiric, consists of calcium gluconate infusions. Intravenous magnesium sulfate also helps to reduce the release of ACh and control the convulsions that sometimes occur. There is a reconstituted antiserum that is available in regions where such envenomation is frequent.

**Malignant Hyperthermia** This condition is also characterized by an acute onset of generalized muscular rigidity accompanied by a rapid rise in body temperature, metabolic acidosis, and myoglobinuria. It is invariably induced by anesthetic agents and other drugs and is fully discussed on page 1563.

**Myalgic States**

Many of the muscle diseases described in the preceding sections are associated with aching and discomfort. These are particularly prominent in conditions that are accompanied by cramp and biochemical contracture (cortisone-induced phosphophorylate and phosphofructokinase deficiency). Ischemia of muscle—that is, intermittent claudication—is also painful, as is dystonia in some cases. Muscle weakness that imposes persistent abnormal postures on the limbs may cause stretch injury of muscles and tendons. This is observed in a number of the congenital myopathies and dystrophies. In all these conditions, clinical study will usually disclose the source or sources of the pain.

Diffuse muscle pain, which merges with malaise, is a frequent expression of a large variety of systemic infections—e.g., influenza, braceolosis, dengue, Colorado tick fever, glanders, measles, malaria, relapsing fever, rheumatic fever ("growing pains"), salmonellosis, toxoplasmosis, trichinosis, tularemia, and Weil disease. When the pain is intense, especially if it is localized to one side of the lower chest and abdomen, the most likely diagnostic possibility is epidemic myalgia (also designated as pleurodynia, "devil's grip," and Bornholm disease, due to coxsackievirus infection, page 787). Poliomyelitis may be induced by intense pain at the onset of neurologic involvement, and later the paralyzed muscles may ache. This is true also of the Guillain-Barré syndrome, in which the pain may precede weakness by several days. Little is known about the pathologic basis of the muscular pain in these diseases; it is not due to muscle inflammation. Muscle pain is a frequent but not a necessary accompaniment of polyarthritis and dermatomyositis.

**Polymyalgia Rheumatica** The major consideration in elderly and middle-aged patients with pain in proximal muscles of the limbs is polymyalgia rheumatica. This subject is mentioned briefly in other sections of this book in relation to back and extremity pain (page 230) and to temporal arteritis, to which it is closely connected (page 193). The muscular soreness may be diffuse or asymmetrical, particularly in the proximal arms and shoulders. Every movement is reported as stiff and painful.
The particular tissues and their muscular attachments are affected primarily and may be tender, but this is difficult to interpret, since it may be found in otherwise normal individuals. The sedimentation rate is greatly elevated in the majority of patients, and a 48-h trial of prednisone, by alleviating muscle pain, confirms the diagnosis. In the context of muscle pain, systemic symptoms such as weight loss, headache, and fatigue are particularly suggestive of polymyalgia rheumatica.

**Fibromyalgia** This would appear, by definition, to represent an inflammation of the fibrous tissues of the muscles, fascia, aponeuroses, and possibly nerves as well. Unfortunately, the pathologic basis of this state remains obscure. Only some clinical facts are at hand. During the first movements after a period of inactivity, a muscle or group of muscles may become painful and tender, particularly after exposure to cold, dampness, or minor trauma, but only for no reason that can be discerned. One looks in vain for signs of tendinous or arthritic disease. The neck and shoulders are the most common sites. Sometimes firm, tender areas, up to several centimeters in diameter, can be palpated within the muscles ("fibrotic nodules"), and active contraction or passive stretching of the involved muscles increases the pain—points said to be of diagnostic value, but still disputed. Symptoms such as mental and physical fatigue, insomnia, giddiness, and headache are frequently associated and raise the suspicion of an anxiety state or depression. Often the condition clears up in a few weeks; local heat and massage and local injections of anesthetics or steroids are found to give comfort while symptoms are present.

The chronic form of fibromyalgia presents far greater problems, usually disabling the patient and causing a change in accustomed habits and employment. It has become one of the prime diagnoses made by rheumatologists and physiatrists, but the patient may first come to the attention of a neurologist. Muscle pain is the primary symptom, with fatigue and the other aforementioned complaints added as an afterthought by the patient, or the muscular symptoms are elicited in exploring a case of chronic fatigue syndrome (pages 231 and 528). There is a great preponderance of women among these patients, and in the majority the illness is not predated by any particular factor, although a few have a viral prodrome or recently preceding trauma.

Most definitions of the syndrome have been circular or somewhat arbitrary. Those thus now in general use are so similar to one proposed by a committee of the American College of Rheumatology. The basis for diagnosis is the presence of widespread pain including focal areas of pain (trigger points) that can be produced by 4 kg of digital pressure in 11 of 18 typical locations over muscles, tendons, or bone—these are concentrated around the shoulders and paraspinal regions—and there is no requirement for the presence of the several common systemic complaints that accompany the illness in most patients (fatigue, difficulty concentrating, sleeping difficulty, or anxiety). Often there is said to be a knot or fibrous band at the site of tenderness, but this is difficult to objectify.

There is controversy regarding the nature of these pressure points and the validity of methods used to elicit them, since mechanical dolorimetry often suggests that these patients have a reduced tolerance to pain at all sites. But there is also uncertainty regarding the relationship of the symptoms to underlying depression. In the past, similar pains were associated with cases of irritable bowel or irritable bladder syndromes, dysmenorrhea, chronic headache, and cold intolerance. Depending upon how broad a definition one allows for the widespread pain and painful trigger points, most or all patients in our experience manifest many of the same complaints as patients with the syndrome. Much of the discussion of the subject, however, has centered around patients who are claimed in the literature to have a "fibromyalgia" syndrome, formal assessment by modern criteria fails to confirm the presence of depression and that, when depression does coexist with the muscular complaints, the two are discordant temporally and in severity. While we acknowledge that antidepressants often give disappointing results and that in our practice there have been several young women with fibromyalgia who appeared to be well adjusted and lacked depression, these are the exceptions. The literature eschews the use of corticosteroids for treatment of the pain, but we have had occasion to see two patients whose symptoms were relieved when these medications were used for other purposes. It can be said in conclusion that fibromyalgia remains a problematic illness, defined by a pattern of pain that justifies its name. Despite attempts to objectify the physical symptoms, psychiatric factors should not be overlooked. This condition is a "favorite" illness with physiotherapists, who claim that their physical measurements are helpful, as they may be. Rarely, a similar syndrome is the forerunner of what proves, after some days, with the onset of neurologic signs, to be a radiculitis, brachial neuritis, or outbreak of herpes zoster (see [Goldenberg]).

**Other Myalgic States** An impressive polymyalgia is one that follows excessive exercise. Often the patient observes that aching pain occurs not at the time of activity but some hours or even a day or two later, resembling the discomfort following the excessive use of unconditioned muscles. The muscles are sore and there is an intolerance of exercise and physical exertion. This is a natural phenomenon and is self-limiting. When such a state persists indefinitely and a program of conditioning exercises does not alleviate the pain, it represents a special category of disease. In a few instances an increased sedimentation rate or other laboratory aids may clarify the diagnosis, and muscle biopsy may reveal a nonspecific interstitial nodular myositis or the giant-cell arteritis associated with polymyalgia rheumatica.

However, this cluster of symptoms often occurs without explanation, and one can only suspect an obscure infection or a subtle aberration of muscle metabolism, presently impossible to demonstrate. Reference was made earlier to the finding of a myoadenylate deaminase deficiency in some of these cases. Sometimes a rapid rise of CK after strenuous exercise will provide a clue. There is also a group of patients who have idiopathic leg pain during rest after activity. Some families afflicted in this way are forced to live a sedentary existence. The condition does not respond to analgesics. In two cases, a deficiency of Ca-ATPase was found and reportedly alleviated by a calcium channel blocker such as verapamil, 120 mg tid ([Walton; Taylor et al.]). It must be distinguished from Fabry disease (page 1422), from the syndromes of painful legs and moving toes, and from the restless leg syndrome of Ekbom (page 412).

The problem of a muscular pain-fasciitis syndrome was discussed earlier. In thin, asthenic adults who exhibit rather vague polymyalgia without other abnormalities, with or without cramps and fasciculations, the authors have found it difficult to exclude hysteria or other neurosis and depression. Before concluding that the condition has a psychiatric basis, it is important in every such individual to search for evidence of a rheumatic disease, brucellosis, or the myopathy that may accompany hyperparathyroidism, hypothyroidism, hypocalcemia, hypoglycemia, and the intrinsic phosphofructokinase defect. Patients with these latter diseases often complain of soreness, stiffness, and lameness after strenuous muscular effort. According to Mills and Edwards, the most valuable screening tests are the sedimentation rate and serum CK concentration. Other patients probably have an obscure metabolic myopathy, presently undiagnosable. In every reported series, such as that of Serratrice and coworkers, about half of the cases with diffuse myalgia are presently impossible to demonstrate. Reference was made earlier to the finding of a myoadenylate deaminase deficiency in some of these cases. Sometimes a rapid rise of CK after strenuous exercise will provide a clue. There is also a group of patients who have idiopathic leg pain during rest after activity. Some families afflicted in this way are forced to live a sedentary existence. The condition does not respond to analgesics. In two cases, a deficiency of Ca-ATPase was found and reportedly alleviated by a calcium channel blocker such as verapamil, 120 mg tid ([Walton; Taylor et al.]). It must be distinguished from Fabry disease (page 1422), from the syndromes of painful legs and moving toes, and from the restless leg syndrome of Ekbom (page 412).

**Localized Muscle Masses**

Masses may be found in one or many muscles in a variety of clinical settings, and the clinical findings in each one have a different significance.

*Muscle rupture* is usually caused by a violent strain attended by an audible snap and then a bulge, which appears when the muscle contracts. A weakening in contractile power and mild discomfort are usually noted by the patient. The biceps and soleus muscles are most often affected. Treatment is immediate surgical repair; in a few instances an increased sedimentation rate or other laboratory aids may clarify the diagnosis, and muscle biopsy may reveal a nonspecific interstitial nodular myositis or the giant-cell arteritis associated with polymyalgia rheumatica.

*Fibromyalgia* (a benign massive growth of fibrous tissue observed most often in parturient women and after surgery), *rhabdomyosarcoma* (a highly malignant tumor with strong liability to local recurrence and metastasis), *liposarcoma*, and *anglioma*. Large neurofibromas or neurofibrosarcomas beneath large muscles such as the hamstring may be difficult to distinguish by physical examination or magnetic resonance imaging (MRI) from masses within the muscle.

*Pseudotumorous masses*, sometimes massive, may follow injury of muscle. Interlacing regenerating muscle fibers and fibroblasts compose the mass. Excision of the entire muscle had been undertaken in several cases in the belief that the growth was a rhabdomyosarcoma, whereas it is actually a benign response to trauma ([Goldenberg and Aklunger]).

**Thrombosis of arteries or**, more often, of *veins* causes inflammation and infarction of muscle. A special type of *muscle infarction* occurs in patients with complicated and poorly controlled diabetes mellitus ([Banker and Chester]). Usually the infarction involves the anterior thigh, occasionally other muscles of the lower limb. The major symptoms are pain at onset of pain and sudden swelling of the thigh, with or without the formation of a tender, palpable mass. Recurrent infarction of the same or opposite thigh is characteristic. The stereotypical clinical picture obviates the need for diagnostic muscle biopsy. The extensive infarction of muscle is due to the occlusion of many medium-sized muscular arteries and arterioles, most likely the result of embolization of atheromatous material from eroded plaques in the aorta or iliac arteries. Recognition of this complication and immobilization of the limb are of prime practical importance, since muscle biopsy and early ambulation may cause serious hemorrhage into the infarcted tissue.

The prebital syndrome, also well recognized, follows direct trauma or excessive activity (marching, exercising, unconditioned muscles). There is swelling of the entire muscle, with or without digitus digitorum fasciculi. Being highly enclosed by the bones and a periliberal fascia, the swelling leads to ischemic necrosis and myoglobinuria. Permanent weakness of this group of muscles can be prevented by incising the prebital fascia.
**Myositis Ossificans** This condition involves the deposition of bone within the substance of a muscle. Two types are recognized. One is a localized form that appears in a single muscle or group of muscles after trauma, and the other is a progressive, widespread ossifying process, entirely unrelated to trauma, in many muscles of the body.

**Localized (Traumatic) Myositis Ossificans** After a muscle tear, a single blow to the muscle, or repeated minor trauma, a painful area develops in the muscle. It is gradually replaced by a mass of cartilaginous consistency, and within 4 to 7 weeks' time a solid mass of bone can be felt and seen in radiographs. As would be expected, this most frequently happens in vigorous adult men; the inner thigh muscles (in those who ride horses) and to a lesser extent the pectoralis major and biceps brachii are the most common sites of the abnormality. The mass tends to subside after several months if the patient desists from the activity that produced the trauma.

**Generalized Myositis Ossificans** This disease, first described by Munchmeyer in 1869, has since been referred to by his name or as myositis ossificans progressiva. It is rare, although Luwak, in 1964, was able to collect 264 cases from the literature. The cause is unknown, but the disease is probably inherited as an autosomal dominant trait. It consists of widespread bone formation along the fascial planes of muscles and has its onset in infancy and childhood in 90 percent of cases. Biopsies of early indurated swellings have revealed extensive proliferation of interstitial connective tissue in which little inflammatory cell reaction is found. Within a few weeks, the connective tissue becomes less cellular and retracts, compressing the adjacent muscle fibers. Osteoid and cartilage formation occur at a later stage, developing in the connective tissue and enclosing relatively intact muscle fibers.

Nearly 75 percent of all reported cases have been associated with congenital anomalies, the most frequent of which is a failure of development of the great toes or thumbs and less often other digits. Less frequently, there is hypoglycemia, deafness, and an absence of upper incisors. The first symptom is often a firm swelling and tenderness in a paravertebral or cervical muscle. There is, in addition, a mild discomfort during muscle contraction, and the overlying skin may be reddened and slightly swollen. Trauma may be recalled as the initiating factor, but as the months pass, other muscles not injured in any recognizable way become similarly involved. At first, radiographs reveal no important changes, but within 6 to 12 months, calcium deposits are observed, and one can feel story-hard masses within the muscles. As the disease advances, limitation of movement and deformities become increasingly evident. Calcified bridges between adjacent muscles and across joints lead to rigidity of the spine, jaw, and limbs, scoliosis, and limited expansion of the thorax. Ultimately, the patient is virtually “changed to stone.”

The principal problem in diagnosis is to differentiate generalized myositis ossificans from calcinosis universalis. The latter usually occurs in relation to scleroderma or polymyositis and is characterized by calcium deposits in the skin, subcutaneous tissues, and connective tissue sheaths around the muscles; in myositis ossificans, there is actual bone formation within the muscles. The pathologic data are often too meager to justify this sharp distinction. The prolonged ingestion of large doses of vitamin D may also result in the deposition of masses of calcium salts around muscles, joints, and subcutaneous tissue. Calcific deposits, perhaps true ossification, may occur in the soft tissues around the hips and knees of paraplegics and rarely following a hemiplegia (“paralytic myositis ossificans”).

The disease may undergo spontaneous remissions and may stabilize for many years, during which the patient is capable of adequate function. In other cases, progression leads to marked debilitation and respiratory embarrassment, the final illness often being a terminal pneumonia or other infection.

The administration of a diphosphonate [ethane-1-hydroxy-1,1-diphosphate (EHDP), 10 to 20 mg/kg orally], a compound that inhibits the deposition of calcium phosphate, has been said to cause regression of new swellings and to prevent calcification (Russell et al). Some of the calcium deposits in calcinosis universalis have receded in response to prednisone, and because of the unclear relationship of this disease to generalized myositis ossificans, it is probably advisable to try this form of therapy as well. Excision of bony deposits may be undertaken if it is certain that they are the cause of particular disabilities.

**CHAPTER REFERENCES**

From time immemorial, in every society, it has been realized that there are many mentally troubled individuals who are neither insane nor feebleminded. They differ from normal persons in being plagued by feelings of inferiority and self-doubt, suspicion about the motives of others, low energy, inexplicable fatigue, shyness, irritability, moodiness, sense of guilt, and unreasonable worries and fears; or they behave in ways that are upsetting to those around them and to society at large. Yet none of these conditions precludes their partaking in many of the everyday affairs of life, such as attending school, working, marrying, and rearing a family. As these conditions were more carefully documented, the ones that caused an individual much personal distress came to be called psychoneuroses and, later, neuroses, and those that created societal difficulties were called psychopathies and, more recently, sociopathies.

The question of the purity and homogeneity of these mental states has excited a lively polemic in the psychiatric literature. The neuroses as a group appeared to be so diverse as to require subdivision (in the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders, or DSM-IV) into no less than seven different types, as elaborated further on. And the psychopathies, in older classifications, came to include conditions as disparate as extreme asociality, criminality, sexual perversions, and drug and alcohol addictions.

Originally, Freud referred to the neuroses as psychoneuroses, and the subject became enmeshed in psychoanalytic theory. The assumption was that an uncurrent of anxiety arising in unconscious conflict was the explanation of all the different types of neurosis as well as the psychopathies. Later, psychiatrists uncommitted to psychoanalytic theory attributed them to social forces leading to maladaptive behavior in childhood. These notions were not acceptable to biologically oriented psychiatrists, with the result that the term psychoneurosis was expunged from later editions of the DSM and even the term neurosis was replaced by terms such as anxiety disorders, phobic states, and obsessive-compulsive disorder. These terms are presently being applied to any mental disorder with the following characteristics: (1) symptoms that are distressing to the affected individual and regarded by him as unacceptable or alien; (2) reality testing (the patient's evaluation of the relationship between himself and the outside world) that remains intact, (3) symptomatic behavior that does not seriously violate social norms, although personal functioning may be considerably impaired; (4) a disturbance that is enduring—not a transitory reaction to stress; and (5) absence of a discernible organic cause.

The foregoing definition of the anxiety and allied disorders, or neuroses, has the virtue of being descriptive without committing one to any hypothesis of causation. It retains the historical connotation of neurosis and provides a terminologic link between psychiatrists throughout the world.

The genesis of the neuroses, a matter that has occupied psychiatrists for many years, remains elusive. It is generally conceded that such disorders do not arise de novo in otherwise normal individuals. Their antecedents are thought to be abnormalities in personality development, possibly molded by stressful events in the life of the individual and influenced by genetic factors. Yet there are undoubtedly traits of this nature that arise in several individuals from the same family. Thus an informative discussion of such disorders requires a brief digression into the origins of normal personality development and departures therefrom.

Personality Disorders

The concept of personality and its development were introduced in Chap. 28. There it was pointed out that the term embraces the totality of a person's physical and mental attributes, his observable behavior and reportable subjective experience—the sum of which distinguishes one individual from all others. Thus it includes elements of the individual's character, intelligence, instinctual drives, temperament, sentiments, behavior, motor control, and memories—in short, all forces from within the organism, as well as the reactions to prevailing influences of the environment that govern behavior. The term character is almost synonymous with personality but is less useful because of its moralistic connotation.

The roots of personality are multiple. Certain personality traits—such as boldness and timidity, novelty seeking and excitability, level of energy and activity, fearlessness and fearfulness, social adaptability and rigidity or stubbornness, etc.—are already evident in the first months of life. Monozygotic twins are alike (but not absolutely identical) in these respects, even when reared apart. Gesell and his colleagues, in their studies of infants (see Chap. 28), observed individual differences that are clearly innate; each of these characteristics is genetically determined, like intelligence. Probably a multiplicity of genes set the general pattern of each person's innate characteristics. In addition, these patterns are subject to incessant modification through familial, educational, social, and other environmental influences. The personalities that result are as individualistic as fingerprints. One example of a genetic predisposition to a human personality trait has been found in the expression of thrill seeking, exploration, and excitability. According to Cloninger et al. (1996), the pleomorphism of the dopamine receptor gene on chromosome 11 accounts in small measure for the genetic variability of this personality type; a long allele at this locus expresses higher degrees of risk taking and short alleles are associated with personalities that are more rigid, deliberate, and orderly. Findings such as these suggest that similar polymorphisms contribute to other traits such as anxiety, obsessiveness, etc., but only in part. The notion, expressed by authors such as Kandel, that genetics will explain a large part of mental function and mental illness sounds reasonable enough, but the data that are necessary to establish this prediction are far from complete.

Pertinent to the subject matter of this chapter is the assumption that in approximately 15 percent of the general population, certain personality traits are so pronounced as to be distressing to the individual and disturbing to others, even though the patient is not manifestly sociopathic or psychotic. Some of these traits first become sources of difficulty during childhood, in relation to eating, behavior during play, school attendance, etc. They may be aggravated by parental abuse, adoption, divorce, and other persistently distressing circumstances. Perhaps, during maturation, the development of certain portions of the personality has lagged or become dissociated from the personality synthesis, or these aspects are repressed to the point of having a diminished or distorted influence on behavior. How this happens and why the deviations take such a variety of forms is not known. Psychodynamic explanations abound, but—being based only on anecdotal evidence—are difficult or impossible to validate. They tend to emphasize psychologic conflict and to de-emphasize genetic and biologic factors. The extent to which these deviations reflect past experience or a genetically predetermined pattern is unsettled.
Another unsolved problem is whether each of the personality types listed in Table 56-1 (taken from the list of personality disorders accepted by the American Psychiatric Association) is predictive or determinative of a particular type of neurosis or psychosis. In this regard, two broad groups of personality disorders can be recognized. In one group—comprising the paranoid, schizoid, cyclothymic, and obsessive-compulsive personality types—there is a probable relationship to a major type of psychiatric illness. Thus, among patients who develop paranoid schizophrenia, a considerable number will have had the attributes described under “paranoid personality type.” Similarly, among patients who develop schizophrenia of another type, the history will frequently disclose a pre-existing schizoid personality. In fact, it may be difficult to judge where the personality disorder left off and the schizophrenic illness began. It seems clear from several family studies that the cyclothymic personality is related to manic-depressive disease. Obsessive-compulsive personality is related not only to obsessive-compulsive neurosis, as one might expect, but also to depressive disease. A relationship exists between sociopathy and the development of alcoholism and of criminality.

Table 56-1 Personality disorders

In other personality disorders, such relationships are far less evident. Care must be taken to distinguish between “hysterical personality” (called “histrionic personality”) and the disease hysteria, or “somatiform disorder.” Some patients with the disease hysteria have a histrionic personality, but this is far from a tight relationship. Similarly, the features of hysterical personality can be observed in individuals who never exhibit “conversion” symptoms (see further on)—and the latter may occur in patients who do not have a hysterical personality. Also, the evidence that asthenic, inadequate, and passive-aggressive or passive-dependent personalities are associated with a major psychiatric illness is rather weak. In this sense, these are “ecentric” personality traits, which in themselves may be lifelong sources of personal distress and difficulties in functioning but which do not, as a rule, lead to the development of any specific psychiatric illness.

It need hardly be stressed that many of the terms listed in Table 56-1 and specifying the several well-recognized personality types are used indiscriminately by lay persons as well as by physicians to judge the personalities and character of others. The defining features of the personality disorders, as listed in the table, fail short of meeting the diagnostic criteria for the neuroses. Yet, an understanding of these personal peculiarities and their less obtrusive traits may be of great help to the physician. This knowledge makes it possible to appreciate their role as sources of perennial complaint, self-concern, and family discord and to explain a patient’s reactions, which may have interfered with diagnostic and therapeutic procedures during a medical illness.

Personality disorders are pervasive, enduring, and little influenced by the physician, although often the contacts between physician and patient over many years and repeated reassurance and explanations of how best to cope with difficulties may in themselves serve as a stabilizing force; and, of course, one should never underestimate the power of maturation to ameliorate the turmoil of adolescence and to settle the mind. The use of medications to influence some aspect of personality should be avoided unless there is evidence that the peculiarity of personality has elaborated into a full-blown neurosis.

In the following pages, prototypes of the clinically recognized neuroses and sociopathies are described, along with current hypotheses of their pathogenesis.

THE NEUROSES

Though considered to be the most frequent of mental illnesses, the neuroses are among the least understood. They were established as clinical entities in the late nineteenth century, but there are still major unresolved issues with respect to their nature, classification, and etiology. Descriptively the neurotic disorders include the following syndromes: (1) anxiety neurosis; (2) phobic neurosis, which includes phobias of illness, social phobia, agoraphobia, etc.; (3) obsessive-compulsive neurosis; (4) hysteria; and (5) hypochondriasis. Former classifications included additional types called neurasthenia (dysthymia or depressive neurosis), which is better considered with the depressive illnesses, and “depersonalization neurosis” (dissociative disorders), which is probably a form of hysterical neurosis. Although each of these syndromes is clinically identifiable and separable when occurring in pure form, experience shows that most patients experience symptoms of more than one type and therefore are said to have “mixed neuroses.” In the most recent classification, i.e., in DSM-IV, all of the neuroses have been replaced by three broad categories of disorders: (1) the anxiety disorders (which include panic states, with and without agoraphobia, and the phobic and obsessive-compulsive neuroses); (2) the somatiform disorders (comprising hysterical neurosis, or conversion disorder, and hypochondriasis); and (3) the dissociative disorders.

It is evident from these and several other attempts at classification that a single definition—one that would satisfactorily explain the attributes of all the neuroses—is still to come. Syndromes as different as hypochondriasis and panic reaction do not lend themselves to a unitary explanation. If there is a central feature of the neuroses, it is thought to be anxiety, which runs as a kind of leitmotif through all of them. Each of these conditions is characterized by a high degree of anxiety, which may be apparent at the time of the manifestations or may be inferred from the history. Though considerable, the evidence that anxiety can have a direct causal relationship to neurosis is not conclusive. The assembly of these conditions and the fact that each has been recognized separately and with considerable authority since the early part of the last century, though considered to be the most frequent of mental illnesses, the neuroses are among the least understood. They were established as clinical entities in the late nineteenth century, but there are still major unresolved issues with respect to their nature, classification, and etiology. Descriptively the neurotic disorders include the following syndromes: (1) anxiety neurosis; (2) phobic neurosis, which includes phobias of illness, social phobia, agoraphobia, etc.; (3) obsessive-compulsive neurosis; (4) hysteria; and (5) hypochondriasis. Former classifications included additional types called neurasthenia (dysthymia or depressive neurosis), which is better considered with the depressive illnesses, and “depersonalization neurosis” (dissociative disorders), which is probably a form of hysterical neurosis. Although each of these syndromes is clinically identifiable and separable when occurring in pure form, experience shows that most patients experience symptoms of more than one type and therefore are said to have “mixed neuroses.” In the most recent classification, i.e., in DSM-IV, all of the neuroses have been replaced by three broad categories of disorders: (1) the anxiety disorders (which include panic states, with and without agoraphobia, and the phobic and obsessive-compulsive neuroses); (2) the somatiform disorders (comprising hysterical neurosis, or conversion disorder, and hypochondriasis); and (3) the dissociative disorders.

Incidence

In an epidemiologic survey sponsored by the National Institute of Mental Health, it was estimated that approximately one-third of the population of the United States, at some point during their lives, have some type of mental disorder. In this survey, mental disorders related to chronic alcoholism were the most common, followed by anxiety, mood, obsessive-compulsive, phobic, conversion, and so-called posttraumatic stress disorders. A different view of the relative frequency of mental disorders is provided by an analysis of 1045 consecutive psychiatric consultations at the New England Center Hospital (now New England Medical Center) during the years 1955 and 1956. In this institution, a tertiary referral hospital, the dominant psychiatric syndrome in about 20 percent of patients was an anxiety state. In addition, symptoms of anxiety were present in some cases of depression, hysteria, and schizophrenia. In contrast, frank hysteria was diagnosed in only 6 percent of cases, and all the other neuroses—together with schizophrenia, alcoholic psychoses, sociopathic states, and the dementias—made up only 10 percent. As indicated on page 1608, depression in one form or another was the most common psychiatric illness (50 percent); psychiatric disease either was absent or could not be diagnosed in the remaining 14 percent of this series.

Other epidemiologic studies have also disclosed a strikingly high incidence of anxiety disorders in the general population (see review of Winokur and Coryell). Lifetime prevalence figures for anxiety disorder indicate that at least 11 percent of the population is so affected—i.e., some 25 million persons in the United States. Such information as is available suggests that the incidence of the neuroses is much the same in an urban population (midtown New York) and a rural one (Stirling County, Nova Scotia), indicating that socioeconomic, racial, and cultural factors are of relatively little importance. Further, in times of calamity, such as the bombing of London, the incidence of neurotic symptoms was said to have increased. Thus one tends to dismiss as an oversimplification the notion that neuroses are merely by-products of life in civilized society or reactions to environmental stress (see also Chap. 54).

Except for hysteria, which, with the qualifications to be indicated, is mainly a disease of women, neuroses of all types occur in both sexes. The onset is in late childhood, adolescence, and early adult life. Admittedly, neurotic symptoms may be recognized for the first time after this age, but a good clinical rule is to suspect any mental illness that appears for the first time after the age of 40 years to be either a depression or a dementia due to degenerative or other organic disease of the brain.
The term anxiety neurosis was introduced by Freud in the later part of the nineteenth century to describe a syndrome consisting of general irritability, anxious expectation, anxiety attacks, somatic equivalents of anxiety, and nightmares. In anxiety neurosis, this symptom complex constitutes the entire illness. However, as indicated earlier, this syndrome may also be a part of several other psychiatric diseases—manic-depressive psychosis, schizophrenia, hysteria, and phobic neurosis. It is useful to think of anxiety neurosis, which it is, as a primary disorder; namely, there is a strong hereditary factor in both, as pointed out by Maudsley and his colleagues in 1940. The term used in DSM-IV is anxiety disorder, of which phobias, obsessive-compulsive disorder, panic attacks, and so-called posttraumatic stress disorder are the important subdivisions. We still prefer the term anxiety neurosis.

Clinical Presentation

Anxiety neurosis is a chronic disease, punctuated by recurrent attacks of acute anxiety or panic. The acute attacks are the hallmark of the disease, and many psychiatrists are reluctant to make a diagnosis of anxiety neurosis in their absence. Because of the clinical peculiarities of panic attacks and particularly their episodic nature, they are of special interest to neurologists and general physicians. Fully developed, panic attacks are almost as dramatic as convulsive seizures. They begin with distressing feelings of dread and foreboding. The patient is assailed by a sense of strangeness, as though his body had changed or the surroundings were unreal (depersonalization; derealization). He is frightened, most often by the prospect of imminent death (angor animi) or of losing his mind or self-control. There may be a feeling of smothering, “I am dying.” “This is the end.” “Oh, my God, I’m going,” or “I can’t breathe” are the characteristic expressions of alarm and panic. The heart races, breathing comes in rapid gasps, pupils are dilated, and the patient sweats and trembles. The palpitation and breathing difficulties are so prominent that a cardiologist is often called. The symptoms abate spontaneously after 15 to 30 min, leaving the patient shaken, tense, perplexed, and often embarrassed. There is no element of confusion, and after the episode, there is full memory of the event.

Most anxiety attacks are of lesser severity than the one described above. The patient complains of faintness, palpitations, or a feeling of postural instability, referred to as dizziness. Breathlessness, vague chest or upper abdominal discomfort, a feeling as if the heart were beating too hard, and asthenia are other common symptoms. The feelings may be of sufficient intensity to cause the patient to fall to his knees or to seek to lie down, although the symptoms do not subside with assumption of a supine position. Certain attacks may vaguely simulate epilepsy insomuch as the patient is so apprehensive that he cannot think clearly. In all such cases there is a constant uneasiness that the spells may occur in public; hence the patient may be fearful of leaving his home, lest help not be available should an attack occur (agoraphobia).

Except in minor details, all the attacks are alike in any one individual. Between attacks, some patients feel relatively well, but many complain of the symptoms of anxiety in lesser but persistent fashion. Cohen and White listed the following symptoms in order of frequency: palpitation, 97 percent; easy fatigue, 93 percent; breathlessness, 90 percent; nervousness, 88 percent; chest pain, 85 percent; sighing, 79 percent; dizziness, 78 percent; apprehension, 61 percent; headache, 58 percent; parasthesias, 58 percent; weakness, 56 percent; insomnia, 53 percent; unhappiness, 50 percent.

Hyperventilation is a special though not invariable feature of the anxiety attack. Hyperventilation itself, by reducing the PaCO2, will cause giddiness, parasthesias of the fingers, tongue, and lips, and at times frank tachy. Patients may become frightened and cry during a period of forced overbreathing. Contrary to the popular belief, in only a minority of patients does a 3-min period of commanded deep breathing reproduce the symptoms of an anxiety attack.

Anxiety attacks may occur at infrequent intervals or several times a day. They may occur in situations where there are no easily recognizable sources of fear, as when the patient is sitting quietly at home or is asleep. In other instances, a trying or upsetting experience induces an attack, which is nonetheless excessive for the condition that provoked it. In some patients, attacks are provoked by confinement to a closed space (claustrophobia), for example—or by crowded surroundings, as in church or in a restaurant or theater. An anxiety state not infrequently follows an accident and may, according to Modlin, be a source of disable. Symptoms of anxiety and depression may be prominent features of the postconcussive syndrome (page 945).

Anxiety neurosis may begin with an acute panic attack, but more frequently the onset is insidious—feelings of tenseness, vague apprehension, fatigue, weakness, and giddiness having been present for weeks or months before the first panic attack. From the history alone, two patterns of chronic anxiety neurosis are discernible. In one, there is a nearly lifelong history of poor exercise tolerance, little stamina, inability to do heavy physical work or participate in vigorous sports, tenseness, neurotic apprehension, and fear of the symptoms of the attack. In the other, acute and symptom-free tolerance of crowds. In the former group, the psychoischemia is prepotent and symptom-free before the anxiety state begins. The latter type usually has its origin in a late-life “anxiety depression.” Most patients with chronic symptoms first consult a physician with complaints referable to the cardiorespiratory system, but in a significant number the initial symptoms are gastrointestinal (dyspepsia, loss of appetite, or “irritable colon”). The former symptoms often come to light during military service and have been designated, since the American Civil War, as neurocirculatory asthenia, “irritable heart,” or “soldier’s heart.”

The physical examination between acute attacks yields relatively little of diagnostic value. The common findings, disclosed by the study of Cohen and associates, were slight tachycardia, sighing respirations, yawning, flushed face and neck, tremor of the outstretched hands, and brisk tendon jerks. The patient tends to be restless and abrupt in movement, expressive of an inner uneasiness. During a panic attack, there may be manifest agitation and a tendency to leave the current venue, and blood pressure is almost invariably elevated.

The onset of both acute and chronic anxiety neurosis is rare before 18 or after 35 to 40 years of age (average age of onset, 25 years). The condition is twice as frequent among men as among women, and there is no evidence that the disease is hereditary. There was a prevalence of 49 percent among the grown children of patients with anxiety neurosis, compared with a prevalence of about 5 percent in the general population. Slater and Shields found that there was a concordance rate of 40 percent in identical twins, compared with 4 percent in dizygotic twins. Among the relatives of index cases, the mothers suffered from anxiety neurosis more often than the fathers; in the latter, alcoholism was more frequent than in the population at large (Modlin). The pattern of inheritance has not been established, but it most closely approximates that of autosomal dominance with incomplete penetrance.

The course of anxiety neurosis is variable. The symptoms fluctuate in severity without apparent relation to environmental stress. A 20-year follow-up study by Wheeler and associates showed that anxiety neurosis were still present in 88 percent but were moderately or severely disabling in only 15 percent. Most of the patients were able to work and to enjoy a reasonably normal family and social life. Their only liability to further psychiatric illness was to recurrent anxiety neurosis or anxiety depression; so-called psychosomatic illnesses and other psychiatric illnesses did not occur more frequently than in the general population. The life span of patients with anxiety neurosis is not shortened. Those with pure, uncomplicated anxiety neurosis rarely commit suicide.

Etiology and Pathogenesis

Anxiety neurosis has been attributed to a genetic abnormality, to constitutional weakness of the nervous system, to social and psychological factors, some of which have already been discussed, and, more recently, to certain physiologic and biochemical derangements; but none of these factors provides a completely satisfactory explanation of the primary disorder. The symptoms of an anxiety attack resemble those of fear in many ways, though nearly always the former symptoms are longer in duration and less distinct. The most important difference, however, is that the cause of fear is known to the patient, whereas that of anxiety is not.

On the physiologic and biochemical side, it has been observed that anger provokes an excessive secretion of norepinephrine, whereas fear is accompanied by increased secretion of epinephrine. Actually fear activates the whole autonomic nervous system, and the increase in epinephrine is more than counterbalanced by a decrease of norepinephrine.

Symptoms of anxiety and depression may be prominent features of the postconcussive syndrome (page 945).

The term anxiety neurosis is that the blood lactic acid levels in response to exercise are higher than normal. The presence of these derangements does not necessarily mean that they are causal; they could be secondary to the poor physical condition and apprehension associated with the syndrome. Nevertheless, several studies have found that infusions of oxygen with anxiety reducing agents—for example, with hyperventilation (depersonalization; derealization)—an elevator, for example—or by crowded environments with anxiety reducing agents—can produce changes in the blood lactic acid levels that are similar to those produced by the anxiety neurosis. In addition, several studies have been proposed on the basis of the increased performance of panic attacks by different substances—carbon dioxide, yohimbine, gamma aminobutyric acid (GABA), and isoprotanol.

Studies correlating cerebral function and blood flow indicate that when panic is induced by an intravenous injection of sodium lactate, there is an immediate increase in blood flow to the cortex of both temporal lobes. In states of fear, the tips of the temporal lobes and also the amygdaloid nuclei become activated. In the relaxed period between panic attacks, the right limbic system and the parahippocampal gyrus are abnormally active.

Of potential importance is the recent finding of a connection between anxiety traits and polymorphisms of the serotonin transporter gene on chromosome 17 (Lesch et al).
These authors estimated that this particular allelic difference contributes perhaps 10 percent to the overall neurotic tendency and implied that numerous other genes may participate in a similar way. Others have not found this particular association or have found it only in patients with generalized anxiety but not those with panic attacks. Therefore the precise relationship of this and other genetic abnormalities to anxiety neurosis cannot be stated at this moment.

Differential Diagnosis

Shorn of the psychologic components of apprehension and fear, the anxiety attack consists essentially of an excessive autonomic discharge. Some of the autonomic symptoms are duplicated by chromaffin tumors, hyperthyroidism, and the menopause. The prominence of chest pain and respiratory distress during an acute anxiety attack may be mistaken for myocardial ischemia, in which case the patient is often subjected to a series of studies of cardiac function. Another form of the illness—in which dizziness, instability of gait, and fear of losing consciousness are the most prominent features—may be mistaken for a neuro-otologic problem. On the other hand, headache is a relatively minor part of the acute symptom complex, and the diagnosis should be suspect if headache is a prominent feature. (Chronic headache may be part of chronic anxiety state or anorexia depression.) Other medical diseases that simulate certain elements of an anxiety state are pulmonary embolism, cardiac arrhythmia, hypothyroidism, alcohol and nicotine withdrawal, and hypoglycemia, hypoparathyroidism, and complex partial seizures. Strict adherence to the diagnostic criteria of these disease states readily permits their differentiation from acute anxiety, but diagnosis may be difficult if the symptoms of anxiety persist for hours or days on end.

Of greater importance is the relationship of anxiety neurosis to other psychiatric illnesses, particularly to depression. Symptoms of depression are frequently added to those of anxiety neurosis, and the majority of patients with depression have symptoms of anxiety. Indeed, some psychiatrists believe that anxiety neurosis is only an allelic variant of depression. As has been mentioned, an anxiety state appearing for the first time after the fortieth year usually proves to be a depression. The uncovering of paranoid symptoms in a patient with an anxiety state should always raise the question of depression, as should the presence of symptoms such as overwhelming fatigue, self-deprecation, and feelings of hopelessness. A relatively small number of patients with a condition diagnosed as anxiety neurosis or alcoholism by competent psychiatrists have committed suicide.

Schizophrenia may begin with prominent anxiety symptoms. Here the diagnosis rests on finding the characteristic thought disorder of schizophrenia, which may emerge only after several interviews. Hysteria may include anxiety symptoms, though they are seldom prominent, as do also phobic and obsessive-compulsive neuroses, but each has other distinguishing attributes.

Treatment

Certain medications, particularly anxio-lytics and antidepressants, are often highly effective in suppressing panic attacks and creating a sense of well-being. Among these, the benzodiazepine alprazolam (2 to 6 mg/day) is currently favored, but lorazepam is almost as effective and is considered slightly less likely to cause dependence. In mild cases, the benzodiazepines may be used intermittently rather than several times daily, but they tend to be less useful once a panic attack has become established. The panic attacks tend to recur when the medications are discontinued, even after prolonged (6 to 12 months) administration. Tricyclic antidepressants and the newer drugs that raise serotonin concentrations in the nervous system (selective serotonin reuptake inhibitors, or SSRIs) are also quite effective in the treatment of panic attacks and agoraphobia. These drugs become necessary for symptoms of anxiety that persist for more than several weeks. They are given in doses similar to those used to treat depression (see Chap. 57). Buspirone, a specific serotonin 5-HT1A agonist, has been promoted as particularly effective in the treatment of anxiety and as a surrogate for benzodiazepines, but its effects have seemed to us to be slight. During the initial weeks of administration of antidepressants, an anxiolytic is usually required until the antidepressant becomes effective. Propranolol, 10 to 20 mg tid, blocks many of the autonomic accompaniments of anxiety, but its effects on the other symptoms are uncertain. In general, it is preferable to not prescribe drugs for prolonged low-grade anxiety.

Behavioral therapy (progressive exposure of the patient to panic-provoking situations) is said to be beneficial, particularly if agoraphobia is a major symptom. Relaxation activities, including biofeedback and meditation, help many patients, although persistence is required in performing these at least once daily and they do not seem to help once a panic attack has begun.

Phobic Neurosis

In this state, patients (women more than men) are overwhelmed by an intense and irrational fear of some animal, object, social situation, or disease. Though acknowledging that there are no rational grounds for a particular fear (hence it is not a delusion) and that such provocative stimuli are innocuous, the patient is nonetheless powerless to suppress it. This disorder was known to Hippocrates, who drew a distinction between normal and morbid fears. Westphal in 1871 was the first to give morbid fears the status of a disease.

Mild phobias of darkness, solitude, snakes, thunder and lightning, and high places are commonplace in childhood; some persist into adult life and may be culturally acceptable. Unlike an anxiety attack, such a phobia always focuses on an object or situation. The patient is chronically fearful of a particular animal or situation and may be extremely anxious or panic-stricken and incapacitated when placed in a situation that compels the phobia. These situations are avoided at all costs. For example, it may be impossible for the patient to leave the house or neighborhood unaccompanied, mingle in a crowd, walk across a bridge, or travel by air. This fear of being in places or situations from which escape might be difficult or extremely embarrassing is spoken of as agoraphobia and results in a homebound state. Alternatively, it may be a feature of the psychotics, the commonest being anxiety with panic attacks. The patient may be unable to eat certain foods, eat in public, have sexual intercourse, urinate in the presence of others, etc. Phobias are essentially obsessive fears and should probably be included in this category of neurosis. The most common phobia is probably claustrophobia (the fear of being confined in a close space, such as an elevator or a magnetic resonance scanner). Other phobias, as remarked earlier, are those of open (agoraphobia), closed, or high places, dogs, cats, dirt, sprays and other contaminants, air travel, the acquired immunodeficiency syndrome (AIDS), cancer, insanity, and death. Feelings of helplessness, pessimism, and despondency, the hallmarks of a depressive illness, may result. Often there are obsessive-compulsive tendencies as well, and some patients are hypochondriacal. The present authors have observed a number of patients whose phobic (or obsessive-compulsive) neurosis decompensated as an endogenous depression developed. Recovery from the depression returned them to their earlier and milder phobic state. All of these features suggest a linkage between these neuroses and depression.

Obsessive-Compulsive Neurosis

Like the pure phobic states, a neurosis dominated by obsessions and compulsions is relatively rare, occurring in less than 5 percent of patients seeking help in a psychiatric outpatient clinic. Minor compulsions (not stepping on cracks in the sidewalk, etc.), like minor phobias, are common in children, cause little or no distress, and tend to disappear in later life. A few, such as rechecking a locked door or a gas stove, may persist throughout life. Also, certain habits and rigid, obsessional ways of thinking, stubbornness, extreme punctuality, and excessive attention to detail are frequent and persistent but excite little attention medically unless they interfere with some diagnostic procedure or the treatment of some disease.

Obsessive-compulsive neurosis, or disorder, as it is now designated in DSM-IV, begins, as do the other neuroses, in adolescence or early adult years, although treatment may not be sought until middle age is reached. The two sexes are equally affected. The onset is usually gradual and cannot be accurately dated, but in some cases it is precipitated by a particular event in the patient’s life, such as the death of a relative. The family history often discloses a high incidence of obsessional personality in other members. In most instances, the obsessive-compulsive neurosis is engendered to a personality in which rigidly, inflexibility, and lack of adaptability are prominent. These traits manifest in the individual’s punctuality and in his dependability and reliability in the affairs of everyday life. There is always a prevailing undermining of distortion.

Obsessions may be defined as imperative and distressing thoughts and impulses that persist in the patient’s mind despite a desire to resist and to be rid of them. Obsessions take various forms. The most common are sexual, oedipal, and aggressive (these are often absurd, blasphemous, obscene, and sometimes frightening) constantly intrude into consciousness; impulsive obsessions, in which the mind is dominated by an impulse to kill oneself, to stab one’s children, or to perform some other objectionable act; and inhibiting obsessions, in which every act must be ruminated upon and analyzed before it is carried out—a state aptly called doubling mania. Every effort at distraction fails to rid the patient of the obsessive thought. It engulfs the mind, rendering him miserable and inefficient. Probably the most disturbing obsessions are the impulsive ones, in which patients constantly struggle with the fear that they will put some terrible thought into action. Even as they tell of the obsession, they reveal their underlying anxiety and seek reassurance that they will not yield to it. Fortunately, such
patients rarely obey their pathologic impulses.

Compulsions are acts that result from obsessions. They are single acts or a series of acts (rituals) that the patient must carry out in order to put his mind at ease. Examples are repeated checking of the gas jets or the locks on doors, adjusting articles of clothing, repeated hand washing, using a clean handkerchief to wipe objects that have been touched by others, tasting foods in specific ways, touching objects in a particular sequence, etc.

Certain motor disturbances—namely, habit spasms or tics—are, in a sense, motor compulsions. They consist of repetitious movements of the shoulders, arms, hands, and certain of the facial muscles (see Chap. 6). One feature that separates quasi-voluntary tics from involuntary movements of extrapyramidal type is the patient’s feeling that the tics must be carried out to relieve tension. Unlike compulsions, however, tics are not usually based on obsessive thoughts—except perhaps the Gilles de la Tourette syndrome, in which multiple tics are combined with compulsive utterances, often offensive ones (see below).

In all these obsessions and compulsions and in the phobias, patients recognize the irrationality of their ideas and behavior yet are powerless to control them, much as they desire to do so. It is this insight into the obsessional experience and the struggle against it that distinguish obsessions from delusions.

The majority of patients with obsessive-compulsive neurosis are tense, irritable, and apprehensive. They suffer a curious feeling of insufficiency or incompetence in being unable to expel their troublesome thoughts. The most distraught emotional state, as mentioned above, is related to the fear that an idea may eventuate in reality. The patient may complain of being unable to think without an idea of disaster entered for a time, then a voice will become depressed. Fatigue, anorexia, and general lack of interest, which are often present, are probably related to the secondary effects of anxiety and depression.

Mechanisms of Phobic and Obsessive Neuroses

For many years, a number of psychoanalytic conceptualizations of obsessive neurosis as the product of intrapsychic conflicts held sway. Only relatively recently has a neurobiologic model been advanced. Patients with this condition are found to have enlarged ventricular-cerebral ratios (Behar et al) and a reduction in the volume of the caudate nuclei, although these observations require corroboration. Weltburg and associates have described a left-sided lesion (on magnetic resonance imaging) in the head of the caudate nucleus and putamen in a patient with obsessive-compulsive disorder, and positron emission tomography studies have demonstrated increased metabolic activity in both caudate nuclei. Many similar studies implicated the caudate nuclei, but the anatomic observations are by no means uniform. The orbitofrontal cortex and amygdala were reported to be shrunken in some cases. In a study of 13 patients who developed elements of obsessiveness and compulsiveness after a viral febrile illness, Berthier et al found lesions in diverse loci, incurring the cingulate, frontal, and temporal cortices as well as the basal ganglia. Two of the most accurately localized lesions in their series were a hamartoma of the right parahippocampal gyrus and an infarction in the posterior putamen. The presence of brain injuries and seizure disorders in other patients made a precise localization problematic.

Some insight into acquired obsessive-compulsive disorder may also be gleaned from its occurrence in a poststreptococcal tic disorder termed PANDAS (pediatric autoimmune psychiatric disorders associated with streptococcal infections, page 118). This disorder is presumably related to Sydenham chorea, in which tics and similar movement disorders as well as behavioral abnormalities also occur. Imaging studies have implicated the basal ganglia in the latter situations. Functional imaging studies in patients with PANDAS have yielded variable findings, but generally there has been increased activity in the caudate nucleus and orbitofrontal cortex in association with compulsive thoughts.

The Gilles de la Tourette syndrome of multiple tics, including vocal ones, beginning in childhood or adolescence and lasting more than a year, is also closely related to obsessive-compulsive disorder. The two conditions often coexist; more than half of Tourette patients have obsessive-compulsive disorder, and both are believed to be inherited as an autosomal dominant trait, with 50 to 70 percent penetrance. There is also a questionable relationship of the Tourette syndrome to the attention deficit–hyperactivity syndrome of children, conduct disorder, stuttering, and phobic states (Kurlan). Dopamine antagonists are the drugs of choice in management of the Tourette syndrome. The observations have given rise to a number of etiologic hypotheses revolving around serotonergic and dopaminergic neurotransmitter systems (Black; Baxter; Behar et al). In the present authors’ opinion, the pathophysiology of Tourette syndrome, both the persistent and transitory or intermittent types, and their relationship to obsessive-compulsive disorder have yet to be established (see page 117 for more extensive comments on the Tourette syndrome).

The neurochemical alterations in obsessive-compulsive disorder have also been studied actively. Most of the conclusions have been based on the responses to medications, notably to the serotonin reuptake inhibitors, e.g., clomipramine. These agents are found to be of therapeutic benefit, as have stereotactically neuronal lesions in the cingulate gyril.

Diagnosis

Since the prevailing emotional state in patients with phobias and obsessives is one of anxiety and depression, it is necessary to distinguish between phobic and obsessional neuroses, anxiety neurosis, and depressive illnesses. In phobic and obsessional neuroses, the depression tends to be inconstant and closely related to a general lack of interest, which are often present, are probably related to the secondary effects of anxiety and depression. As the latter improve, the depression lightens. In uncomplicated anxiety states, baseless and indefinable fears are common but never so persistent or disabling as in phobic and obsessional neurosis; also, the indecisiveness and compulsive tendencies are lacking. Schizophrenia must be considered when an adolescent or young adult begins to harbor peculiar ideas or becomes hypochondriacal, but then a careful medical examination reveals the other characteristic disturbances of the underlying disease (Chap. 6B).

Treatment

This is best left to the psychiatrist. At least there should be a trial of therapy using behavioral modification techniques. In the case of phobic neurosis, the aim of such treatment is to reduce the patient’s fear to the extent that exposure to the phobic situation can be tolerated. A popular form of therapy is systematic desensitization (Wolpe), which consists of graded exposure of the patient to the object or situation that arouses fear. Psychotherapy, if undertaken, need not be intensive, consisting instead of repeated explanation, reassurance, and guidance in dealing with symptoms.

Currently, certain medications, such as the tricyclic antidepressants or the SSRI fluoxetine, are considered to be the most effective form of therapy—abolishing or greatly reducing obsessions in more than half the patients.

Cases of obsessive neurosis that are cyclic in nature, with exacerbations and remissions and with no apparent relationship to environmental factors, have the best prognosis. Some psychiatrists treat this cyclic form like cyclic depression, with antidepressant drugs and electroconvulsive therapy (ECT). It is not certain that these measures accomplish more than can be attributed to the spontaneous changes in the disease. More often the course of obsessional neurosis is steady and severely disabling, and in these patients the outlook for recovery has been poor (Bodkin; Polit). As with phobic neurosis, several reports have indicated that the compulsive rituals can often be abolished by the techniques of behavior therapy—based on the graduated exposure of the patient to the fear-producing stimulus. Much in vogue is the so-called cognitive-behavioral psychotherapy, alluded to earlier and discussed in the next chapter (page 1620). This too is best left to the experienced psychiatrist (see also chapter by March).

Cingulotomy has produced symptomatic improvement in both phobic and obsessional neuroses. This measure, if it is used at all, should be considered only as a treatment of last resort in exceptionally severe cases, in which the patient has failed to respond to all other methods of treatment and is totally disabled.

Hysteria (Briquet Disease; Somatization Disorder)

Although hysteria has been known since ancient times, many writers credit the first description of the syndrome (on somewhat uncertain grounds) to the French physician Briquet in 1859. Later, Charcot elaborated certain manifestations of the disease and interested Freud and Janet in it. Charcot believed that the symptoms could be produced and relieved by hypnosis (mesmerism). Janet postulated a dissociative state of mind to account for certain features such as trance and fugue states. Freud and his students conceived of hysterical symptoms as a product of “ego defense mechanisms,” in which psychic energy, generated by unconscious psychic conflicts, is converted into physical symptoms. This latter concept was widely accepted, to the point where the term conversion came into the nomenclature of the nerves and the terms conversion symptoms and conversion reaction came to be equated with the disease hysteria. In the present authors’ opinion, the term conversion, if it is used at all, should refer only to certain “conversional symptoms,” such as amnesia, paralyses, blindness, aphonia, etc., that mimic neurologic disease. We see no merit in the dichotomy, based on unsubstantiated psychodynamic theory, of a conversion type as separate from a dissociative type, as claimed by the DSM classification. Nerniah, who is in other respects partial to the psychoanalytic interpretation, agrees. In our view, the term hysteria is best reserved for a disease that is practically confined to women and is characterized further by a distinctive age of onset, natural history, and many somatic symptoms and signs,
which typically include "conversion symptoms," dissociative reactions, and states of multiple personality.

The term hysteria has a number of other connotations, most of them pejorative. Lay people refer to individuals with tantrums or loss of self-control in the face of an emotional crisis as "hysterical." Some psychiatrists dub any dramatic, historic, manipulative, or "seductive" behavior as hysterical (referring to the hysterical personality). Others equate hysteria with hypersuggestibility and susceptibility to hypnosis. These are traditional ideas based on the incorrect belief that these qualities are the defining attributes of the disease. As indicated earlier, some patients with hysteria also have the hysterical personality (i.e., they are histrionic, emotionnally labile, egocentric, "seductive," and dependent), but many such individuals never develop conversion symptoms.

In clinical neurology one encounters two types of hysteria: (1) a chronic illness marked by multiple and often dramatically presented symptoms and somatic abnormalities, for which no cause is evident (mainly in girls and women), and (2) an illness predominantly of men but also of women who develop physical symptoms or remain inexplicably disabled for the purpose of obtaining compensation, influencing litigation, avoiding military duty or imprisonment, etc. This latter state is called compensation neurosis, compensation hysteria, or hysteria with sociopathy.

**Classic Hysteria**

This neurosis, which accounts for 1 to 2 percent of admissions to a neurologic service, usually has its onset in the teens or early twenties. However, a few cases may begin before puberty. Often established, the diagnosis remains unchanged over many years. Once the symptoms unchangeable, they may begin recurring frequently, throughout the adult years, even to an advanced age. No doubt there are cases of lesser severity in which symptoms occur only a few times or perhaps only once, just as there are mild forms of other diseases. The patient may be delay on the first time for finding medical life, and the earlier history may not at first be forthcoming. Careful probing, however, will almost invariably reveal that the earliest manifestations of the illness had appeared before the age of 25 years.

Other important data are also brought to light by eliciting a careful past history. During the adult years of adolescence, the normal activities of the patient, including education, have been often interrupted by periods of ill-defined illness. Rheumatic fever or some obscure disease may have been suspected. Later in life, problems in work adjustment and marriage are frequent. There is a notably high incidence of marital incompatibility, separation, and divorce. The patient's life history is punctuated by symptoms that do not conform to recognizable patterns of medical and surgical disease. For these, many forms of therapy, including surgical operations, will have been performed. Rarely has adult life been reached without at least one abdominal operation, which was usually done because of vague abdominal pain, persistent nausea and vomiting, or some gynecologic complaint. Often the indications for the surgical procedures are unclear; moreover, the same symptoms or others often recurred to complicate the convalescence. The biographies of these patients are also replete with disorders that center about menstrual, sexual, and procreative functions. Menstrual periods may be painfully short, irregular, or excessive. Sexual intercourse may be painful or unpleasant. Pregnancies may be difficult; the usual vomiting of the first trimester may persist all through the gestational period, with weight loss and prostration; labor may be unusually difficult and prolonged, and all manner of unpredictable complications are said to have occurred during and after parturition.

Hysteric is then, a polysymptomatic disorder, involving almost every organ system. The most frequent symptoms, all statistically significant, that were elicited during a study of 250 cases of female hysteria as compared with a control group of 50 healthy women included the following: headache, blurred vision, lump in the throat, loss of voice, dyspnea, palpitation, anxiety attacks, anorexia, nausea and vomiting, abdominal pain, food allergies, severe menstrual pain, urinary retention, sexual indifference, painful intercourse, paraphrenia, dizzy spells, nervousness, and easy crying (Purtell et al.).

The examination of the female hysteric demonstrates a number of characteristic findings, mostly in the sphere of mental status. There is a lack of precision in relating the details of the illness. Questions regarding the chief complaint usually elicit a vague reply or the narration of a series of incidents or problems, many of which prove to have little or no relevance to the question. Memory defects (amnesic gaps) are usually demonstrated while the history is being taken; the patient appears to have forgotten important segments of the history, some of which she had clearly described in the past and are part of the medical record. However, unlike the situation in a psychiatric illness, the patient's ideas about most aspects of her life are rational and coherent, and there is no evidence of hallucinations, delusions, disturbance in logical thinking, or loss of appreciation of the reality of the situation. The manner of the patient is often amiable and even ingratiating. Incongruity of affect is notable; the description of symptoms may be dramatic and exaggerated and not in accord with the facts as elicited from other members of the family. Or a rather clinical disorder is observable in the patient's personal life; in her daily living the physical condition is checkered with instances of dramatic behavior and unexplained illness. This calm attitude toward a turbulent illness and seemingly disabling physical signs is so common that it has been singled out as an important characteristic of hysteria, la belle indifference. Other patients, however, are obviously tense and anxious, and report frank anxiety attacks; or the patient may be effusive in her enthusiasm, flighty and flighty, always putting on an act, and demanding constant attention. Her emotional reactions are superficial and she creates scenes that are disturbing to others but are quickly forgotten. If physical signs are present, attempts by the physician to disprove their somatic nature usually meet with anxiety and protest. Claims of early-life sexual abuse are common and often prove to be figments of the imagination. Antisocial behavior occurs in a minority of patients.

There are no pathognomonic physical findings. Although many writers have commented on the rather youthful, girlish appearance and coquettish ("seductive") manner of the patients, these by no means characterize all of them. The so-called stigmata of hysteria—i.e., corneal anesthesia; absence of gag reflex; spots of pain and tenderness over the scalp, sternum, breasts, lower ribs, and ovaries—are often suggested by the examiner and are too inconsistent to be of much help in the diagnosis. The variation and pleomorphism of the physical signs are limited only by the patient's ability to produce them by voluntary effort. Accordingly, symptoms and signs that are beyond volitional control cannot be accepted as manifestations of hysteria. Often the patient's physical signs are an imitation of those of another member of the family or are evoked by a stressful event in the patient's personal life. However, this may not be disclosed at the time of the first examination. The present authors place great weight on the importance of hypersuggestibility, in keeping with older studies that emphasized these patients' unusual susceptibility to suggestion and hypnosis. Interesting in this regard were the observations of Charcot's students, who noted that on their wards the patients' symptoms disappeared in the absence. When diagnosis is based on the totality of the clinical picture and not on the "discrepancy method," it can be quite accurate. In a follow-up study of a cohort of 56 patients with so-called conversion disorder (exclusive of pseudoexuences), only two developed a neurologic lesion (cerebral infarct; multiple sclerosis) that in retrospect was related to the initial episode (Couperie et al.). Our experience has been similar.

**Special Hysterical Syndromes**

A few hysterical syndromes occur with great regularity, and every physician may expect to encounter them. They constitute some of the most puzzling diagnostic problems in medicine.

**Hysterical Pain** This may involve any part of the body: generalized or localized headache, "atypical facial pain," vague abdominal pain, and chronic back pain with neurotiness over the scalp, sternum, breasts, lower ribs, and ovaries—are often suggested by the examiner and are too inconsistent to be of much help in the diagnosis. The variation and pleomorphism of the physical signs are limited only by the patient's ability to produce them by voluntary effort. Accordingly, symptoms and signs that are beyond volitional control cannot be accepted as manifestations of hysteria. Often the patient's physical signs are an imitation of those of another member of the family or are evoked by a stressful event in the patient's personal life. However, this may not be disclosed at the time of the first examination. The present authors place great weight on the importance of hypersuggestibility, in keeping with older studies that emphasized these patients' unusual susceptibility to suggestion and hypnosis. Interesting in this regard were the observations of Charcot's students, who noted that on their wards the patients' symptoms disappeared in the absence. When diagnosis is based on the totality of the clinical picture and not on the "discrepancy method," it can be quite accurate. In a follow-up study of a cohort of 56 patients with so-called conversion disorder (exclusive of pseudoexuences), only two developed a neurologic lesion (cerebral infarct; multiple sclerosis) that in retrospect was related to the initial episode (Couperie et al.). Our experience has been similar.

**Hysterical Vomiting** This is often combined with pain and tenderness in the lower abdomen and results in unnecessary appendectomies and removal of pelvic organs in adolescent girls and young women. The vomiting often occurs after a meal, leaving the patient hungry and ready to eat again; it may be induced by unpleasant circumstances. Some of these patients do vomit when they want, regurgitating food from the stomach like a ruminant animal. Vomiting may persist for weeks with periods of time; the absence of other diseases that could account for pain; the assumption of bizarre attitudes and postures; and, most important, the coexistence of other clinical features or previous attacks of hysterical nature. A greater error is to mistake the pain of osteomyelitis, metastatic carcinoma, or brain tumor—before other symptoms have developed—for a manifestation of hysteria. There are several helpful diagnostic features of hysterical pain: the patient's inability to give a clear concise description of the type of pain; the location of the pain, which does not conform to the pattern of pain in the familiar medical syndromes; the dramatic exacerbation of its intensity (speaking in inflected aspects of voice—"like a giant knife stabbing") and effects; its persistence, either continuous or intermittent, for long periods of time; the absence of other diseases that could account for pain; the assumption of bizarre attitudes and postures; and, most important, the coexistence of other clinical features or previous attacks of hysterical nature.

**Hysterical Seizures, Trances, and Fugues** These conditions seem to be less frequent than in the days of Charcot, when la grande attaque d'hysterie was often

**References**

squirming, thrashing of the limbs, and side-to-side motions of the head, and striking at or resisting those who offer assistance; the retention of consciousness during a motor seizure that involves both sides of the body; the long duration of the seizure, its abrupt termination by strong sensory stimulation, lack of postictal confusion, and failure to produce a rise in creatine kinase and prolactin—are all typical of the hysterical attack. Sometimes hyperventilation will initiate an attack and is therefore a useful diagnostic maneuver. Both epilepsy, particularly of frontal-lobe type, and hysteria may occur in the same patient, a combination that invariably causes difficulty in diagnosis.

Hysterical trances or fugues, in which the patient wanders about for hours or days and carries out complex acts, may simulate temporal lobe epilepsy or any of the conditions that lead to confusional psychosis or stupor. Here the most reliable point of differentiation comes from observation of the patient, who, if hysterical, is likely to indicate a degree of alertness and promptness of response not seen in temporal lobe seizures or confusional states. Following the episode, an interview with the patient—under the influence of hypnosis, strong suggestion, or midazolam or amobarbital—will often bring to light memories of what happened during the episode. This helps to exclude the possibility of an epileptic fugue.

Hysterical Paralyses, Gait, and Tremors Hysterical palsies may involve an arm, a leg, one side of the body, or both legs. If the affected limb can be moved at all, muscle action is weak and tremulous. Movements are characteristically slow, tentative, and poorly sustained; often it can be demonstrated that the strength of voluntary movement is proportional to the resistance we offer the examiner, thus imparting a “give-way” character. One can feel agonist and antagonist muscles contract, and when the resistance is suddenly removed, normally the tone is instantly less; in the hysterical, it may be doubled. Other tests have been devised to demonstrate inconsistency with normal physiologic principles and a conscious lack of cooperation. These discrepancies are elicited by testing an agonist, antagonist, or fixator movement while the patient is focused on making an effort with another group of muscles (e.g., the Hoover sign, see page 65). The muscular tone in the affected limbs is usually normal, but rigidity may sometimes be found. A seeming lack of effort and full compliance with the examiner’s requests during the testing of muscle strength, while common in hysterical patients, is not confined to them; one encounters such findings not infrequently during the examination of suggestible but nonhysterical patients who harbor a neurologic disease. Walking may be impossible, there may be a veritable astasia-abasia, or the gait may be bizarre (page 130). Weakness and poor balance are combined elements in both the quadriparetic and hemiparetic forms. In Keane’s series of 60 cases of hysterical gait, the hemiparetic and monoparesis forms were twice as frequent as the quadriparetic. The gait disorder is difficult to describe because of its variability. Sudden falls without voluntary protective movements and inconsistencies of balance are helpful features. The discrepancy between the inability to walk and to move the legs is, of course, not unique to hysteria; it also occurs in so-called frontal lobe apraxia and in ataxia from midline cerebellar lesions. Maintenance of the limb(s) in a rigid position, or rigidity of the elbow or other joints are often noted; many of the symptoms are the same as those listed under female hysteria. Or the patient may be monosymptomatic (e.g., “seizures”), and the history reveals a similar episode in the past. The patient may have a history of chronic pain that, in the absence of an organic basis, is a clue to a hysterical basis. Hysterical gait disorder is complicated in the majority of cases by a component of true muscle weakness and atrophy, which is important when muscles are tested for strength, tone, and resistance to passive movement.

Hysterical Blindness This dramatic event may affect one eye or both and may be coupled with hemiparesis or appear in isolation. The symptoms usually develop suddenly, often after an alteration or other emotionally charged event. The patient stares straight ahead blandly when undisturbed but may squint or move the head as if straining to see when asked to view an object. Some such individuals can reduce reflexive blinking in response to a visual threat, but the psychic nature of the problem may be recognized by a nurse who observes the patient reaching for a cup or the phone. The preservation of vision is confirmed by the presence of normal pupillary reflexes and optokinetic nystagmus, although one occasionally encounters a patient who has learned to suppress the latter response as well. The presence of visual evoked responses confirms the intactness of retino-occipital connections. The patient expresses little concern about her condition, which is usually short-lived. Cortical blindness and variants of the Balint syndrome (pages 489 and 491) from biocapillar infarcts are the main diagnostic considerations.

Hysterical Amnesia Patients brought to a hospital in a state of amnesia, not knowing their own identity, are usually hysterical females or sociopathic males involved in a crime. Usually, after a few hours or days, with encouragement, they divulge their life history. Epileptic patients or victims of a concussion, transient global amnesia, or acute confusional psychoses do not come to a hospital asking for help in establishing their identity. Moreover, the complete loss of memory for all previous life experiences by patients who are otherwise able to comport themselves normally is not observed in any other condition.

In the Ganser syndrome (amnesia, disturbance of consciousness, and hallucinations), patients pretend to have lost their memory or to have become insane. They act in an abnormally manner, in the way they believe that an insane or demented person should act, and give a senseless or only approximate answer to every question asked of them.

Unexplained Hyperpyrexia Among patients who turn up on every medical service with unexplained fever, there are always a few hysterics. One cannot help but be impressed with the number of student nurses, nurses, and nurses’ aides among this group of patients. Most of them will be found to have no fever if the nurse or doctor checks the temperature. Others have oral temperatures of 37 to 38°C (99 to 100°F), which must be regarded as normal for some individuals. Finally, there are a few cases of hyperpyrexia that appear to be of psychogenic origin; in these the possibility of some obscure hypothalamic disorder cannot be excluded. Diagnosis is assisted by a longitudinal history and the elicitation of the other symptoms and signs of hysteria.

Dermatitis Factitia (Hysterical Dermatoneurosis) This condition is seen more often in the sociopath than in the hysterical patient. The skin eruptions induced by the patient are characterized by erythema, ulcerations, gangrene, and variable degrees of dermatitis. Usually a caustic or irritating chemical or a sharp instrument such as a nail file has been used. The lesions are most commonly observed on parts of the body accessible to the right hand, i.e., right side of the face, neck, anterior trunk, anterior surface of left arm. They are multiple, sharply outlined, appear at variable intervals of time, and do not conform to any of the standard dermatologic diseases. They resist all treatment until the skin is protected from the persistent manipulations of the patient, and then they heal promptly.

Hysteria in Men (Compensation Neurosis in Men and Women) As stated above, hysterical symptoms do occur in men, most often in those trying to avoid legal difficulties or military service or attempting to obtain disability payments, veterans’ and other pensions, or, most often, compensation following injury. Sociopaths may also present with this type of illness. Unless such a factor can be identified, the diagnosis becomes considerably more difficult. In the male patient, assume the possibility of hysteria in the male should be made with great caution. In compensation neurosis, as in the classic form of hysteria, multiple symptoms are often noted; many of the symptoms are the same as those listed under female hysteria. Or the patient may be monosymptomatic (e.g., “seizures”), and the symptoms, particularly chronic pain, may be confined to the neck, head, arm, or low back. The description of symptoms tends to be lengthy and circumstantial, and the patient finds it give an answer to questions that are necessary for diagnosis. A tangible pain from the illness may be discovered that are cured by simple questioning. This is usually in the form of monetary compensation, which, surprisingly, is sometimes less than the patient could earn if he returned to work. Many such patients are actively engaged in litigation and are therefore a useful diagnostic maneuver. Both epilepsy, particularly of frontal-lobe type, and hysteria may occur in the same patient, a combination that invariably causes difficulty in diagnosis.

Etiology and Pathogenesis Psychoanalytic theory, which holds that both conversion and dissociative symptoms are based on particular psychodynamic mechanisms, is impossible to affirm or refute. Sociologic and educational factors are probably important, for it is generally agreed that hysterical women as a group are less intelligent and less educated than nonhysterical women. A genetic causation must also be considered. Family studies have disclosed that about 20 percent of first-degree relatives of female hysterics have the same illness, an incidence 10 times that in the general population. This supports the idea that hysteria is a disease
and not merely a surfacing of a basic personality disorder (see Goodwin and Guze).

Whether conversion symptoms are consciously produced by the patient or arise unconscious, without the patient's awareness, is a question that has been debated endlessly, without resolution. Babinski attributed the symptoms to hypersuggestibility. In fact, he defined hysteria as an illness whose symptoms could be induced (and removed) by suggestion. There is strong evidence to support this idea, since most patients can be readily hypnotized and their symptoms temporarily eliminated by this procedure, or by an interview and examination under the influence of midazolam or amytal.

As pointed out by Carothers and by Guze and colleagues, hysteria and sociopathy are closely related. Hysteria is a disease of women and sociopathy mainly of men; as restated by Cloninger and colleagues, they may constitute expressions of a single underlying variable. This relationship is supported by family studies. First-degree male relatives of hysterical women have an increased incidence of sociopathy and alcoholism; among first-degree female relatives of convicted male felons, there is an increased prevalence of hysteria. Moreover, careful histories of sociopathic girls reveal that many of them develop the full syndrome of hysteria. Women felons often present a mixed picture of hysteria and sociopathy, according to Cloninger and Guze.

Diagnosis The method of diagnosis subject to the least error is the one employed in medicine generally, i.e., obtaining an informative history (from the patient as well as from sources other than the patient) and performing physical and mental status examinations. The characteristic age of onset; the longitudinal history of recurrent multiple complaints, as outlined above, the attitude of the patient and the manner of presenting her symptoms; the incongruity between the neurologic deficit and the signs on examination; the impossibility of explaining the patient's signs on an anatomic or physiologic basis; and the absence of symptoms and signs of other medical and surgical disease will permit an accurate diagnosis in the majority of cases.

There is a significant overlap of hysteria and other medical and neurologic diseases. There are on record seven studies (between 1962 and 1985) in which patients with an initial diagnosis of hysteria by general physicians were followed for many years; 13 to 34 percent of them turned out eventually to have an "organic condition" which, in retrospect, explained the initial symptoms (see Couprie et al). This means that the original clinical diagnosis of hysteria is often erroneous. When the diagnostic criteria in these cases are closely analyzed, it appears that diagnosis was often made solely by the "discrepancy method"—i.e., the patient's symptoms or signs were not deemed to be credible manifestations of disease, based on the clinical experience of the examiner. (Of course, this assumes that the examiner has a wide experience; for the novice, many syndromes are unknown or incomprehensible.) The third and even less reliable method of diagnosis is dependent on purely psychologic criteria. In decreasing order of reliability, in the opinion of Lazare and of Gatfield and Guze, are the presence of (1) sociopathy or schizophrenia (present in 33 to 50 percent); (2) a model for the conversion symptom from some previous illness in the patient or in another important person in the patient's life ("modeling," in the language of Raskin et al); (3) emotional stress before onset of hysterical symptoms; (4) disturbed sexuality; (5) an assumed symbolism of the symptom, expressive of repressed wishes; (6) secondary gain; and (7) hysterical personality. In our case material, these psychologic factors have been inconsistent and often misleading.

So-called projective tests (the Rorschach and Thematic Apperception Tests), which for a time were popular with dynamic psychiatrists, are not helpful in diagnosis and are now used very little. The presence of extreme suggestibility and the tendency to dramatize symptoms (as measured by one part of the Minnesota Multiphasic Personality Inventory) is helpful in diagnosis but not pathognomonic of the disease; these traits appear under certain conditions in individuals who never develop hysteria.

Treatment of Hysteria

This may be considered from two aspects: the correction of the long-standing basic personality defect and relieving the recently acquired physical symptoms. Little or nothing can be done about the former. Psychoanalysts have attempted to modify it by long-term re-education, but their results are unavailable, and there are no control studies for the few reports of therapeutic success. One has the impression that in most cases the underlying illness is so pervasive and deeply rooted that nothing can be accomplished except to grant that the patient is inadequate in certain respects and requires medical support. Many psychiatrists, for this reason, are inclined to regard the female hysteric with a lifelong history of ill health as having a severe personality disorder—i.e., sociopathy. In other, less severe cases and especially in those in whom hysterical symptoms have appeared under the pressure of a major crisis, explanatory and supportive psychotherapy appears to be helpful, and the patients have been able thereafter to resume their places in society.

The acute symptoms can usually be controlled by persuasion. The best tactic is to treat the patient as though she has had an illness and is now in the process of recovering. The earlier this is done after the development of symptoms, the more likely they are to be relieved. In chronically bedridden patients, strong pressure to get out of bed and resume function must be applied. Compensation and litigation neuroses are quite difficult to treat, and settlement of the patient's claim ("the green policy") is usually necessary before the symptoms subside.

The following principles should govern the treatment of classic female hysteria:

1. Hysteria must be treated as a tangible, definite illness. In our view, the patient should not be told, "There's nothing wrong with you," "It's all in your mind," or "It's your nerves." This at once alienates the patient, and she almost invariably terminates her relations with the physician. The patient should not be dismissed as a malingerer or a faker of illness.

2. Simple, understandable language should be employed in interviews with these patients; abstruse psychologic terms should be avoided. It is unnecessary to employ the term hysteria in discussions with these patients or their families, since it has a derogatory connotation that the physician should not imply.

3. The care of the patient should be entrusted to one physician.

4. All indicated examinations and laboratory procedures for the investigation of the chief complaints should be conducted before actual treatment is begun. Once treatment is started, one should avoid, if possible, checking or repeating physical or laboratory examinations.

5. Persuasion and suggestion, both direct and indirect, should be employed. Illustratively, the patient should be repeatedly encouraged, told that she is improving, and urged to resume work or household duties and to continue participation in routine activities. Medication should be withheld.

6. A regimen of physical therapy should be instituted, utilizing an experienced therapist and setting simple goals for success.

7. There should be several interviews in which the patient is permitted to direct the discussion. She should be assured of the privacy of the interview, of the impersonal, "morally neutral" position of the physician, and of the advantages of "thinking things out more thoroughly." Any questions that the patient asks should be answered truthfully, in accordance with the physician's knowledge, in simple, direct terms.

8. Every illness in such patients should be evaluated objectively, so as not to overlook any medical or surgical disease, which may strike a hysterical patient just as it does any other person. Surgical procedures should be used only if strict criteria of surgery-requiring disease are satisfied.

How successful this program will be over a long period of time is not known. The eradication of some recently acquired hysterical symptom is relatively easy. The real test of therapy, however, is whether it enables the patient to adjust satisfactorily to family and society and to perform daily activities effectively, and whether it prevents addition, unnecessary medical treatments, and operations. Estimates of the recurrence rate of hysterical symptoms vary widely, from 12 to 80 percent. In the series of Gatfield and Guze and of Mersky, the recurrence rate of hysterical symptoms is similar or of other types was as high as in sociopathies. We have seen patients with monosymptomatic hysteria (paraparesis, bizarre gait, crippling dystonia) that persisted for years on end.

Hypochondriasis

Hypochondriasis (hypochondriacal neurosis) is the morbid preoccupation with bodily functions or physical signs and sensations, leading to the fear or belief of having serious disease. Hallmarks of this condition are the failure of repeated examinations to disclose any physical basis for the patient's symptoms and the failure of reassurance to affect either the patient's symptoms or his conviction of being sick.

It is estimated that 85 percent of hypochondriasis is secondary to other mental disorders, chiefly depression, but also schizophrenia and the neuroses. In about 15
percent of cases, however, there appears to be no associated illness (primary hypochondriasis). Most patients in this latter category are habitues of medical outpatient clinics, who are passed from specialist to specialist, perplexing and angering doctors along the way, because their symptoms defy both satisfactory diagnosis and cure. Often referred to by house officers as ‘crazos,’ these patients seldom benefit from conventional therapy.

Of a different order are the hypochondriacal reactions that one encounters in otherwise normal individuals during periods of stress. Medical students, for example, traditionally develop symptoms of a variety of diseases during their first exposure to clinical medicine. However, when an adolescent or young adult develops hypochondriacal symptoms that are not related to such forms of situational stress, one should suspect a more serious underlying disorder, such as depression or schizophrenia.

The first step in the management of hypochondriasis is to determine whether it is part of another psychiatric syndrome. As a rule, this question can best be answered by a psychiatrist, and it is advisable to have each case evaluated from this point of view. If depressive symptoms are an important part of the clinical picture, the patient should be given a trial of antidepressant medication. Particularly troublesome are young adults who present with a fixed somatic delusion such as a belief that the tongue is swollen, the jaw is not properly aligned, or the penis is enlarged when in fact no such abnormalities are present. The malignant aspect of such an illness is the persistence of the symptom and disability that extends for years, all tests having been negative. Probably these patients should be treated like schizophrenics, which many of them probably are.

The treatment of primary hypochondriasis is difficult if not impossible unless the physician keeps in mind the personality of the patient and the therapeutic goals. For a variety of reasons, these patients need to retain their symptoms, so that the usual concept of “curing” is inapplicable. The presence of symptoms provides the context for a relationship with a physician. It is the continuation of this relationship, which is often the only dependable human contact in the patient’s life, that motivates some hypochondriacs. Thus it is understandable why this type of hypochondriasis is seldom moved to institutions, where vigor and health will be restored. Such patients are best managed by physicians who realize that these are patients who do not necessarily want or expect a cure, who are content with small gains and the avoidance of unnecessary surgery, and who have an interest in the way symptoms persist rather than in any improvement.

### THE SOCIOPATHIES AND SEXUAL PERVERSIONS

#### Antisocial Personality (Sociopathy)

Of all the abnormal personality types listed in Table 56-1, the antisocial is the best defined and the one most likely to cause trouble in the family and community. Formerly sociopathy was referred to as psychopathic personality, constitutional psychopathy, and chronic psychopathic inferiority and was defined (in DSM-III) as a state in which the individual “is always in trouble, profiting not from experience or punishment, unable to empathize with family or friends or to maintain loyalties to any person or group he knows.” He is likely to be shallow, callous, and hedonistic, showing marked emotional immaturity with lack of sense of responsibility, lack of judgment, and an ability to rationalize his behavior so that it appears warranted, reasonable and justified.” Also included under this heading were certain instances of sexual deviation and of addiction.

Since Prichard, in 1835, first described this condition under the term imoral insanity, there have been many attempts to give it a more precise definition and to avoid using it as a psychiatric wastebasket. At the turn of the century, Koch introduced the term psychopathic inferiority, implying that it was a constitutionally determined deviation in personality. Later the term psychopathic personality came into common use. Some authors used this last term indiscriminately to embrace all forms of deviant personality. Subsequently the term came to be used in a more restricted sense to define a subgroup of antisocial or aggressive psychopaths (antisocial personality disorder, DSM-IV). Aureby Lewis has given a lucid account of the history of the concept of sociopathy.

By far the best modern study of sociopathy is that of L. N. Robins, based on a 30-year follow-up study of 524 cases from a child guidance clinic and 100 controls. Other investigations of note are those of Cleckley, of McCord and McCord, and of Guze and coworkers, who studied psychiatric illness in large numbers of felons and their first-degree relatives. Those descriptions that follow and the quotation above are taken largely from these writings and those of Reid.

#### Clinical State

This condition, unlike many psychiatric disorders, is manifest by the age of 12 to 15 years and frequently earlier. It consists essentially of deviant behavior in which individuals are driven to make trouble in everything they do. Every code imposed by family, school, church, and society is broken. Seemingly the sociopath acts on impulse, but after committing the unsocial act, he shows no remorse. The most frequent antisocial activities are theft, incorrigibility, truancy, running away overnight, associating with undesirable characters, staying out late, indiscriminate sexual relations, repeated fighting, recklessness and impulsivity, lying without cause, vandalism, abuse of drugs and alcohol, and, lastly, inability to work steadily or keep a job. Of children or adolescents who exhibited 10 or more of these antisocial symptoms, 43 percent were classified as sociopaths in adulthood. If only 8 or 9 of these traits were present, 29 percent were so classed; if 6 or 7, 25 percent; and 3 to 5, only 15 percent. Conversely, not a single adult sociopath was observed who did not manifest antisocial symptoms in earlier life. Interestingly, a number of other problems of childhood and adolescence—such as enuresis, dirty appearance, sleepwalking, irritability, nail biting, oversensitiveness, poor eating habits, nervousness, being withdrawn or seclusive, unhappiness, tics, and fears—were not predictive of adult sociopathy. None of Robins’ patients was mentally defective.

However, there is an increased incidence of sociopathic traits among the large population of sociocultural retardates (discussed in Chap. 28).

As noted above, more than half the deviant children in Robins’s study (even those with 10 or more antisocial manifestations) had lost most of their sociopathic traits by age 20. This is in contrast to what they reported they had done and let others think they had done, the large majority developed other adult psychiatric illnesses, particularly addiction to alcohol. Only in the group of children with less than three antisocial symptoms did a reasonable number (one-third) remain well in adult life. Because sociopathic behavior in children may terminate spontaneously or evolve into other disorders, it is advised (in DSM-IV) that the diagnosis of antisocial personality disorder be reserved for adults; the same behavior pattern in children is designated as conduct disorder.

Robins’s criteria for making the diagnosis sociopathy in the adult were persistent disturbances in so-called life areas, as exemplified by at least five of the following: poor work record, marital difficulties, inability to function as a responsible parent, financial irresponsibility and dependency, illegal occupations, multiple arrests, abuse of alcohol, sexual perversion, and evidence of neglect of personal hygiene in the American social setting. In addition, “the labels ‘sociopath’ or ‘sociopathic inferiority’ have been applied to patients who exhibit some of the symptoms listed above and other deviant behavior but who are not considered by the psychiatrist to have an antisocial personality disorder.”

Among the latter there was a high incidence of hysterical manifestations—further evidence that female hysteria may be the counterpart of male sociopathy. In Robins’s series, a search for evidence of encephalitis, often postulated as the basis of sociopathy, was not revealing, nor was there any proof of other brain damage.

It has been shown that electroencephalographic (EEG) abnormalities, taking the form of mild to moderate bilateral slowing, are more frequent in criminals and sociopaths than in the normal population. Furthermore, the biologic parents of sociopaths also show a higher frequency of such EEG abnormalities than the general population. These and other findings suggest that there may be a genetic predisposition to antisocial behavior.

Surveys of the families of sociopaths have also disclosed a high incidence of broken homes, alcoholism, and poverty. Two factors that seem most closely related to the development of sociopathy are a lack of parental discipline and having an antisocial or alcoholic father. However, as Robins’s study has shown, if only some of these factors are causal, they must be mediated through the occurrence of deviant behavior in childhood. In the absence of the latter, broken homes, slum neighborhoods,
Munchausen’s syndrome
Cadoret et al

Included under the heading of psychosexual disorders are a variety of psychologically determined sexual deviations, the most common of which are (1) paraphilias or what were formerly referred to as sexual deviations such as transsexualism (the wish to be rid of one’s own genitalia and live as a member of the other sex) and (2) paraphilias or what were formerly referred to as sexual behaviors that are considered deviant in Western society. 

Sexually perverse individuals are neurotic or psychopathic, a position emphasized by the authors. They argue that unusual sexual practices that become ends in themselves are deviant in Western society. 

Psychosocial Disorders

Although sexual perversions are usually included in the section on neurosis or sociopathy in most textbooks of psychiatry, it is a mistake to assume that every sexually perverse individual is neurotic or psychopathic, a position emphasized by Kinsey and colleagues in their two texts. Some psychiatrists would define any sexual activity that does not lead to reproduction as perverse, but this would place even masturbation and sexual intercourse with contraceptives in this category. Yet all would agree that unusual sexual practices that become ends in themselves are deviant in Western society.

There is no information as to the best methods of treatment. Most psychiatrists have been discouraged by the results of psychotherapy, but whether behavioral therapy, psychoanalysis, or drugs have more to offer cannot be determined from available data. Medical efforts should be directed to evaluating the patient’s neurologic status, assessing his intelligence, and explaining the nature of the disorder to parents and social agencies. This task is best performed by a psychiatrist, acting as a spokesman for the medical profession.

Malingering

This problem arises frequently in connection with both hysteria and sociopathy, and the physician should know how to deal with it. It is not a medical diagnosis except under the rare circumstances in which a patient is caught in the act of producing a sign of disease or confessions to having done so. The term malingering refers to the conscious and deliberate feigning of illness or disability in order to attain a desired goal. It does not occur as an isolated phenomenon, and its occurrence must be interpreted as a sign of a serious personality disturbance, often one that prevents effective work or military service, though noteworthy exceptions to this statement can be found.

Certainly there is a close similarity between hysteria and malingering, but the nature of the relationship is nebulous, and there may be great difficulty in establishing a clinical differentiation. As Jones and Llewellyn have observed:

Nothing . . . resembles malingering more than hysteria; nothing, hysteria more than malingering. In both alike we are confronted with the same discrepancy between fact and statement, objective sign and subjective symptom—the outward aspect of health seemingly giving the lie to all the alleged functional disabilities. We may examine the hysterical person and the malingerer, using the same tests, and get precisely the same results in one case as the other.

Most authors cite the following as the main points of difference between the two conditions:

1. The conscious or unconscious quality of the motivation, which always seems more unconscious in the hysterics and more conscious in the malingerer.
2. The influence of persuasion, which is usually effective in hysteria and not in the malingerer.
3. The attitude of the patient. The hysterics appear more genuinely ill and invite examination; the malingerer seems less ill and evades examination. The tendency of the sociopath to malinger has already been mentioned. Most of the more obvious cases of malingering seen by the present authors have been in sociopaths, for which reason discussions of the two conditions have been juxtaposed.

In the malingering one observes pain, hyperventilation, anemia, limping gait, tremor, contracture, paralytic, amaurosis, deafness, stuttering, mutism, amnesia, epileptiform seizures and fugues, unexplained gastrointestinal bleeding, and unexplained skin lesions—in short, the same array of symptoms and signs, singly or in combination, as in the patients with compensation hysteria. A particular form of sociopathy or malingering, which consists essentially of deceiving the medical profession, has been described under the title of Munchausen’s syndrome—named, not altogether aptly, after a seventeenth-century German senator, Baron von Munchhausen, who invented incredible tales of adventure and daring. Ireland and colleagues, who analyzed 59 well-documented cases (45 men, 14 women), list the following characteristic features, which will be recognized at once by all neurologists with extensive hospital experience: feigned severe illness of a dramatic and emergency nature; factitious evidence of disease, surreptitiously produced by interference with diagnostic procedures or by self-mutilation; a history of many hospitalizations (sometimes more than a hundred); extensive travel or visits to innumerable physicians; evidence of laparotomy scars and cranial burr holes; pathologic lying; aggressive, unruly, evasive behavior; and, finally, departure from the hospital against medical advice. Unlike the usual forms of compensation hysteria, an anterior motive is not readily discernible. The psychopathology of this syndrome is quite obscure. It has been regarded as a form of sociopathy, malingering, and compensation hysteria, but the distinctions between them are too ambiguous to be of clinical value. Probably the medical profession has placed too great a reliance on degree of conscious awareness of deception. In such unstable and immature individuals, the terms conscious, unconscious, and deception are too vague and subjective to serve as useful guides in practical work.

Intermittent Explosive Disorder

Designated by this title is an uncommon disorder, the characteristic feature of which is the occurrence of repetitive, unpredictable outbursts of violent, aggressive behavior out of all proportion to the provoking situation. This condition needs to be set apart from the uncontrollable outbursts of violent behavior that sometimes are associated with mental retardation, schizophrenia, drug addiction, or alcoholism, or those that follow serious head injuries or other brain diseases.

Some persons with intermittent explosive disorder have, from early childhood, reacted to frustration with a loss of self-control, striking out in blind rage at anyone who crossed them (episodic dyscontrol syndrome); as adults, they may inflict serious injury or kill. Lesser degrees are recognized as expressions of “hot temper.” Sometimes such behavior appears to be a continuation of the temper tantrums of earlier childhood.

The causes of aggressive violence are poorly understood. There appears to be a heritable tendency (Cadoret et al): males predominate and a sex-linked form, extending over several generations, has been described. In some patients, a seizure disorder can be identified, particularly temporal lobe epilepsy, which is not excluded by a normal EEG. Arresting examples, occurring in patients with temporal lobe tumors and encephalitis, raise the possibility that all cases have a pathologic basis. Adrenergic hyperactivity has been suggested and supported to some extent by these patients’ response to propranolol (see Chap. 25 on the limbic system).

These cases aside, the authors believe that most instances of explosive disorder represent a variant of the sociopathy described above. In DSM-IV, intense outbursts and physical violence are important features of a diagnostic category called borderline personality disorder, the other manifestations of which include “a pervasive pattern of instability of mood, interpersonal relationships, and self-image.” Elliott, and Jenkins and Maruta report a beneficial effect of propranolol. Others find lithium, carbamazepine, and phenytoin to be helpful in controlling and preventing attacks.

Prognosis

This is of interest for several reasons. One is the relation between deviant behavior in childhood and adolescence and the development of sociopathy and other psychiatric illnesses in adult life, which has already been discussed. In addition, it should be noted that improvement of gross antisocial behavior in adult sociopaths is possible, occurring in somewhat more than one-third of such individuals. Improvement occurs most frequently between the ages of 35 and 40 years (median age, 35). This bears out the Gluecks’ contention that repetitive criminality diminishes with age. Improvement of sociopathic behavior does not necessarily mean that these individuals have become well adjusted but rather that they have married and are maintaining a home and working. Probably maturation, marriage, assumption of family responsibilities, and fear of imprisonment are the main stabilizing forces; at least these are the ones proffered by sociopaths to explain their improvement.

Most psychiatrists have been discouraged by the results of psychotherapy, but whether behavioral therapy, psychoanalysis, or drugs have more to offer cannot be determined from available data. Medical efforts should be directed to evaluating the patient’s neurologic status, assessing his intelligence, and explaining the nature of the disorder to parents and social agencies. This task is best performed by a psychiatrist, acting as a spokesman for the medical profession.
deviations. Included in this latter category are fetishism (the use of nonliving objects to achieve sexual excitement), frotteurism (intense sexual urges involving touching and rubbing against a nonconsenting person), pedophilia (sexual activity with a prepubescent child), transvestism (habitual dressing in the clothes of the opposite sex), zoophilia, exhibitionism, voyeurism, sexual masochism, and sadism. These represent special problems rarely encountered by the neurologist and are not included here for that reason. The reader seeking information on these subjects and on sexual dysfunctions is referred to the chapters by Levine and by Green and Blanchard in the Comprehensive Textbook of Psychiatry and to the discussion of sexual disorders in DSM-IV.

Alcohol and Drug Addiction

These conditions are unquestionably associated with sociopathy, as indicated above, but they also represent special problems of immense proportions and are therefore discussed in Chap. 42 and Chap. 43.

ANOREXIA NERVOSA AND BULIMIA

Anorexia nervosa is a behavioral disorder of previously healthy girls and young women, mainly from the upper and middle social classes, who become extremely emaciated as a result of voluntary starvation. It is rare in Asians and African-Americans and rarely occurs in males. Herzog reminds us that it was Richard Morton who first described the condition in 1649, under the title of “nervous phthisis,” a “nervous consumption” resulting from “sadness and anxious cares”—a title that embodied etiologic concepts in psychologic derangements. Bulimia (literally ox-hunger), to which it is closely related, was not isolated as an eating disorder until the latter part of the nineteenth century.

As a rule, anorexia nervosa begins shortly after puberty—sometimes later, but seldom after 30 years of age. Some of the patients have been overweight in childhood, especially in the prepubertal period. Dieting is much talked about and may have been encouraged, especially by mothers who want their daughters to become more attractive. Sometimes there appears to be a precipitating event, such as leaving home, a disruption of family life, or other stress. Whatever the provocation, it leads to an obsessive refusal to eat. What is more important, the abnormal eating habits persist even when the patient has become painfully thin, and when counseled to eat normally, she will use every artifice to starve herself. Food is hidden instead of being eaten, vomiting may be provoked after a meal, or the bowel may be emptied by laxatives. No amount of persuasion will induce the patient to take adequate amounts of food. The patient shows no concern about her obvious emaciation and remains active. If left alone, these patients waste away, and about 5 percent have succumbed to some intercurrent infection or other complication, placing it among the most lethal of psychiatric conditions.

On physical examination, one is struck with the degree of emaciation; it exceeds that of most of the wasting diseases. Often 30 percent or more of the body weight will have been lost by the time the patient’s family insists on medical consultation. A fine lanugo covers the face, body, and limbs. The skin is thin and dry, without its normal translucence, and the nails are brittle. Pubic hair and breast tissue (except for loss of fat) are normal, and in this respect anorexia nervosa is unlike hypothalamic cachexia (Simmonds disease). The extremities are often cold and blue. There are no neurologic signs of nutritional deficiency. The patient is alert and cheerful indifferent to her condition. Any suggestion that she is unattractively thin or seriously depleted is rejected.

Anorexia nervosa is practically always present in the extreme weight loss. Luteinizing hormone (LH) concentrations are reduced to pubertal or prepubertal levels. Clomiphene citrate fails to stimulate a rise in LH, as it does normally. Administration of gonadotropin releasing factor raises the LH and FSH levels, suggesting a hypothalamic disorder. The basal metabolic rate is low; T3 and T4 are low, while levels of physiologically inactive 3,3,5-triiodothyronine (reverse T3) are normal or increased. Plasma thyrotropin (TSH) and growth hormone levels are normal. Serum cortisol levels are usually normal; excretion of 17-hydroxysteroids is slightly reduced. In sum, there is evidence of hypothalamic-pituitary dysfunction; probably this is not primary but is secondary to starvation. These abnormalities are summarized in the review by Becker and colleagues. However, Scheltzelaer and colleagues found no definite changes in the pituitary gland in 12 fatal cases. CT scanning shows slight to moderate enlargement of the lateral and third ventricles, which return to normal size as the anorexia subsides.

The etiology of anorexia nervosa is unknown, although there is no dearth of hypotheses. Holland and coworkers reported a strikingly high concordance in monozygotic twins as compared with dizygotic twins, indicating that constitutional factors are important. Ear-mark signs of hysterical tendencies, obsessive personality traits, and depression are mentioned as being frequent in some reported series but not in others. Certain polymorphisms in the serotonin transporter gene, of types different from those that have been tentatively attached to anxiety and to obsessive traits, have also been reported. The meaning of these genetic findings is difficult to interpret. A functional imaging study has shown activation of the left insula, amygdala, and cingulate when high-calorie drinks were imbibed by anorectic women (Ellison et al.), but this may conceivably have reflected anxiety that the authors termed “calorie fear” rather than a specific biologic feature of the disease.

Reports concerning the percentage of first-degree relatives with manic-depressive disease are also contradictory. An increased prevalence of neurosis or alcoholism has been noted in other members of the family. However, all psychiatrists seem agreed that the patient does not have symptoms that conform to any of the major neuroses or psychoses. Certain loss of appetite, lack of self-esteem and interest in personal appearance, and self-destructive behavior—common features of anorexia nervosa—are also symptoms of depressive illness, yet most of the patients do not look or admit to being dejected. Moreover, endogenous depression affects both sexes. The pathologic fear of becoming fat and the obsession with weight might be interpreted as a phobic or obsessional neurosis. A characteristic personality disorder has not been defined, however.

The fact that anorexia nervosa is practically confined to females must figure in any acceptable explanation of the syndrome. Among psychiatric disorders, only hysteria has this sexual predilection. Yet most psychiatrists do not believe anorexia nervosa to be a manifestation of hysteria. The racial-social relationships of the syndrome are noteworthy. Undoubtedly important is the fact that anorexia nervosa has its onset in relation to the menarche, at a time when the female exhibits rather large fluctuations in appetite and weight. This suggests an imbalance between the satiety center, believed to lie in the ventromedial hypothalamus, and the feeding center, in the lateral hypothalamus (McHugh). The intestinal hormone cholecystokinin may be implicated; it is released when food enters the intestine and may function as a feedback mechanism, acting on the satiety center and inhibiting food intake. Obesity before or around puberty is more pronounced in girls than in boys. It is as though the appetite-satiety mechanism of the female hypothalamus were unstable.

The most effective treatment consists of winning the patient's confidence, supportive psychotherapy, assignment of one individual to sit with the patient each meal is eaten, and a gradual increase of a balanced diet (Anderson). Extreme cases may require hospitalization. If the patient refuses to eat, tube feeding is the only alternative, and she must understand that it is simply a question of eating voluntarily or being tube-fed. As weight is gained over several weeks, the patient usually becomes more normal in her attitude and will continue to recover on this regimen at home. The menses will not return until considerable weight has been gained (about 10 percent above the weight at the time of the menarche). Our colleagues report an increased success with such a regime when imipramine or fluoxetine is added. Others have found these drugs to be ineffective except in patients with prominent symptoms of depression.

Becker and her colleagues have recently reviewed the problem of eating disorders. They emphasize the potentially devastating effect on health of the many medical complications to which severely anorectic patients are prone and the need to evaluate and treat these complications at the same time that nutritional therapy is undertaken. In particular, an electrocardiogram is essential in order to exclude a prolonged QT interval—the presence of which contraindicates the use of tricyclic antidepressants and increases the risk of ventricular tachycardia.

On average, 50 percent of patients recover completely or almost completely (Steinhausen and Seidel). In the remainder, the outcome is quite unfavorable. They either relapse after an initial period of improvement or remain chronically anorectic. Many patients are said to lapse into a chronic neurotic state characterized by a persistent preoccupation with food, weight, and dieting. It is not generally appreciated that chronic anorexia nervosa significantly shortens life; after a mean follow-up period of 12 years, 1 percent of a group of 84 patients had died (Deter and Herzog), and 15 percent after 20 years (Rathnasuriya et al.). Suicide is a major contributor to this high mortality rate (Sullivan).

The few adolescent boys that we have seen with this syndrome have recovered on antidepressant medication. A few cases, due to tumors within the hypothalamus, have been mentioned in Chap 27.

The association of anorexia with disease involving the appetite centers has not been established, though the cases of Lewin and colleagues and of White and Hain are suggestive. Martin and Rechlin, in citing these rare cases, attribute the anorexia and cachexia to lesions of the lateral hypothalamus. A rare disorder of infants has been described under the title of diencephalic syndrome. Progressive and ultimately fatal emaciation (failure to thrive), despite normal food intake, in an otherwise alert and cheerful infant is the main clinical feature. The lesion has usually proved to be a low-grade astrocytoma of the anterior hypothalamus or optic nerve (Burt et al.). See Chap. 27 for further discussion and references.

The few adolescent boys that we have seen with this syndrome have recovered on antidepressant medication. A few cases, due to tumors within the hypothalamus, have been mentioned in Chap 42.
Bulimia is a related eating disorder characterized by massive binge eating followed by the induction of vomiting and excessive use of laxatives. Insofar as the central psychologic disturbance is the pursuit of thinness at all costs, it is generally conceived as a variant of anorexia nervosa. Indeed, binge eating is a frequent manifestation of anorexia nervosa, although it also occurs as the only, or predominant, eating disorder. However, a close relationship with the menarche as well as emaciation and endocrinologic disturbances are not as evident in bulimic patients as in those with anorexia nervosa. Pope and colleagues have reported considerable success in 19 of 20 bulimic patients treated with imipramine and followed for 2 years; the newer antidepressants appear to be equally effective. In general, the therapeutic benefit of these drugs is considerably greater in cases of bulimia than in anorexia nervosa.

REACTIVE DEPRESSION, ENDOGENOUS DEPRESSION, AND MANIC-DEPRESSIVE DISEASE

There are four major categories of psychosis: (1) the confusional-delinquently states, (2) the psychoses associated with focal or multifocal cerebral lesions, (3) the affective disorders (manic-depressive and depressive psychoses), and (4) the schizophrenias. The first two categories are discussed in Chap. 20 and Chap. 22. The latter two groups make up the subject matter of this and the following chapter.

Depression is the cause of more grief and misery than any other single disease to which humankind is subject. This view, expressed by Kline almost forty years ago, is still shared by everyone in the field of mental health. Although depression has been known for over 2000 years (melancholia is described in the writings of Hippocrates), there is still uncertainty as to its medical status. Is depression a disease state (kraepelinian concept) or a type of psychologic reaction (meyerian concept)? In other words, is it basically a biologic derangement or a response to psychosocial stress with which a person cannot cope? These two disparate concepts are not irreconcilable. An eclectic position is that both are correct—i.e., that there are two basic forms of depression: exogenous and endogenous. Exogenous (or reactive) depressions have an overt external cause, such as the loss of a loved one, loss of one's fortune or position, or a disabling or life-threatening illness. In this framework, grief would exemplify a reactive or exogenous depression. In contrast, the endogenous depressions have no apparent external cause; they seem to occur in susceptible individuals as a response to some unknown biologic alteration. In respect to endogenous depression and manic-depressive psychosis, the genetic and neurochemical data (cited further on) support the kraepelinian view of a disease state. Nonetheless, a lay concept persists, perpetuated perhaps by some process-oriented psychiatrists, that events in one's life, either distant or current, underlie both types of depressive illness. An unfortunate consequence of this view is the assumption that an inability to deal with these stresses represents a personal failure of sorts and may inhibit the acceptance of psychiatric help.

A few additional remarks are necessary to explain the grouping of entities to be considered in this chapter. A depressed or dysphoric mood is the symptom that relates all of them, but it is the setting in which the depression occurs as well as differences in certain clinical attributes that underline the distinction of a number of separable clinical states. Taken together, they are the most frequent of all psychiatric illnesses. In a tertiary general referral hospital, as indicated on page 1587, they accounted for an estimated 50 percent of psychiatric consultations and 12 percent of all admissions. Grief reactions are ubiquitous, but only exceptionally do they require psychiatric referral.

Depressive states are so often associated with obscure physical symptoms that they are more likely to come to the attention of general physicians and internists than of other psychiatric entities. Moreover, they are frequently misdiagnosed, the symptoms being mistakenly attributed to anemia, low blood pressure, hypothyroidism, migraine, tension headaches, a chronic pain syndrome, chronic infection, emotional problems, worry, and stress. Neurologists in particular are likely to encounter depressed patients who complain of fatigue and weakness, chronic headache, and difficulty in thinking or remembering. An important reason why all physicians should be knowledgeable about depressive illnesses is the danger of suicide, which may be attempted and successfully accomplished before the depression is recognized. Timely diagnosis may prevent such a tragedy—one that is all too regrettable since most depressive illnesses can be successfully treated.

Nosology and Classification

As remarked in Chap. 24, the term depression embraces more than a feeling of sadness and unhappiness. It stands for a complex of disturbed feelings (called mood, or affective, disorder)—which includes despair, hopelessness, a sense of worthlessness, and thoughts of self-harm—associated with decreased energy and libido, loss of interest in life's events, impaired concentration, various abnormalities of behavior, and prominent physical complaints—the most important of which are insomnia, either anorexia or overeating, headache, and various types of regional pain. At one extreme are depressive symptoms of psychotic proportions (including paranoid or somatic delusions), which create chaos in the lives of the patient and those close to him. At the other extreme are the common feelings of unhappiness, anhedonia (loss of pleasurable responses), discouragement, and resentment that occur in almost everyone as a reaction to the disappointments of everyday life, such as loss of employment, a failure to gain recognition, or unsuccessful sexual or social adjustment, all of which are closely linked in their duration to the persistence of the precipitating factors.

Some moos, or affective, disorders take the form of a relatively pure, uncomplicated depressive illness; others are mixed with symptoms of anxiety and agitation. Both are types of an apparent tendency to appear for the first time in middle and late adult life, the latter syndrome was referred to in the past as involutional melancholia. This term takes license with the concept of involution, for such an illness may occur at any time in adult life, with no relationship to the climacteric ( Winokur and Cadoret).

Some depressions are clearly reactive to real and imaginary life situations. If a depression arises in proximate relation to the loss of a family member, the condition is called grief; if in relation to a life-threatening or disabling medical or neurologic disorder, it is referred to as induced or reactive depression. As indicated in the preceding chapter, grief may complicate phobic and obsessive-compulsive states and even hysteria; in a sense the depression in these circumstances is also reactive or secondary. Then there are depressions that present as hypochondriasis; although the latter psychiatric syndrome may rarely occur as a protracted and obstinate neurosis, the coexistence of an underlying depressive illness must always be considered in assessing a hypochondriacal patient.

An abnormally elevated mood, or mania, is about one-third as frequent as depression. It may develop as the result of a pure manic episode, or it may be superimposed on other psychiatric phenomena that are classically described as manic-depressive disorder, in which case it has been variously called hypomaniac, or manic-depressive illness. (bipolar disorder in the classification of the Diagnostic and Statistical Manual of Mental Disorders, or DSM-IV). Prolonged milder forms of moodiness and depression, lasting for years, have been classified as dysthymia. Hypomania and cyclothymic disorder are the names given to milder forms of mania and bipolar disorder, respectively. The DSM-IV classification also acknowledges the existence of mixed acausalffective states with attributes of depression and schizophrenia. These fall into the category of either dysthyemic or reactive depression. In our view, distinguishing these various types of depressive illness is of therapeutic as well as theoretical importance because each of them may respond better to one form of treatment than to another.

As already indicated, when depression masquerades as a chronic pain or fatigue state or some other medical condition, it has been called “masked depression” or “depressive equivalent.” In the following pages the masked depression as a diagnostic problem is emphasized. Finally, the neurologist should always bear in mind the possibility of an incipient dementia presenting as a depression, although the reverse, a masked depression causing difficulty with thinking and memory (pseudodementia) is more common.

To summarize, from a general medical standpoint there are four main depressive illnesses with which the physician should be acquainted:

1. Grief reaction
2. Reactive or secondary depression in relation to a medical or neurologic disease
3. Endogenous or primary depression (with or without agitation and anxiety) and manic-depressive disease
4. Depression in relation to a fixed personality trait or neurosis

The foregoing classification of depression and mania does not strictly follow the DSM-IV classification but is nonetheless in harmony with it. Also, the nosology in this

Grief Reactions

Discussion of the depressive illnesses may suitably begin with the most common form, the grief reaction. Analysis of the typical grief reaction discloses the following characteristics (according to Lindemann): (1) an intense subjective sensation of mental pain accompanied by a feeling of exhaustion, (2) preoccupation with the image of the deceased, (3) a sense of guilt concerning the relationship to the deceased, (4) sometimes an inexplicable and unwarranted hostility toward friends and relatives, and (5) a loss of or change in the usual pattern of conduct. Bereaved persons have difficulty in initiating or organizing their daily affairs and tend to perform them in an automatic and uninterested fashion ("going through the motions" is a common description).

The authors cannot vouch for the validity of each of these characteristics, especially the third and fourth, but accept them as reasonable. There is no doubt, however, that a sense of exhaustion and disorganization of daily activities are to some extent invariable accompaniments. As a rule, the grief reaction lasts for a period of 4 to 12 weeks, by which time it begins to abate, with a gradual resumption of normal activities, which come to occupy the mind more and more of the time and to expel thoughts of the deceased. Grieving is to be regarded as a natural reaction to personal tragedy; its absence in circumstances where it should be called forth is believed by psychiatrists to be abnormal. However, the overt expressions of grief are highly individual, depending on personality as well as cultural and other factors.

Distortions of the normal reaction to personal loss are not infrequent; they are referred to as pathologic grief. The most frequent distortion is prolongation of the reaction—i.e., there is no sign of resolution by the end of a 3-month period. Mothers who have lost a child tend to suffer for an unduly long period of time, and the elderly who have lost a spouse may never recover completely. Patients with a history of previous depressive episodes may also remain in mourning longer than usual. In peculiar psychological states, a bereaved person has shown no improvement within 3 to 4 months of the loss, one should suspect a pathologic grief reaction that calls for psychiatric consultation. Unlike the normal grief reaction, prolonged grief is not an unusual setting for suicide.

In other variations of the grief reaction, the bereaved person may show little or no immediate reaction to the loss (the "stiff-upper-lip" attitude, much admired in Anglo-Saxon culture), or the bereaved may even become hyperactive and undertake a series of ill-advised social and economic ventures. Occasionally patients will acquire the same symptoms as the deceased and may be convinced that they have the same disease. This may be the origin of some of the hypochondriacal ideas that accompany depressive reactions. The identification of this variant of grieving requires only that the examiner, after excluding the presence of disease in the patient for want of clinical evidence, inquire about the illness that took the life of the deceased.

Management of the usual grief reaction consists of maintaining a sympathetic attitude and helping the bereaved person to acknowledge the loss and to face the changes required as a result of it. Stoicism should not be encouraged or reinforced. To express sadness through tears, anguish, and even hostility is helpful for many individuals. The practice of treating grief-stricken patients with antidepressants is seldom effective, for it attempts to suppress what is a natural and necessary human reaction. Early on, undue restlessness, anxiety, and insomnia can be relieved by anxiolytic and sedative medication. Diazepam, lorazepam, or—if there is a great deal of associated anxiety—alprazolam are suitable for daytime sedation and can be used at bedtime for sleep. These drugs have a wide margin of safety, which decreases the danger of their use as a means of committing suicide. The possibility of suicide must be entertained in managing all depressed patients, including mourners, and care must be taken not to supply them with large amounts of sedative medication.

Antidepressants can be utilized if the grief reaction is unusually prolonged or disabling, although they can generally be avoided. In treating patients of this latter type, the help of a psychiatrist should be enlisted to determine whether the plan of treatment is sound; often these patients require specialized psychiatric help.

Other Reactive Depressions

Patients reacting to a medical or neurologic illness seldom express feelings of sadness or despair without mentioning physical concomitants, such as easy fatigability, anxiety, tension headaches, dizziness, loss of appetite, reduced interest in life and love, trouble in falling asleep, or premature awakening. It follows that whenever these symptoms become manifest in the course of medical disease, they should arouse suspicion of a depressive reaction (see Table 57-1).

**Table 57-1 Depression secondary to neurologic, medical, and surgical diseases and drugs**

Chronic pain is a particularly frequent somatic manifestation of depression. The pain may be based on an attendant disease but is prolonged, disabling, sometimes vague in nature, and recalcitrant to straightforward medical and surgical approaches. In other words, depressed mood exacerbates and prolongs pain of any type. All patients with chronic pain syndromes should be evaluated psychologically, as pointed out in Chap. 6.

In a number of major medical illnesses, depressive symptoms occur with such frequency as to become almost part of the disease. They constitute important diagnostic and therapeutic problems. Contrariwise, in certain chronic, occult diseases, symptoms such as lassitude and fatigue may resemble and be mistaken for a depressive reaction. Hypothyroidism, infectious mononucleosis, infectious hepatitis, carcinoma of the head of the pancreas, metastatic carcinoma of the liver, malnutrition, polymyalgia rheumatica, and frontal lobe tumors, especially meningiomas, may simulate depression for several weeks or months before the diagnosis becomes evident. Sedative drugs, beta-adrenergic blocking agents, beta-interferon, and the phenothiazines may evoke a depressive reaction; corticosteroids can induce a peculiar psychiatric state in which confusion, insomnia, and either an elevation of mood or depression are combined. A depressed mood may also emerge during the tapering-off period of steroid medication.

Of particular significance is the depression that occurs on learning of a medical or neurologic disease. Often such an emotional reaction, which the physician may tend to ignore, is the dominant manifestation of a disease that threatens the life pattern and independence of the patient. Recognition by the patient that he has undergone a stroke or that he has cancer, multiple sclerosis, or Parkinson disease is almost always followed by some degree of reactive depression, often with an element of anxiety.

A prime example is the depression that follows myocardial infarction (Wishnie et al). Usually it begins toward the end of the patient’s stay in the acute-care ward. In the beginning, it may attract little attention, being obscured by bed rest and sedative medication. Once the patient is home, fatigability that approaches exhaustion is the main complaint and interferes with accustomed activities; it may be described as weakness and falsely attributed to a failing heart. Symptoms of irritability, anxiety, and despondency are next in order of frequency, followed by insomnia and feelings of aimlessness and boredom. Although most of these patients usually recover without medical assistance (the disorder, in this sense, is self-limited), the depression exacts a high toll in terms of mental suffering.

An analogous depressive reaction occurs in patients with stroke. It appears that patients with left anterior cerebral lesions, involving predominantly the lateral frontal cortex or basal ganglia (as judged by CT scanning) and examined within several weeks of the stroke, have a greater frequency and severity of depression than patients with lesions in any other location (Starkstein et al; Robinson). According to these authors, lesions of the right hemisphere do not show this correlation with depression but do show a higher association with pathologic cheerfulness or mania. House et al, in a British community-based study of stroke survivors, failed to confirm these findings, perhaps because the infarcts were small in size (more than half the patients had never been admitted to hospital) and many patients were examined for the first time only at 6 and 12 months after their strokes. Levine and Finkelstein have reported the occurrence of psychotic depression with hallucinations.
delusions in patients with right temporoparietal infarcts. Our own experience suggests a not surprising relationship between the degree of motor and language disability and the severity of poststroke depression but a less predictable relationship to the location of the lesion. Also not surprisingly, strokes in the anterior (carotid) circulation give rise to more emotional changes than those in the posterior circulation. The possible predisposing effects of minor previous episodes, family history of depressive illness, medications, etc., have not been studied systematically.

Parkinson disease is complicated by a depressive reaction in approximately one-quarter of the cases. In this disorder, weakness and fatigability, the principal psychologic manifestations, are added to the bradykinesia, and the resulting therapeutic problem becomes formidable. Another hazard in Parkinson disease is the tendency for L-dopa itself to provoke a depression in a limited number of patients, sometimes with suicidal tendencies, paranoid ideation, and psychotic episodes. The treatment of a variety of depressions with monoamine oxidase (MAO) inhibitors is contraindicated in patients receiving L-dopa. Huntington chorea is often associated with depression, even before the movement disorder and dementia become conspicuous; in one series, 10 of 101 patients with Huntington disease either committed suicide or attempted it. Also, Alzheimer disease is often accompanied by depressive symptoms, in which instance it is difficult or impossible to evaluate the relative contributions of the mood disorder and the dementia.

ENDOPHRENIC DEPRESSION AND MANIC-DEPRESSIVE DISEASE

Definitions and Epidemiology

Manic-depressive disease is a mood disorder consisting of prolonged episodes of depression, mania, or both. A traditional view of this disease was that of a periodic or cyclic condition in which one major mood swing was followed by an equal but opposite excursion. This is seldom the case, however. Episodes of depression are twice as frequent as manic episodes, and the most common course of the illness is characterized by episodic depression alone. Recurrence of episodes of pure mania without intervening episodes of depression is well known but relatively uncommon. As a consequence, manic-depressive psychosis has been divided into two subtypes: a unipolar group, in which only an endogenous depressive illness occurs, and a bipolar group, in which mania occurs with or without depression.

In addition, there are mixed affective states, in which symptoms of both depression and mania occur within a single episode of the illness. Dysphoria (formerly referred to as depressive neurosis or neurotic depression) is the name given to an extremely chronic and intermittent but relatively mild depressive illness. Cyclothymic disorder is the term applied to another mild affective syndrome in which there are swings in mood between hypomania and depression, the latter being of insufficient severity to meet the criteria for a major depressive episode. Seasonal affective disorder refers to a depression that recurs at a similar time each year, most often in the winter; it is in most ways similar to the usual depressive illness except that it may respond to therapy with natural light. A rapid-cycling form of manic-depressive disease has been recognized in which four or more circumscribed episodes occur in a year. Like other variants of the disease, it tends to have an aberrant response to medication. Still other patients present with atypical features; instead of anorexia, weight loss, and insomnia, for example, they sleep and eat excessively. These patients are also difficult to treat. In adolescents, the latter symptoms are difficult to differentiate from the Kleine-Levin syndrome (page 598).

Manic-depressive psychosis was given its name by Kraepelin in 1896, and it was with him that our current clinical concept of this disorder originated. He viewed the manic and depressive attacks as opposite poles of the same underlying process and pointed out that, unlike dementia praecox (his name for schizophrenia), manic-depressive psychosis entails no intellectual deterioration with recurrent episodes.

The prevalence of manic-depressive disease cannot be stated with precision, mainly because of differing criteria for diagnosis. The apparent increase of the disease in the past 50 years probably reflects a growing awareness of the condition, among both physicians and the laity. Studies of large groups of patients from isolated areas of Iceland and the Danish islands of Bornholm and Samsø indicate that 5 percent of men and 9 percent of women will develop symptoms of depression, mania, or both at some time during their lives (Goodwin and Guze). The estimate for an American urban community (New Haven, Connecticut) is higher; the lifetime expectancy for an attack of major depression is 8 to 12 percent in men and twice this number in women (Weissman and Myers).

Manic-depressive disorder occurs most frequently in middle and later adult years, with a peak age of onset between 55 and 65 for both sexes. However, a significant proportion of patients experience the first attack in childhood, adolescence, or early adult life. Depression is also a significant problem in the elderly. Blazer and Williams, who studied 987 persons over the age of 65 in North Carolina, found symptoms of a major depressive illness in 3.7 percent. The disease is two or three times more frequent in women. There are some studies suggesting that more and more women are developing depression in their later years, but some have speculated that just as many men are depressed, only they deny it or turn to alcohol. It was reported in the 1930s to be more common in individuals of Jewish and Irish ethnicity and among those in upper socioeconomic strata, but subsequent studies have not confirmed these findings. The bipolar variant occurs in about 10 percent of patients with affective disorder. Patients in the bipolar group often develop depression at an earlier age of onset, more frequent and shorter cycles of illness, and a greater prevalence of affective disorder among their relatives than do patients with unipolar disease (Wittchen). Clinical Presentation

The fully developed endogenous depression may evolve within a few days, or, more often, it emerges more gradually, on a background of vague prodromal symptoms that had been present for months. A detailed description of the symptoms and signs of depression is given in Chap. 24. Here it need only be repeated that the patient expresses feelings of sadness, unhappiness, discouragement, hopelessness, and despondency, with loss of self-esteem. Reduced energy and activity, typically expressed as mental and physical exhaustion, is universally present, to the point of catatonia in the most severe cases. There is heightened irritability as well as a lack of interest in all activities that formerly were pleasurable. The patient tends to move slowly, sighing is frequent, and speech is reduced. The mental life of such an individual may narrow to a single-minded concern about his physical or mental decline or both. In dialogue, the patient's rejoinders become so stereotyped that the listener can soon predict exactly what is going to be said. There is a poverty of ideation as well as an attitude of absence of insight. Consciousness is clear, and though there may be a contributory element of a schizophrenia-type of thought disorder, delusions, ideas and less often hallucinations may be prominent in some patients, justifying the term depressive psychosis. The delusions are generally congruent with the patient's mood and are not as fixed or bizarre as those of schizophrenia or paranoia. In our experience, delusions are common in older patients and tend to appear only after weeks or months of more typical symptoms of depression. In younger patients, delusions may take the form of beliefs or fears such as a concern about cancer or AIDS. Hallucinations, when they occur, are usually vocal and accusatory; their presence should always raise the possibility of an associated structural disease, drug intoxication, or alcoholic hallucinosis.

Frequently, agitation and irritability, rather than physical inactivity and mental slowness, are the principal behavioral abnormalities. The source of the agitation is an underlying anxiety state. Facing the floor and wringing the hands, particularly in the early morning hours, are characteristic. Such patients tend to be overtalkative and vexed in their manner of expression, irritable, shorttempered, impatient, and intolerant of minor problems—changes noted mainly by family members. Attempts at reassurance may meet with initial success, only to be dispelled in the next rush of doubts. These patients remain impervious to reason and logic in respect to their situation. Although they may have speculated that just as many men are depressed, only they deny it or turn to alcohol. It was reported in the 1930s to be more common in individuals of Jewish and Irish ethnicity and among those in upper socioeconomic strata, but subsequent studies have not confirmed these findings. The bipolar variant occurs in about 10 percent of patients with affective disorder. Patients in the bipolar group have an earlier age of onset, more frequent and shorter cycles of illness, and a greater prevalence of affective disorder among their relatives than do patients with unipolar disease (Wittchen).
paranoid delusions may be rampant; furthermore, as the term delirium implies, the patient may be disoriented, with a clouded sensorium. Fortunately, this extreme is rarely encountered. As mentioned earlier, one observes patients with repeated attacks of mania without depression at any time, but this is rare.

Hypomania represents a milder degree of the disorder, but this term is also used loosely to depict behavior in a normally functioning individual who is unusually energetic and active. In this latter sense hypomania is a personality trait found in many talented and productive persons and need not arouse concern unless it is excessive and out of character for the individual. This is best determined by questioning the family.

First attacks of either depression or mania last an average of 6 months if untreated, although the range of duration of attacks varies greatly. With modern therapy, this can be halved by more than half in most patients. Although most attacks of manio-depressive disease subside in a matter of months, a significant number, unipolar patients more than bipolar ones, remain chronically ill for long periods of time. According to Winokur and colleagues, 14 percent of their bipolar patients had not recovered after 2 years and 5 percent after 5 years. Comparative figures for primary unipolar patients were 19 and 12 percent, respectively. More than one-half of all depressed patients have one or more recurrences. Variables that are predictive of an unfavorable outcome are high degrees of neuroticism, long duration of illness before treatment, strongly positive family history, and presence of depression-provoking circumstances (Hirschfeld et al.).

Diagnosis

According to DSM-IV, the essential diagnostic criteria of endogenous depression ("major depressive syndrome") consist of a dysphoric mood or loss of interest or pleasure in all usual activities (including sexual activity) in combination with at least four of the following seven symptoms: (1) disturbance of appetite and change in weight; (2) sleep disorder; (3) psychomotor retardation or agitation; (4) decreased energy and fatigue; (5) self-reproach, feelings of worthlessness or guilt; (6) indecisiveness, complaints of memory loss and difficulty in concentrating; and (7) thoughts of death or suicide or actual suicide attempts. Each of the four diagnostic symptoms should have been present for at least 2 weeks.

Adherence to the aforementioned criteria undoubtedly facilitates diagnosis, but not infrequently a single one of these symptoms so dominates the clinical picture as to suggest the diagnosis of another disease state and obscure the presence of an underlying depression. As mentioned earlier, depressed patients who are referred to the neurologist tend to complain inordinately of physical and cognitive symptoms and to minimize or deny the purely affective ones.

Complaints of fatigue, weakness, malaise, or headache and achiness, for example, suggest variety of medical diseases, such as Addison disease, hypothyroidism, chronic infection, polymyalgia, early rheumatoid arthritis, etc. Often the fatigue state is misinterpreted as muscular weakness, and this directs a medical search for muscular or other neurologic disease. Similarly, complaints of persistent headache may suggest the presence of intracranial disease.

Complaints of poor memory, inability to concentrate, and other cognitive impairments raise the question of a dementia—until it is found, by careful examination, that mental competence belies the patient's appraisal of his own presumed deficits.

Hypochondriacal preoccupation with bowel and digestive functions accounts for repeated visits to the medical clinic. In one study, 21 of 120 such hypochondriacal patients were subsequently diagnosed as being depressed. Persistent insomnia may be the major complaint of the depressed patient. Early awakening is typical, and the sleep-deprived hours are then the worst period of the day. Other patients have difficulty falling asleep, especially if there is an associated anxiety state. A complaint in the male of loss of libido and impotence is another nonsymptomatic presentation; only with probing inquiry about other disturbances common to depression will the diagnosis become evident.

A number of psychologic testing scales are used to detect and score the severity of depression. Although they are utilized mainly for clinical studies and less for diagnostic purposes, several of them can be quite helpful in particular circumstances, since they are sensitive to one or another aspect of depression. They do not supplant the clinical examination in determining if an individual is depressed but may be helpful in differentiating depression from dementia and in detecting depression in cases where physical complaints are more prominent than psychic ones. The ones most familiar to neurologists are the Hamilton scale and the Beck scale, but others are used for research purposes.

In our experience, the following are some of the common and troublesome clinical situations in which it may prove difficult to recognize an underlying depression:

1. Patients with chronic pain. The association of chronic pain and depression has long been known. Patients who show this association are far from a homogenous group. The special case of chronic headache, confronted often by neurologists, is mentioned below. In some patients with chronic pain, the symptoms and signs of depression are quite apparent. If the pain has been present for less than a year and has had its onset at the same time as other depressive symptoms, response to antidepressant treatment is likely to be favorable.

Far more difficult to understand and to manage are patients with persistent pain as the only complaint; the head, face, and lower back are the most common loci. If an exhaustive search for the source of the pain proves unsuccessful, the conclusion is reached that the pain is "psychogenic." This attribution of pain to some obscure psychologic mechanisms, in the absence of any objective proof from a properly conducted neurologic examination, is generally unjustified. In a small proportion of such patients, pain will be alleviated by antidepressant drugs, suggestive, at least in these cases, of a linkage of the pain and depression.

In this group of patients, the problem is frequently made even more difficult by repeated surgical operations as well as dependency on analgesic drugs, which in themselves deplete energy and have other adverse effects. Such patients are to be found among those disabled after multiple operations for prolapsed intervertebral disc or arthritic hips or those with atypical facial pain. Where pain is the initial event (postherpetic neuralgia, for example), followed by chronicity of pain, abuse of drugs, chronic fatigue, and depressive symptoms, we tend to view the latter symptoms as reactive and direct our therapeutic efforts to the relief of both the pain and depression.

Intractable headaches may be the most prominent manifestation of depression. Weeks or months of unrelenting daily tension-type headaches in the context of a normal examination are highly suggestive of depression at any age.

2. Depression and alcoholism. These are commonly associated, and it is important to determine which is primary and which is secondary. A depressive syndrome developing for the first time on a background of alcoholism (secondary depression) is a very common clinical occurrence. In a large series of alcoholics studied by Cadoret and Winokur, secondary depressions occurred in 30 of 112 males; moreover, alcoholism was established, depression became evident much earlier in the women than in the men. The opposite occurrence (i.e., the development of alcoholism on the background of a primary depression) is less common. Again, women are disproportionately affected. Moreover, women with primary depression and subsequent alcoholism have a higher incidence of affective disorder in first-degree relatives (Schuckit et al.). As mentioned earlier, these differences may be spurious; Winokur's family studies suggest that the same genetic predisposition leads to depression in females and alcoholism and sociopathy in men.

3. Depression in childhood and adolescence. We have frequently observed depressed states in children, and they have often been misdiagnosed by both pediatricians and psychiatrists. The common manifestations have been chronic headache, refusal to go to school, withdrawal from social activities, anorexia, vomiting and weight loss, and scholastic failure. Nearly all of our cases of so-called male anorexia nervosa have proven to be due to depressive states. Puberty is a time of onset in many cases, but we have seen the disease in late childhood, and it is extremely frequent in high school and college students. It is a tragic mistake not to appreciate this fact and to be treating the patient for some presumed non-affective nervous symptoms, only to have the patient commit suicide. This has happened to more than a dozen of the children of our colleagues.

4. Anxiety neurosis, hypochondriasis, and pseudodemencia. There are several other clinical circumstances in which an underlying depressive illness may not be immediately apparent but must always be suspected. One of these is the relatively acute development of anxiety or hypochondriacal symptoms in a young person. These symptoms are discussed in detail in the preceding chapter. The complaint of severe chronic fatigue without medical explanation should raise the same suspicion (Chap. 24). And always to be kept in mind in an elderly person with seemingly early signs of dementia is that this may, on closer examination, turn out to be a severe depressive illness (pseudodemencia, page 453).

5. Depressive states with prominent affective and hallucinatory-delusional symptoms and disordered thinking—the so-called schizothymic or schizoaffective syndrome. As will be pointed out in the next chapter, most such states will eventually be identified as instances of manic-depressive disease. However, they do bring into question the validity of our current classification of major psychoses.
Etiology
The following are the main theories, not mutually exclusive, that have been proposed to explain the origin of depression.
Genetic Factors The capacity to experience sadness and depression is common to all people. Although there is no question that depression can be provoked by
misfortune and stressful life events, some individuals are more liable to depression than others who are subjected to similar psychosocial forces. In general, there
seems to be a familial diathesis for most depressive illness, but especially for unipolar and bipolar affective disorder. Adopted children whose biologic parents had
affective disorder were at greater risk of developing this disease than adoptees whose biologic parents were not affected ( Mendlewicz and Rainer; Cadoret). The
frequency of these illnesses is increased in the relatives of affected patients (prevalence rate of 14 to 25 percent in first-degree relatives). Furthermore, the type of
illness tends to breed true, at least in the bipolar form, which is more common among relatives of bipolar patients than among relatives of unipolar patients. Similarly,
the morbidity risk among first-degree relatives is increased (15 percent, in comparison to 1 to 2 percent risk in the general population). If all twin studies are taken
together, 72 percent of monozygotic twins are concordant for bipolar disease, compared with 14 percent of same-sex dizygotic twins; comparative figures for unipolar
disease are 40 percent and 11 percent, respectively (see Goodwin and Guze). All of these findings are indicative of a genetic factor. Although the exact pattern of
inheritance has not been defined, the authors, from their personal experience, believe that a dominant mode of heredity with incomplete penetrance is likely. The
gene(s) for manic-depressive disease remain to be discovered, and current theory holds that several of them are likely to be involved. One of the first indications that
specific genes may alter the susceptibility to depression has been presented by Ogilvie and colleagues. They found that allelic variations in the serotonin transporter
gene (the main target of the selective serotonin antidepressants) were associated with a greatly increased (sevenfold) risk of major depression. Not all studies agree
on these points. Other hypotheses postulate susceptibility loci on chromosomes 18, 21, and X. As already stated, a single gene locus seems highly unlikely (see
Sanders et al). However, findings such as these tie the genetic hypotheses to the biochemical ones, which are described next.
Biochemical Theories The biogenic monoamines (norepinephrine, serotonin, and dopamine) are the key elements in these theories. Following the observations that
the tricyclic antidepressants and the MAO inhibitors exert their effect by increasing norepinephrine and serotonin at central adrenergic receptor sites in the limbic
system and hypothalamus and that depression-provoking drugs (such as reserpine) deplete biogenic amines at these sites, the theory followed that naturally
occurring depressions might be associated with a deficiency of these latter substances. Furthermore it was observed that depressed patients and their first-degree
relatives, as well as healthy individuals, develop a greatly depressed mood after dietary depletion of the monoamine precursor tryptophan. Also noteworthy is the
finding that concentrations of 3-methoxy-4-hydroxyphenylglycol (MHPG), a metabolite of norepinephrine, are subnormal in the cerebrospinal fluid (CSF) of patients
with endogenous depression and elevated in manic states. Some neurochemical imaging studies, still preliminary, corroborate these findings. This view is supported
by the finding that 5-hydroxyindoleacetic acid (5-HIAA), a deaminated metabolite of serotonin, is reduced in the CSF of depressed patients ( Carroll et al). However,
the aforementioned CSF findings have not been consistent; in some patients with depressive illnesses, the CSF concentrations of bioamine metabolites are entirely
normal. Most of the neurochemical theories of depression have been the result of reasoning backwards from the known effects of antidepressants on various
neurotransmitters. Certain of the newer antidepressants are said to act as specific serotonin reuptake inhibitors and apparently produce their salutary effects by
increasing the amount of serotonin that is functionally available at the nerve terminals (the concentrations of norepinephrine are also increased). For these reasons,
serotonin and its pathways are currently most strongly implicated in the genesis of depression; however, the reader should be reminded that only a decade ago it was
widely held that depletion of norepinephrine fulfilled this role. It is also not yet clear which neurochemical alterations are primary deficiencies and which are
modulators of other systems. For example, recent work suggests that substance P plays an important role in the causation of depression ( Kramer et al) and that
blockade of substance P receptors has antidepressant effects.
Another set of observations, summarized by Schlesser and coworkers, seemed to implicate a disorder of hypothalamic-pituitary-adrenal function. In a series of cases
of endogenous unipolar and bipolar depressions, the parenteral administration of 1 to 2 mg of dexamethasone failed to suppress serum cortisol secretion while the
patient was ill but did so after recovery. In a comparable series of reactive depressions, there was a normal suppression of cortisol secretion. Dextroamphetamine
restored to some extent the normal response in the patients with endogenous depressions. Originally the dexamethasone suppression test was believed to separate
the two large groups of depressed patients and to predict the response to drug therapy. However, subsequent studies ( Amsterdam et al, Insel et al) showed that the
specificity of this test was less than earlier reports had indicated. Accumulated evidence now indicates that almost one-half of severely depressed patients do not
show suppression of cortisol secretion in response to dexamethasone administration; conversely, a positive test can be obtained in a significant number of patients
with other psychiatric disorders. Moreover, repeated testing in individual patients may yield variable results without apparent changes in the clinical state ( Charles et
al).
Sleep studies have disclosed that in approximately one-third of depressed patients there is a shortened time between falling asleep and the appearance of the first
period of rapid-eye-movement (REM) sleep, which is characterized by an increase in REM density (number of rapid eye movements) and duration. Also there is a
decrease in slow-wave (delta) sleep. Again, these abnormalities are not specific, occurring also in anorexia nervosa, narcolepsy, and schizophrenia.
Research on the amphetamines, cocaine, ECT, and lithium salts has also produced data that in general agree with the biogenic amine hypothesis. Although this
possibility has received much attention, it leaves several fundamental questions unanswered. How is a genetic abnormality translated into a disorder of biogenic
amines? Findings of the type reported by Ogilvie and colleagues, described earlier, may elucidate this relationship. Why are the therapeutic results so inconsistent
with the use of tricyclic antidepressants, the MAO inhibitors, and the serotonin reuptake inhibitors, all of which should favorably influence the balance of biogenic
amines at the proper receptor sites? And why are the clinical effects of these drugs delayed for weeks while the biochemical reactions are almost immediate? How
can one explain the observation that steroids play a part in the etiology of affective disorders? At the present time, it must be conceded that there is no reliable
biologic test for depression. One must resort to clinical analysis (i.e., the interpretation of symptoms and signs) not only for diagnosis but also for the differentiation of
special types of depressive reaction. Obviously, further knowledge of the metabolism and physiology of transmitter function of the biogenic amines is needed before a
complete theory can be developed.
Anatomic Correlates Attempts to establish a functional anatomy of depression have been fraught with problems of definition and methodology, but repeatedly the
cingulate and orbitofrontal cortices and other parts of the medial limbic system have been implicated. Some functional imaging studies have also show abnormalities
in the insular cortex, amygdala, and basal ganglia. Of all these abnormalities, hypometabolism in the left frontal cortex seems to be the most consistent. An intriguing
observation in this regard, and one that does not accord with the above, has been made by Bejjani et al in the course of deep brain stimulation for the treatment of
Parkinson disease. One of their patients displayed transient but overt manifestations of depression when high-frequency stimulation was delivered to the left
substantia nigra. Functional PET imaging during stimulation showed activation in the left orbitofrontal cortex and, briefly, in the left amygdala, globus pallidus,
thalamus, and right parietal lobe. Stimulation on the right side of the midbrain did not produce these symptoms. Functional changes of mania could not be produced.
Fisher noted a hypomanic episode in the early stages of herpes encephalitis, and numerous cases of secondary mania have been reported after stroke and after
brain trauma, the latter affecting mostly the right temporal lobe (see also page 1611). The reviews of Starkstein and Robinson and their colleagues, mentioned earlier,
may be consulted for further information.
Psychosocial Theories Many experienced psychiatrists have emphasized the importance of psychosocial factors in the genesis of depressive illness. Among
patients with primary depressive disorders, life events of a stressful nature were found to have occurred more frequently in the months preceding the onset of
depression than in matched control groups. In the study of Thomson and Hendrie, this was equally true of patients with a positive family history of depression and
those without such a history. Nor did patients with endogenous depression differ in this respect from those with reactive depression. Left unanswered is the question
of why some individuals are subject to a reactive depression. Are they predisposed by psychologic or personality makeup? Perhaps the genetically transmitted factor
is a heightened vulnerability to the effects of psychosocial stress. Epidemiologic data favoring one or another of these speculations are lacking. One is tempted to
conclude that many depressions being attributed to psychosocial stress are contaminating a group of endogenous depressions. Psychiatrists have also failed to find a
consistent correlation between depressive illness and personality type or a particular psychodynamic mechanism. In our view, the adoption studies noted above
diminish the importance of environmental factors.
Treatment
The physician untrained in psychiatry would be rash to undertake the management of manic-depressive disease or endogenous depression without the assistance of
a psychiatrist. However, if the symptoms are primarily neurologic (e.g., chronic headache, generalized weakness and fatigability), and if there is a low risk of suicide
and the patient rejects the idea of seeing a psychiatrist, it is appropriate for the experienced neurologist or generalist to institute treatment with antidepressant
medication. If there is any question of suicide, the patient should be hospitalized and, if necessary, involuntarily committed. Successive attacks of manic-depressive
illness are remarkably similar in the same individual, so that one can predict the course and intensity of an episode of illness on the basis of the previous one. If a
suicide attempt was made in the past, the probability is that another will be made.


If the depressed patient is psychotic (i.e., suffering from delusions or hallucinations) or is severely agitated, one of the antipsychotic medications (haloperidol, thioridazine, chlorpromazine, clozapine, risperidone) should be given initially, before other antidepressant treatment is instituted (see below).

Antidepressant Medication When first seen, many patients have already been given a sedative such as a benzodiazepine. These drugs may have assuaged the anxiety symptoms and the insomnia, but controlled studies indicate that they have little effect on the symptoms of depression. In the management of bipolar and unipolar disease, five main categories of drugs are in general use—the tricyclic antidepressants, an “atypical” or nontricyclic group of compounds, the MAO inhibitors, serotonin agonists (reuptake inhibitors), and lithium compounds. The pharmacologic properties and modes of action of these drugs have already been considered in Chapter 43. Additional points of therapeutic interest are mentioned here. Metanalyses of several large studies on the therapeutic effects of antidepressants have indicated that clinical improvement attributable to the drugs themselves occurs in only about one-half of the patients; remarkably, an additional improvement of up to 25 percent is attributable to placebo effect or to the natural course of the disease.

The tricyclic antidepressants comprise amitriptyline (Elavil), imipramine (Tofranil), doxepin (Sinequan), clomipramine (Anafranil), and trimipramine (Surmontil) and the closely related drugs desipramine (Norpramin), nortriptyline (Pamelor), and protriptyline (Vivactil). Among this group, most psychiatrists start with imipramine or amitriptyline because of their safety. In general, these drugs are equally effective, although an individual patient may have a better response to one than to another. The starting dose for these two drugs is 25 mg/day, which is then raised by 25 mg every 3 to 4 days as needed up to 150 mg/day. These drugs, taken at bedtime, alleviate insomnia. The therapeutic effect of tricyclic medication is often not evident for 2 to 4 weeks after treatment has been initiated, and it is important that this be explained to the patient and family. Common side effects are orthostatic hypotension, dry mouth, constipation, tachycardia, urinary hesitancy or retention (especially in patients with prostatic hypertrophy), tremor, and drowsiness. Closed-angle glaucoma may decompensate. Caution should be exercised in elderly patients with cardiac disorders of all types. For such patients, one of a newer group of nontricyclic antidepressant drugs—bupropion (Wellbutrin) and trazodone (Desyrel)—may be preferable. The latter drugs appear to be as effective as the tricyclic agents in the treatment of depression without the adverse anticholinergic and cardio toxic effects.

Many psychiatrists now prefer to begin treatment with one of the functional serotonin agonists—fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), citalopram (Celexa), and others, or one of a related group, exemplified by venlafaxine (Effexor) and nefazodone (Serzone). New ones of similar types are appearing yearly. These drugs have less sedating and anticholinergic effects than the tricyclic antidepressants. Fluoxetine has a tendency to produce insomnia and weight loss, making it particularly useful in the treatment of depressions that are characterized by overeating and hypersomnia. A few of our women patients have experienced an improvement of their sexual function by the use of fluoxetine. Differences in effectiveness of the SSRIs (selective serotonin reuptake inhibitors) and the monoamine oxidase inhibitors (MAOis) of this type may be significant. Fluoxetine may have an advantage in the treatment of depression with prominent anxiety symptoms and the insomnia, but controlled studies indicate that they have little effect on the symptoms of depression. Together, these mechanisms may be more effective in the treatment of depression. In a similar vein, fluoxetine would be a logical drug of choice for patients in whom lethargy is a prominent complaint. Certain side effects such as loss of libido or impotence occur in a proportion of patients and are difficult to differentiate from signs of depression.

If one of the aforementioned drugs, given in full doses for 4 to 6 weeks, does not produce the desired effect (or if the patient is intolerant of the drug), a drug from an alternative group, e.g., an MAO inhibitor, should be tried—but in the latter case only after a drug-free interval of 1 to 2 weeks. Some studies suggest that MAO inhibitors are superior drugs in depression with atypical features, such as increased appetite. Phenelzine (Nardil), iso urboxazid (Marplan), and tranylcypromine (Parnate) constitute the MAO inhibitor group, of which the first is the least likely to produce serious side effects. The usual starting dose is 15 mg tid, which is gradually increased as needed to a maximum of 45 mg tid. The most serious side effect of MAO inhibitors is a hypertensive crisis; therefore, these drugs should be dispensed with extreme caution in patients with hypertension and with cardiovascular or cerebrovascular disease. Patients taking these drugs should avoid foods with a high tyramine content (aged cheese, pickled herring, chicken liver, beer, wines, yeast extract) as well as medications containing sympathomimetic agents or L-dopa (decongestants, amphetamines, caffeine, or carbodopa-levodopa) and the aforementioned serotonin agonists.

Recently it has become popular to supplement the administration of conventional antidepressants with an anticonvulsant, particularly valproate or gabapentin, but also carbamazepine or phenytoin. There are few credible studies by which to judge the value of this strategy, but these drugs may provide some benefit, if only as anxiolytics. Many psychiatrists are the data suggesting that anticonvulsant drugs are useful in treatment of the manic state.

Since many patients are usually responsive to one of the tricyclic drugs, MAO inhibitors, or serotonin agonists but not to all of them, it is important to find out which of these drugs has been most helpful in the past. This will guide one in current management.

As already mentioned, response to antidepressant drugs is not expected for several weeks. Treatment should then be continued for 4 to 6 months and generally should be combined with some type of psychotherapy. The dosage should then be reduced slowly over a period of weeks. Rapid reduction may result in withdrawal symptoms (nausea, vomiting, malaise, and muscular pains). If symptoms recur upon withdrawal, the effective dose should be reinstituted.

Lithium Carbonate This is the drug of choice in treating the manic phase of manic-depressive disease, and it is useful also in preventing relapses of depression. Hospitalization is usually required to protect the manic patient from impulsive and often aggressive behavior, which might cause a loss of standing in the community or jeopardize his career. Chlorpromazine (Thorazine) and haloperidol (Haldol)—or ECT if these drugs are ineffective—can be used to control the mania until lithium can be started. The starting dose for these two drugs is 25 mg/day, which is then raised by 25 mg every 3 to 4 days as needed up to 150 mg/day. These drugs, taken at bedtime, alleviate insomnia. The therapeutic effect of tricyclic medication is often not evident for 2 to 4 weeks after treatment has been initiated, and it is important that this be explained to the patient and family. Common side effects are orthostatic hypotension, dry mouth, constipation, tachycardia, urinary hesitancy or retention (especially in patients with prostatic hypertrophy), tremor, and drowsiness. Closed-angle glaucoma may decompensate. Caution should be exercised in elderly patients with cardiac disorders of all types. For such patients, one of a newer group of nontricyclic antidepressant drugs—bupropion (Wellbutrin) and trazodone (Desyrel)—may be preferable. The latter drugs appear to be as effective as the tricyclic agents in the treatment of depression without the adverse anticholinergic and cardio toxic effects.

Electroconvulsive Therapy (ECT) and Transcranial Magnetic Stimulation ECT continues to be an effective treatment for severe endogenous depression and can also be used to interrupt manic episodes. The latter often requires only two or three treatments. The technique is relatively simple and safe in experienced hands. The patient is anesthetized by an intravenous injection of a short-acting barbiturate, benzodiazepine, or propofol and medicated with a muscle relaxant (succinylcholine). The patient is stimulated by a rectangular magnetic field, produced by a current of about 400 mA and 70 to 120 V is passed between them for 0.1 to 0.5 s. The succinylcholine prevents strong and injurious muscle spasms. The patient is awake within 5 to 10 min and is up and about in 30 min. The mechanism by which ECT produces its effects is not known. In treating depression, ECT is usually given every other day for 6 to 14 treatments. The only absolute contraindication is the presence of increased intracranial pressure, as may occur with a neoplasm or hematoma. Whether epilepsy is precipitated or worsened by ECT is still debated. This treatment should also be used cautiously in the presence of uncontrolled systemic hypertension or with a known sensitivity to anesthetic agents (malignant hyperthermia; page 1563).

The major drawback of ECT is the production of a transient impairment of recent memory for the period of treatment and the days that follow, the degree of impairment being related to the number of treatments given. Placing both electrodes on the nondominant side (unilateral ECT) or using lower amounts of current and a pulse rather than a sine wave may produce less memory disturbance but is thought to be less effective against the depression.

With the recognition that transcranial magnetic motor stimulation sometimes produced an elevation of mood, its use as a substitute for ECT was suggested. The magnetic technique has the great advantage of being free of any but minor physical effects, and since it produces no loss of consciousness, anesthesia and neuromuscular paralysis are not needed. Brief pulses of high-frequency stimuli are used. Few controlled studies have as yet been performed, but the initial results have been promising, and this technique could conceivably replace ECT. Whether it is as effective for severe depressions and catatonia is not yet known.

Until the advent of the antidepressant drugs, ECT was the treatment of choice for the agitated depression of middle and late life and for catatonia. Following a course of 6 to 14 treatments, close to 90 percent of patients recover within 2 months or less. Prior to the use of ECT, this type of depression might last for 2 years or longer before remission occurred. Since ECT is often complicated by confusion and amnesia, most psychiatrists favor the initial use of a neuroleptic agent, such as haloperidol, followed by a trial of an antidepressant before resorting to ECT. These trials, of course, must be conducted in a setting where the chance of suicide is
Psychotherapy

In all patients with manic-depressive disease, psychotherapy (frequently repeated explanations of the patient's illness, reassurance that the illness is self-limited, and encouragement) and instruction of the family are of value in helping both the patient and family to understand the illness and cope with it. As a general rule, manic-depressive illness is best managed by a physician who is willing to follow the patient over a long period of time and who is known to the family. Although the prognosis for any individual attack is relatively good, it is wise to arrange for a plan of action that will be set in operation at the first hint of a recurrence.

A more structured and problem-oriented approach to psychotherapy, utilizing “cognitive-behavioral” and “interpersonal” strategies, has gained considerable popularity since its introduction in the 1970s, by Aaron Beck. This approach, which draws to some extent on psychoanalytic theory, has been used not only in patients with depression but also in those with neuroses, chronic pain, sexual dysfunction, and other disorders. According to Blenkiron, cognitive-behavioral therapy is most effective in patients with mild to moderate (not chronic) depression, generalized anxiety and panic disorder, and obsessive-compulsive and phobic disorders. Essentially, in the short term, the therapist provides the patient with information on the nature of his illness, its common symptoms, and the active interventions that are to be undertaken to alter his specific cognitive distortions and the dysfunctional behaviors that spring from them. A detailed description of cognitive behavioral therapy is beyond the scope of a textbook of neurology, but the interested reader can find an extensive discussion of this subject in the current edition of Kaplan and Sadock's Comprehensive Textbook of Psychiatry (Sadock and Sadock, eds.). It is difficult to draw firm conclusions on the efficacy of any form of psychotherapy, but psychiatrists who practice cognitive-behavioral psychiatry attest to its efficacy. Noteworthy is the contrary opinion of Gabbard, that behavioral-cognitive psychotherapy has been shown in metaanalyses to be no better or worse than other forms of psychotherapy.

Suicide

Some 30,000 suicides are recorded annually in the United States, and attempted suicides exceed this number by about 10 times. All psychiatrists agree that these are conservative figures. Suicide is the eighth leading cause of death among adults in the United States and the second leading cause among persons between the ages of 15 and 24 years, figures that emphasize the importance of recognizing depressions that have a high potential for self-destruction. Every physician should be familiar with the few clues we possess to identify those patients who intend to end their lives. Some of the questions that should be broached in the interview were listed earlier (page 1613). Physicians must also be aware that the majority of suicides are accomplished by taking an overdose of prescribed medications, and great caution needs to be exercised in their prescription and administration.

Current opinion, summarized by Mann, indicates that suicidal intent is a special form of depression and that certain individuals are by nature susceptible as a result of neurobiologic factors. In other words, suicide is not simply a cognitive response to extreme stress or despondency. There is no way for the authors to judge this view, but proponents have pointed to particular indices of serotonin dysfunction that differ between depressed individuals who attempt suicide and those who do not. It has also been observed that the inception of modern antidepressant medications has not greatly altered the rate of suicide among depressed patients.

Manic-depressive psychosis, endogenous depression, depression resulting from a debilitating disease (particularly Huntington disease, cancer, and AIDS), pathologic grief due to the death of a loved one, alcoholism, or the existence of an organic disease such as alcoholism, cancer, heart disease, and progressive, incurable neurologic conditions all contribute to the risk of suicide. Thus, a portrait of a likely prospect for suicide might be a man in late adult life, in poor health through heavy drinking, recently widowed, who has attempted suicide before, and whose father committed suicide. However, no single one of these traits stands out as highly significant in terms of predicting suicide. As a consequence, we are left with our clinical judgment and index of suspicion as our main guides. The only rule of thumb is that all suicidal threats are to be taken seriously and all patients who threaten to kill themselves should be evaluated by a psychiatrist. The authors have found that important deterrents to suicide are devout Catholicism (suicide is a sin), concern about the suffering it would cause the family, and fear of death sincerely expressed by the patient.

Some physicians are reluctant to question depressed patients about the presence of suicidal thoughts on the grounds that this might upset them. More likely it is the physician who is upset by this questioning, for surely the mention of suicide will not alarm persons who are determined to end their lives or offend those with no such intention. Rather, a query of this type is apt to be appreciated by the depressed patient because it expresses the physician's concern and indicates that the patient's behavior is being taken seriously. Should a patient's manner or conversation raise a suspicion of suicidal intent, the issue should be quickly taken up by the physician. This in itself sometimes brings to awareness unrecognized suicidal urges. As emphasized above, if there appears to be an immediate danger of suicide, a bed should be obtained in a general hospital (preferably on the psychiatric ward) and a psychiatrist consulted. The point is to get the patient under cover until a psychiatrist can be obtained. If the patient refuses hospitalization, the family should be assembled, along with an intimate friend or clergyman if appropriate, to urge the patient's cooperation. Should all efforts fail, the only recourse is a commitment to a psychiatric ward. Commitment procedures and laws vary from state to state, but all provide for temporary confinement of individuals who are thought to be self-destructive. Although an action of this sort is bound to be stressful for all concerned, prudence and caution are more important than the patient's plea for freedom. Hard feelings engendered by a short period of enforced confinement sustain those who mourn the loss of a loved one through a preventable suicide are apt to be unforgiving.

Patients who arrive at the hospital having attempted suicide should be under constant surveillance once consciousness is regained, and a psychiatrist should be consulted. It is unwise to allow the family to keep watch unless their competence is unquestioned. Among patients who have been hospitalized because of a preoccupation with suicide, a particular danger attends the phase of recovery from depression, when the physician may be lulled into a false sense of security. As the patient recovers, the psychiatrist should assume the responsibility for setting up a program of therapy and arranging for transfer to a psychiatric ward, if this is necessary, or for outpatient treatment.

For the depressed patient with terminal disease, the authors believe in providing comfort by all possible means but not in assisting the patient to commit suicide.

CHAPTER REFERENCES

ANDREASEN NC, BLACK DW: Manic-depressive illness. In Robins's series of 134 patients who committed suicide, 47 percent had a depressive illness and 25 percent were alcoholic. Other series have recorded even higher rates of depression, alcoholism, and other forms of drug abuse (see Andreasen and Black).

Most suicides are planned, not impulsive. Furthermore, the intention of committing suicide is more often than not communicated to someone significant in the patient's life. In Robins's series, 4 out of 5 patients had made medical contact in the year before death. The message may be a direct verbal statement of intent, or it may be indirect, such as giving away a treasured possession or revising a will. It is known that successful suicide is three times more common in men than in women and particularly common among men over 40 years of age. Patients with a history of suicide in either mother or father carry a higher risk than those without such a history. A previous suicide attempt adds to the risk. Most successful suicides indicate as one of their motives "a concern about ill health." Chronic illnesses such as alcoholism, cancer, heart disease, and progressive, incurable neurologic conditions all contribute to the risk of suicide. Thus, a portrait of a likely prospect for suicide might be a man in late adult life, in poor health through heavy drinking, recently widowed, who has attempted suicide before, and whose father committed suicide. However, no single one of these traits stands out as highly significant in terms of predicting suicide. As a consequence, we are left with our clinical judgment and index of suspicion as our main guides. minimized. Following ECT therapy, maintenance therapy with a tricyclic compound, serotonin agonist, or lithium is necessary to prevent relapse.

Schizophrenia is among the most serious of all unsolved diseases. This was the opinion expressed almost 50 years ago in *Medical Research: A Mid-century Survey*, sponsored by the American Foundation. Because of a worldwide lifetime prevalence of about 0.85 percent and particularly because of its onset early in life, its chronicity, and the associated social, vocational, and personal disabilities, the same conclusion is probably justified today. (Carpenter and Buchanan)

**Definitions** Neurologists and psychiatrists currently accept the idea that schizophrenia comprises a group of closely related disorders characterized by a particular type of disordering thought, affect, and behavior. The syndromes by which these disorders manifest themselves differ from those of delirium, confusional states, dementia, and depression in ways that will become clearer in the following discussion. Unfortunately, diagnosis and classification of the condition are still in the formative stage. Psychologic disturbances largely unsupported by physical findings and laboratory data. This inevitably results in a certain diagnostic imprecision. In other words, any group of patients classified as schizophrenic will to some extent be "contaminated" by patients with diseases that only resemble schizophrenia, whereas variant or incomplete cases of schizophrenia may not have been included. Moreover, there is not full agreement as to whether all the conditions called schizophrenic are the expression of a single disease process. In America, for example, *paranoid schizophrenia* is usually considered to be a subtype of the common syndrome, whereas in Europe it is thought to be a separate disease.

**Historical Background** Present views of the disease we now call schizophrenia originated with Emil Kraepelin, a Munich psychiatrist, who first clearly separated it from manic-depressive psychosis. He called it dementia praecox (adopting the term introduced earlier by Morel) to refer to a deterioration of mental function, at an early age, from a previous level of normalcy. At first, Kraepelin believed that "catatonia" and "hebephrenia," which had previously been described by Kahlbaum and by Hecker respectively, as well as the paranoid form of schizophrenia, were separate diseases, but later, by 1886, he had concluded that these were all subtypes of a single disease. Onset in adolescence and early adult life and the chronic course, often ending in marked deterioration of the personality, were emphasized as the defining attributes of all forms of the disease.

Early in the twentieth century, the Swiss psychiatrist Eugen Bleuler substituted the term *schizophrenia* for dementia praecox. This was an improvement insofar as the term dementia was already being used to specify the clinical effects of another category of disease, but unfortunately the new name implied a "split personality" or "split mind," a feature thought by Morton Prince to be typical of a neurosis. Nonetheless, schizophrenia became and is still the accepted name for the disease. By the "splitting" of psychic functions, Bleuler meant the lack of correspondence between ideation and emotional display—the inappropriateness of the patient's affect in relation to his thoughts and behavior. (By contrast, in manic-depressive disease, the patient's mood and affect accurately express his morbid thoughts.) He also introduced the terms *autism* ("thinking divorced from reality") and *ambivalence* to describe particular aspects of schizophrenia, and called attention to a fourth syndrome, that of *simple schizophrenia*.

Bleuler believed that all the schizophrenic syndromes were composed of primary or basic symptoms, easily recognized as the "four A's" (loose associations, flat affect, ambivalence, and autism), and by secondary or "partial phenomena" such as delusions, hallucinations, negativism, stupor, etc. However interesting this formulation proved to be, the psychologic abnormalities are so difficult to define precisely that this arbitrary division has been of only mnemonic value.

Other early theories were those of Adolf Meyer and Sigmund Freud. Meyer, who introduced the "psychobiologic approach" to psychiatry, sought the origins of schizophrenia, as well as other psychiatric syndromes, in the personal and medical history of patients and their habitual reactions to life events. Freud viewed schizophrenia as a manifestation of a "weak ego" and an inability to use the ego defenses to handle anxiety and instinctual forces—the result of a fixation of libido at an early ("narcissistic") stage of psychossexual development. Berze in 1914 singled out the "insufficiency and lowering of all psychic activity" as being the fundamental defect in schizophrenia and attributed it to organic damage of unknown nature. None of these theories has been corroborated, and none ever gained widespread acceptance.

In 1937, Langfeldt advanced the important concept that schizophrenia consists principally of two different types of psychosis—namely, (1) a type that corresponds to the disease considered briefly above, i.e., Kraepelin's dementia praecox and Bleuler's schizophrenia (characterized essentially by early onset of anhedonia and asociality and by a poor prognosis), and (2) a type that occurs acutely, on a background of a stable premorbid personality, often with clouding of consciousness, prominent delusions and hallucinations, and demonstrable precipitating factors. For the second type, which could be a manifestation of several diseases, Langfeldt proposed the term *schizophreniform psychosis*. Cases of the latter type tend to have a favorable prognosis. Subsequent studies validated this distinction, as indicated further on.

A more contemporary biologic approach to the phenomenology of schizophrenia has involved the isolation of the many persistent mental and behavioral features and subjecting them to factor analysis. This has disclosed three clusterings of symptoms: (1) so-called negative symptoms of diminished psychomotor activity (poverty of speech and spontaneous movement, flatness of affect); (2) a "disorganization" syndrome, or thought disorder (fragmentation of ideas, loosening of associations, tangentiality, and inappropriate emotional expression); and (3) reality distortion, comprising hallucinations and delusions or so-called positive symptoms (Liddle and Barnes). A separation of behavior into "positive" and "negative" symptoms was at one time thought to be useful in distinguishing among the types of schizophrenia and perhaps to reflect dysfunction of different neurochemical systems, but this view is an oversimplification (see review by Andreasen). Although there may still be disagreement as to whether each of these groups of symptoms is primary or secondary, positive or negative, they do lend themselves to objective study and correlation with other biologic parameters. And these syndromes correspond more or less with the more conventional clinical views of schizophrenia, described below.

**Epidemiology** Schizophrenia is found in every racial and social group so far studied. The reported incidence rates vary considerably because not all psychiatrists have used the same diagnostic criteria. On average, 35 new cases per 100,000 population appear annually (Jablonsky). As indicated above, studies of prevalence suggest that, at any given time, 0.85 percent of the world population is suffering from schizophrenia, and expectancy rates are estimated to be as high as 1000 per 100,000 (i.e., one chance in 100 that a person will manifest the condition during his or her lifetime).

Schizophrenic patients occupy about half the beds in mental hospitals—more hospital beds than are allocated to any other single disease. They constitute 20 to 30 percent of all new admissions to psychiatric hospitals (100,000 to 200,000 new cases per year in the United States); at any one time, about 300,000 such patients are in hospitals and 1.5 million are living outside. The age of admission to hospital is between 20 and 40, with a peak at 28 to 34 years. The economic burden created by this disease is enormous—In 1990, the direct and indirect costs in the United States were estimated to be $33 billion (Riepe and Keith).

The incidence of schizophrenia has remained more or less the same over the past several decades. Males and females are affected with equal frequency. For unknown reasons, the incidence is higher in social classes showing high mobility and disorganization. It has been suggested that deteriorating function caused by the disease results in a "downward drift" to the lowest socioeconomic stratum, where one finds poverty, crowding, limited education, and associated handicaps; but the
same data have been used to support the idea that schizophrenia can be caused by such social factors. The fertility of schizophrenics, formerly lowered by institutionalization, is now approaching that of the general population, which will probably result in a decrease in the number of cases.

The Clinical Syndrome of Schizophrenia

Included in the early definitions of the disease, both of Kraepelin and of Bleuler, were a characteristic premorbid personality, an insidious onset of the more flagrant symptoms in adolescence or early adult life, and a chronic but fluctuating course with a tendency to progressive deterioration. Both regarded hallucinations and delusions as secondary or accessory symptoms that could be absent, as in their “dementia praecox simplex” or “simple schizophrenia.” They emphasized the absence of the more florid aspects of perception, orientation, and cognitive functions, which played such a large role in other cerebral diseases. Embodied in both their definitions was the concept of disease (rather than a psychopathologic reaction) characterized by a poor prognosis and a unique constellation of symptoms different from those of delirium, confusion, depression, mania, dementia, and other brain diseases.

Attempts to apply these diagnostic criteria met with difficulty, especially when hallucinations and delusions were absent. In order to overcome this difficulty, Schneider proposed that the distinction between primary and accessory manifestations be abandoned. He attached importance and reliability to the occurrence of auditory hallucinations, perceptual delusions (misinterpretation of what the patient hears and feels), and disturbances of thinking, often reflected in the experience that one’s thoughts and actions are being broadcast and are not one’s own but influenced by some outside agency (experiences of alienation and influence). This constellation of symptoms, which was precise and easy to recognize, came to be known as Schneider’s first-rank symptoms of active schizophrenia.

Strict adherence to Schneider’s diagnostic criteria, when applied to a group of patients admitted to the hospital with a diagnosis of schizophrenia, served to distinguish two groups of patients; those with and those without first-rank symptoms. The former responded more poorly to treatment and required a more prolonged period in hospital and higher doses of neuroleptic drugs than the latter. The two groups correspond closely to the two categories of schizophrenic disorders recognized by Robins and Guze on the basis of prognosis. The Schneider-positive, poor-prognosis schizophrenia (also referred to as nuclear or process schizophrenia) corresponds closely to Kraepelinian schizophrenia; many of the Schneider-negative patients with good prognosis are probably suffering from some other nonschizophrenic illness or the so-called schizophasiform illness of Langfeldt or manic-depressive disease (“hympanic psychosis”) (see Chap. 57).

From the neurologic point of view, the central abnormality in schizophrenia appears to be a special disorder in the perception of one’s self in relation to the external world. It is unlike the condition that prevails in delirium and other delusional states, dementia, and depression. Some patients with chronic schizophrenia, before the onset of a florid psychosis or when in remission, show none of the schizophrenic first-rank symptoms and—during brief testing of mental status—might even pass for normal. But on long-term observation they are vague and preoccupied with their own thoughts. They seem unable to think in the abstract, to fully understand figurative statements such as proverbs, or to separate relevant from irrelevant data. There is a circumscription in the pertinacity and tangentiality about their remarks. They fail to communicate their thinking; they pass from one topic to another superficially, with unrelated thoughts, which are confused with the voice or are blended together or confused in an illogical way. Opposites may be considered as identical, and conceptual relationships are distorted. In an analysis of a problem or a situation, there is a tendency to be overinclusive rather than underinclusive (as happens in dementia). In conversation and in writing, the trend of an argument or thought sequence is often incorrect and inappropriate to the setting or to the disorder of the patient’s behavior. Thinking is unremitting and incoherent. Some parts of the patient’s thinking are reflected in the patient’s behavior; there is a general deterioration in functioning, social withdrawal and at times bizarre actions, idleness, self-absorption, and amnesia. Lack of initiative, drive, and interest, blunting of affect, and anhedonia are subtle features that may pass unnoticed.

In more severely affected schizophrenics, thinking is even more disintegrated. They appear to be totally preoccupied with their inner psychic life (autism) and may do no more than utter a series of meaningless phrases or neologisms, or their speech may be reduced to a “word salad.” They are unable to attend to any task or to concentrate, and their performance is interrupted by sudden “blocking” or by insertion of some extraneous idea or inexplicable act, somewhat like that observed in a severely confused or delirious patient. At times these patients are talkative and exhibit odd behavior; at other times they are quiet and idle; in the extreme, the patients may be mute and immobile, i.e., catatonic. From the neurologic point of view, the central abnormality in schizophrenia appears to be a special disorder in the perception of one’s self in relation to the external world. It is unlike the condition that prevails in delirium and other delusional states, dementia, and depression. Some patients with chronic schizophrenia, before the onset of a florid psychosis or when in remission, show none of the schizophrenic first-rank symptoms and—during brief testing of mental status—might even pass for normal. But on long-term observation they are vague and preoccupied with their own thoughts. They seem unable to think in the abstract, to fully understand figurative statements such as proverbs, or to separate relevant from irrelevant data. There is a circumscription in the pertinacity and tangentiality about their remarks. They fail to communicate their thinking; they pass from one topic to another superficially, with unrelated thoughts, which are confused with the voice or are blended together or confused in an illogical way. Opposites may be considered as identical, and conceptual relationships are distorted. In an analysis of a problem or a situation, there is a tendency to be overinclusive rather than underinclusive (as happens in dementia). In conversation and in writing, the trend of an argument or thought sequence is often incorrect and inappropriate to the setting or to the disorder of the patient’s behavior. Thinking is unremitting and incoherent. Some parts of the patient’s thinking are reflected in the patient’s behavior; there is a general deterioration in functioning, social withdrawal and at times bizarre actions, idleness, self-absorption, and amnesia. Lack of initiative, drive, and interest, blunting of affect, and anhedonia are subtle features that may pass unnoticed.

Highly characteristic of schizophrenia is the patient’s expression of remarkably unusual experiences and ideas. The patient may express the thought that his body is somehow separated from his mind, that he is not himself, that his body belongs to someone else, or that he is unsure of his own identity or even sex. These experiences have been called depersonalization. Thought insertion, wherein it seems to the patient that an idea has been implanted into his mind, or thought withdrawal, wherein an idea has been extracted from his mind by an outside agency, are other parts of this state. Closely related, and characteristic of schizophrenia, are the ideas of being under the control of some external agency or being made to speak or act in ways that are dictated by others, often through the medium of radar, telepathy, and so on (passivity feelings). Frequently, there are ideas of reference—that the remarks or actions of others are subtly or overtly directed to the patient. Finally, the patient may feel that the world about him is changed or unnatural, or his perception of time may be altered, not in a brief episode like the jamais vu of a temporal lobe seizure, but continuously. This is the phenomenon of derealization.

Auditory hallucinations are frequent; they consist of voices that comment on the patient’s character and activities and are usually accusatory, threatening, or claiming control of the patient’s actions. The voices may or may not be recognized; they may belong to one person or two or more persons who converse with the patient or with one another. Seldom can the voices be localized to a point outside the patient. Instead, they seem to come from within the patient, in which case they cannot be distinguished from his own feelings and thoughts. Certain somatic hallucinations and delusions may predominate. Visual, olfactory, and other types of hallucinations also occur but are much less frequent. The patient believes in the reality of these hallucinations and often weaves them into a delusional system.

Of recent interest has been the related belated affirmation of the importance of negative symptoms in schizophrenia. Liddle and Barnes, looking objectively at all aspects of schizophrenic thought and behavior, divided them into four groups: (1) flat affect, diminution in expressive gestures, latency of response, physical asynergia, reduced spontaneous movements, apathy, restricted recreational activities, inability to feel intimate or close, and motor retardation. These negative symptoms correlated with reduced activity in the frontal lobes and the organization of thought, incoherence, inappropriate affect, illogicity, bizarre behavior, aggression, agitation, and tangentiality. These abnormalities are nonfrontal. (2) Hallucinations and delusions that the patient’s mind is being read and that his thoughts are being extracted from his mind or being controlled or broadcasted. (4) Suspicion, hostility, and delusions of reference. These authors also found an overlap of symptoms from one syndrome to another, i.e., the four syndromes can coexist in various combinations. However valid such subdivisions prove to be, they are of importance in offering a more neurologic approach to schizophrenia and in directing attention to the functional anatomy and physiology of particular neuronal systems in the brain (see further on; also Friston et al.).

The behavior of the individual experiencing these ideas and feelings is correspondingly altered. Early in the course of the illness, normal activities may be slowed or interrupted. No longer does the patient function properly in school or at work. Associates and relatives are likely to find the patient’s complaints and ideas disturbing. The patient may be idle for long periods—preoccupied with inner ruminations—and may withdraw socially. A panic or frenzy of excitement may lead to an emergency ward visit (a high degree of anxiety occurring for the first time in a young person should always raise the suspicion of a developing schizophrenia); or the patient may become mute and immobile, i.e., catatonic. However, attacks of catatonia are infrequent, and lack of will, drive, assertiveness, etc., is more characteristic of the disease.

Much has been said of the patient’s ability to hallucinate. Usually the subject is said to be “flat,” i.e., the patient’s manner is bland or aphatic; he may casually express ideas that would be disturbing to a normal person, even smiling or laughing over a morbid idea. To the authors, this patient not only has an impressive feeder of the mind. Often one observes agitation and an appropriate display of emotion in response to a threatening hallucination or delusion, although later there appears increasing indifference and preoccupation, as though the patient had become inured to the abnormal thoughts and feelings.

Other behavioral and delusional features are discussed in relation to the special types of schizophrenia.

Subtypes of Schizophrenia

Psychiatrists have traditionally distinguished a number of subtypes of schizophrenia, although the usefulness of these distinctions has been questioned in recent years. Indeed, the various types may overlap or change during the course of the illness. And there are cases that do not conform entirely to the conventional subtypes recognized by Robins and Guze on the basis of prognosis. The Schneider-positive, poor-prognosis schizophrenia (also referred to as nuclear or process schizophrenia) corresponds closely to Kraepelinian schizophrenia; many of the Schneider-negative patients with good prognosis are probably suffering from some other nonschizophrenic illness or the so-called schizophasiform illness of Langfeldt or manic-depressive disease (“hympanic psychosis”) (see Chap. 57).

In the least florid form, the patient exhibits thought disorder, bland affect, social withdrawal, and reduction in speech and movement, all of
which impair work performance; however, hallucinations and delusions are absent. Poverty of psychomotor activity is the dominant feature. At this stage the diagnosis is often uncertain. A disorder of thinking may be difficult to elicit, but from time to time a peculiar idea emerges in conversation or is discovered in letters. Objective study of thinking, by means of formal psychologic tests (Solovay et al.), has shown it to be "disorganized, confused, and ideationally fluid with many peculiar words and phrases." This is a refinement of Bleuler's characterization of "loosening of associations." Terms such as schizophrenic, schizotypal, and schizoid have been applied to this form of the illness. This seems to be an extension of the childhood schizoid personality traits into adolescence. Eventually, an outbreak of flagrant hallucinations and delusions occurs—an acute schizophrenic episode that brings the patient to the attention of a physician. The patient usually needs to be hospitalized and be given medication because of a suicidal or, rarely, homicidal attempt or some other unexpected behavioral abnormality. As a rule, a remission occurs within a few weeks or months of treatment, but at a level of function which is expected on the basis of his natural abilities and intelligence, and he continues to be lacking in normal drive, initiative, and enterprise, much as he was before the outbreak. These patients attract notice because they behave in an odd manner, tending to remain by themselves ("toners"), making no effort to adjust to a social group at school or to find work, "have dates," or establish a family unit. If the parents do not provide support and protection, such persons drift from one menial job to another, always shy, withdrawn, and relatively indifferent to their surroundings. Some individuals of this type roam the streets and live in appalling conditions on the fringes of society.

Cata tonic Schizophrenia This, the most readily recognizable type of schizophrenia, is now quite rare. Characterized by an extreme diminution in psychomotor activity, it was originally described by Kahlib and considered to be a mental disturbance sui generis until Kraepelin recognized that it was another form of schizophrenia. The component of cases in which onset is relatively acute. In the remainder, after a long syndrome of slackening interest, apathy, and dreamy preoccupation, a state of dull stupor supervenes, with mutism, inactivity, refusal of food, and a tendency to maintain one position ("like a mummy") (catatopy). The facial expression is vacant, the lips are pursed; the patient lies supine without motion or sits for hours with hands on knees and head bowed (catatopy). If a limb is lifted by the examiner, it will sometimes be held in that position for hours (flexiblescerebra). Urine and feces are retained or there is incontinence. The patient must be tube-fed (or eat mechanically) and has to be dressed and undressed. Pinprick or pinch induces no reaction. Extreme negativism, every command being resisted, characterizes some cases. Echolalia and echopraxia are observed occasionally. Yet these patients may be fully aware of what is said to them or happening around them and will reproduce much of this information during a spontaneous remission or one induced by intravenous sodium amytal. Even if untreated, the patient, after weeks or months in this state, begins to act and talk more normally, and there is then rapid recovery. In certain phases of catatonia there may be a period of excitement and impulsivity, during which the patient may be suicidal or homicidal.

As mentioned, and for reasons that are unclear, this form of schizophrenia is now seen infrequently, and there is increasing recognition of the fact that many of its features are often manifestations of a depressive illness rather than of schizophrenia.

Disorganized, or Hebephrenic, Schizophrenia This was believed by Kraepelin to be a particularly malignant form. It tends to occur at an earlier age than the other varieties of schizophrenia. The onset is relatively acute. In the remainder, after a long syndrome of slackening interest, apathy, and dreamy preoccupation, a state of dull stupor supervenes, with mutism, inactivity, refusal of food, and a tendency to maintain one position ("like a mummy") (catatopy). The facial expression is vacant, the lips are pursed; the patient lies supine without motion or sits for hours with hands on knees and head bowed (catatopy). If a limb is lifted by the examiner, it will sometimes be held in that position for hours (flexiblescerebra). Urine and feces are retained or there is incontinence. The patient must be tube-fed (or eat mechanically) and has to be dressed and undressed. Pinprick or pinch induces no reaction. Extreme negativism, every command being resisted, characterizes some cases. Echolalia and echopraxia are observed occasionally. Yet these patients may be fully aware of what is said to them or happening around them and will reproduce much of this information during a spontaneous remission or one induced by intravenous sodium amytal. Even if untreated, the patient, after weeks or months in this state, begins to act and talk more normally, and there is then rapid recovery. In certain phases of catatonia there may be a period of excitement and impulsivity, during which the patient may be suicidal or homicidal.

There are, of course, other psychiatric illnesses in which paranoid delusions appear, notably manic-depressive psychosis, dementia, and delirium. Alcoholic auditory hallucinosis stands as a separate illness. There are, in addition, a special form of delusional disorder (paranoia) in which the individual is consumed by a single persecutory, grantiole, or amorous delusional illusion without any other disorder of thought. An exorbitant form is known as folie à deux, in which two closely related persons share a delusional system. These several types of paranoia are discussed further on in this chapter.

Acute Schizophreniform Psychosis A special problem arises in the diagnosis of a rapidly evolving psychotic syndrome with florid hallucinations and delusions that clear in several weeks or less, with or without treatment. This so-called acute schizophrenia most often turns out to be the initial attack of mania or intoxication with a psychotropically hallucinogenic drug, for which reason it is not accorded a separate subtype of schizophrenia. The resolution of the diagnostic dilemma often depends on the patient's premorbid status and the course of events that follows the acute episode. This topic is discussed further on under "Diagnosis," below.

Suicide in Schizophrenia That schizophrenia of all types carries a significant risk of suicide is not generally appreciated. In a 30- to 40-year follow-up study of surviving schizophrenia patients, 63 percent of the older group and 26 percent of the younger group showed a frequent occurrence of hallucinations and delusions. This was believed by Kraepelin to be a particularly malignant form. It tends to occur at an earlier age than the other varieties of schizophrenia. The onset is relatively acute. In the remainder, after a long syndrome of slackening interest, apathy, and dreamy preoccupation, a state of dull stupor supervenes, with mutism, inactivity, refusal of food, and a tendency to maintain one position ("like a mummy") (catatopy). The facial expression is vacant, the lips are pursed; the patient lies supine without motion or sits for hours with hands on knees and head bowed (catatopy). If a limb is lifted by the examiner, it will sometimes be held in that position for hours (flexiblescerebra). Urine and feces are retained or there is incontinence. The patient must be tube-fed (or eat mechanically) and has to be dressed and undressed. Pinprick or pinch induces no reaction. Extreme negativism, every command being resisted, characterizes some cases. Echolalia and echopraxia are observed occasionally. Yet these patients may be fully aware of what is said to them or happening around them and will reproduce much of this information during a spontaneous remission or one induced by intravenous sodium amytal. Even if untreated, the patient, after weeks or months in this state, begins to act and talk more normally, and there is then rapid recovery. In certain phases of catatonia there may be a period of excitement and impulsivity, during which the patient may be suicidal or homicidal.

Remissions and Exacerbations Some schizophrenic patients are subject to periodic exacerbations of their illness, sometimes at regular intervals, as though their illness were determined by a metabolic disorder. Functional remissions are more frequent and lasting when medication is given and long institutionalization is avoided. Many such patients settle into a chronic hallucinatory psychosis with disorders of thinking, featured by mis-trust and suspiciousness. They appear cold, aloof, and indifferent.

Many psychiatrists, impressed with the lack of schizoid traits in the premorbid period and in the family history, have insisted that paranoid schizophrenia is a separate disease. The studies of Rosenthal and colleagues tend to bear them out. Also, the clinical and family studies of Winokur indicate that simple, catatonic, and hebephrenic schizophrenias are probably different illnesses from paranoid schizophrenia.

There are, of course, other psychiatric illnesses in which paranoid delusions appear, notably manic-depressive psychosis, dementia, and delirium. Alcoholic auditory hallucinosis stands as a separate illness. There are, in addition, a special form of delusional disorder (paranoia) in which the individual is consumed by a single persecutory, grandiole, or amorous delusional illusion without any other disorder of thought. An exorbitant form is known as folie à deux, in which two closely related persons share a delusional system. These several types of paranoia are discussed further on in this chapter.

Neurologic and Neuropsychologic Abnormalities in Schizophrenia

Recent research by Solovay et al. has provided new insights into the neurochemical abnormalities associated with schizophrenia. These abnormalities have been implicated in various cognitive and motor functions, including attention, learning, memory, and motor coordination. The findings suggest that schizophrenia is a complex disorder involving multiple neurotransmitter systems.

Further research by Murray et al. has shown that EEG abnormalities are more common in schizophrenia patients with a positive family history. These abnormalities may be due to alterations in the activity of the thalamus, which is involved in the regulation of sleep and wakefulness. The thalamus is a structure that plays a critical role in the modulation of sensory inputs to the cerebral cortex. Alterations in the activity of the thalamus may contribute to the disorganized thinking and affect seen in schizophrenia.

In summary, schizophrenia is a complex disorder involving multiple neurotransmitter systems, including dopamine, glutamate, and GABA. These abnormalities are thought to be implicated in various cognitive and motor functions, including attention, learning, memory, and motor coordination. Further research is needed to better understand the underlying mechanisms of schizophrenia and to develop more effective treatments.
problem solving, and memorizing. Cutting found a surprising degree of impairment in both acute and chronic schizophrenic patients (and in patients with retarded depression) not attributable to electroconvulsive therapy, seizures, drugs, or other diseases. In the acute schizophrenic patient, verbal memory was more affected than visual memory, in agreement with the findings of Flor-Henry that left-hemispheric functions are more reduced than right-sided ones; in the chronic schizophrenic, there was evidence of bilateral hemispheric impairment.

Theories of Cause and Mechanism

Although there is no universal agreement as to the cause of the disease, an increasing weight of evidence favors a genetic basis. There is also emerging evidence that a genetic predisposition may be only one of a number of factors in the etiology; in certain families, brain developmental, and psychosocial factors are also considered important. The evidence for each is presented below. A more detailed analysis of potential causes than can be given here may be found in the reviews of Waddington, of Carpenter and Buchanan, of Harrison, and, most recently, ofPearson.

Genetic Factors

The early studies of Kallmann showed that the frequency of schizophrenia in 5000 siblings of schizophrenic patients was 11 percent, in contrast to 1 percent (or slightly less) in the general population. In 90 sets of fraternal twins of whom one had schizophrenia, the incidence of disease in the other twin was also 11 percent, the same as in nontwin siblings; however, in 62 sets of monozygotic twins, the incidence in the second twin was 88 percent. In other words, the closer the resemblance, the higher the probability of the same illness in that individual. Thus, the risk that the child of a schizophrenic parent will develop schizophrenia is the same as that for the sibling of a schizophrenic patient (i.e., 11 percent); if one sibling and one parent have schizophrenia, the risk is 17 percent; if both parents are schizophrenic, the chances are 46 percent that the child will have the disease. Subsequent family and twin studies have repeatedly confirmed these findings (see Goodwin and Guze for a more complete tabulation). It is noteworthy that the penetrance of this inherited trait appears to be less than for manic-depressive disease.

Although the importance of genetic factors in the etiology of schizophrenia is undeniable, a mendelian pattern of inheritance has not been determined. Nor have any chromosomal loci or gene abnormalities been unequivocally incriminated by molecular genetic linkage analysis (Kendler). Several sites, particularly on chromosomes 6 and 13, seem to confer some susceptibility to developing the disease but are in themselves inadequate to explain its occurrence. One of these, an allelic variation in the gene that codes for serotonin receptors, is appealing because it ties genes with neurochemical changes, as discussed further on.

There has been much discussion in the medical literature concerning the relative importance of genetic and environmental factors in the causation of the disease. The lack of complete concordance between monozygotic twins and the fact that approximately 80 percent of patients diagnosed as schizophrenic have no other family members with the disease indicate that factors other than genetic ones must play a role. In the study of Rosenthal et al., a group of children of schizophrenics were removed at an early age from their natural parents and placed in adoptive homes; these children were compared with a group of adopted children whose natural parents had no known psychiatric disease. Follow-up observations disclosed that the incidence of schizophrenia in the first group of children was about twice that in the second. In two similar studies, both Karlsson and Heston showed that children who were separated early in life and reared apart from schizophrenic parents had the same disposition to schizophrenia (11 percent) as children raised in the homes of their biologic parents. Fischer approached the problem differently. Only one of a twin was schizophrenic, the other was studied; the incidence of schizophrenia in the children of the nonschizophrenic member of the twin pair was the same as that in the children of the schizophrenic member.

Developmental Abnormalities

The neuropsychiatric literature contains numerous bits of evidence that schizophrenia is a developmental disorder consequent upon brain injury during the intrauterine or neonatal period. Reportedly there is an increased incidence of complications during the gestational period and birth of schizophrenics. Others have proposed that damage to the temporal lobes from intrauterine or perinatal injury or a genetic factor that predicates both the injury and mental disorder is involved. In the northern latitudes, more schizophrenics are born in the winter months and to women who were exposed to influenza during midpregnancy—inviting speculation that a viral infection may have damaged the fetal brain. Mortenson and colleagues reported on a series of children born in particular in February or March, carried with it a higher risk for developing the disease than having an affected parent or sibling. They suggested that these inexplicable demographic features accounted for more cases than did inheritance. Jones and colleagues reported on a cohort of 5362 infants who were followed prospectively since their birth in 1946. As a group, the 30 individuals who later developed schizophrenia were delayed in the attainment of motor milestones and speech and exhibited greater social withdrawal and schoolroom anxiety as well as lower scholastic achievement. Thus it appears that schizophrenic patients are not normal in early childhood, but whether their abnormalities are already early manifestations of schizophrenia or risk factors for the disease has not been determined.

Neurotransmitter and Metabolic Abnormalities

When certain hallucinogens, such as mescaline and lysergic acid diethylamide (LSD), were first observed to induce hallucinations and abnormalities of thinking, it was hoped that these drugs might provide experimental models of schizophrenia. This hope was never realized, but there are instances, difficult to interpret, in which these drugs induced a prolonged relapse in a schizophrenic patient. Similarly, when methionine, a potent source of methyl groups, was observed to exaggerate some of the symptoms of schizophrenia, it was thought that a primary metabolic fault had been discovered; increased serum concentrations of dimethoxyphenylethylamine and N-methylated indoleamines lent support to this idea. Again, none of these observations has been unequivocally corroborated.

The leading biochemical hypothesis has been based on the response of psychotic symptoms to phenothiazine medications, which allegedly implicate the dopaminergic system of the temporal lobe (see review of Carlsson). The evidence for this hypothesis is circumstantial but is supported by observations that antipsychotic drugs reduce the electrical activity of mesolimbic dopaminergic neurons in experimental models. Further, there have been several demonstrations of increased concentrations of dopamine or its metabolite, homovanillic acid, in schizophrenic brains obtained at autopsy. The finding that dopamine receptors are organized in two systems, one mesolimbic and the other mesocortical, led to an expanded but purely speculative hypothesis that an excess of dopaminergic activity in the mesolimbic system gives rise to the positive symptoms of schizophrenia—i.e., psychosis—whereas a diminished activity in the mesocortical system accounts for the negative symptoms. The involvement of the mesolimbic system, which plays a role in attention, has prompted further speculation that the thought disorder of schizophrenia is attributable to a breakdown of the normal “filtering” of stimuli reaching cognition. Yet another theory, seeking to explain the late-adolescent onset of schizophrenia, supposes that intralimbic damage to temporal lobe dopaminergic pathways is somehow unmasked by the developmental changes that occur during this period of life.

Since the antipsychotic drugs display an affinity for dopamine receptors, it has been widely concluded that these drugs produce their therapeutic effects (and side effects) by receptor blockade. Other hypotheses have proposed a reduction in dopaminergic transmission, implicating neurotransmitters such as norepinephrine, acetylcholine, serotonin (see below), and gamma-aminobutyric acid (GABA), which interact or maintain a balance with dopamine. The many hypotheses concerning the role of dopaminergic and other neurotransmitters in the neuropathology of schizophrenia, none of them entirely convincing, have been reviewed by Sedvall and Farde.

Second only to the dopaminergic hypotheses of schizophrenia are the serotoninergic hypotheses. As with the dopaminergic model, attention was drawn to mechanisms relating to serotonin when a new class of antipsychotics (clozapine, risperidone), which have effects on the latter system, were found to ameliorate the psychosis. Several groups have reported alterations in serotonin receptors in the brains of schizophrenics (see below). A further connection is based on the finding by Williams and colleagues, of an allelic variation in the gene on chromosome 13 encoding for a serotonin receptor (5-HT) that confers a susceptibility to schizophrenia. A similar variation has been reported in a Japanese population, and for no other psychiatric disorder. The hypothesis was that many patients who are homozygous for the suspect allele do not have the disease and the allelic variations do not alter their protein product. Perhaps a nearby region relating to the receptor may be at fault through linkage disequilibrium (see commentary by Harrison and Geddes).

Also, there have been many attempts to isolate some metabolite or toxic substance from the blood of schizophrenic patients that could reproduce the clinical state when injected into nonschizophrenic subjects. Such positive results as were claimed have not been verified. From time to time an aminoaciduria, a folate or vitamin B12 deficiency, or some other condition has been discovered in a psychotic patient who is said to have schizophrenia, but isolated findings of this sort in patients in
whom the diagnosis can be questioned have little meaning. Usually such psychomotor psychoses are of brief duration, which is the reason why, in the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (DSM-IV), one of the diagnostic criteria of schizophrenia is that the symptoms must have been continuous for at least 6 months.

A great variety of physiologic and endocrine differences between schizophrenic and normal subjects have been claimed. None has proved to be significant. Psychoses may complicate corticosteroid administration and certain endocrine disorders (Cushing syndrome, thyrotoxicosis), there have been many attempts to uncover such abnormalities in the schizophrenic patient. All have failed.

**Psychosocial Factors** The notion that psychosocial factors play an important role in the genesis of schizophrenia was a recurrent theme in older psychiatric writings but is now given little credence. Prominent in these early writings was Freud's view, already mentioned, that the schizophrenic process represents a fixation at an early autogenic stage of sexual development. There is no way of affirming or refuting this proposition. The same can be said for the many suggestions that disturbed intrafamily relationships were responsible for engendering schizophrenic traits or possibly provoking psychosis in persons who are genetically vulnerable. Behind all these suggestions was the notion that disturbed interpersonal relations in the family in some way interfered with the normal maturation of personality. Adolf Meyer believed that schizophrenia was a reaction to a series of traumatic life situations—a maladaptive response to some organic, psychologic, or sociologic factor. Others have stressed the importance of disturbed interpersonal relationships. However, with all these hypotheses, proof is totally lacking that such environmental factors are unique to the development of schizophrenia. Furthermore, the extent to which these aberrations of family relationships are primary or secondary cannot be ascertained.

The often cited observations of Harlow on the deleterious effects of maternal and peer deprivation in primates suggested the notion that similar deprivations in human beings were responsible for the development of schizophrenia. However, such severe degrees of familial deprivation have rarely been documented in humans; when they were, as in some orphans, the effects were only transitory.

**Neuropathologic and Neurophysiologic Findings** Kraepelin conceived of schizophrenia (dementia praecox, in his terminology) as a disease process that was organic and progressive. For the following hundred years this insightful clinical judgment stimulated neuropathologists in a search for its histologic basis. Alzheimer and his pupils, who had access to Kraepelin's pathologic material, made a study of 55 cases, including 18 of the uncomplicated and 6 of the acute type. They noted hypertrophy ("amneoid" change) of the astrocytes, to which importance was attached because this change was not found in cases of manic-depressive psychosis. Further, in the cerebra of deteriorated schizophrenics, an outfall of neurons in the second and third laminae of the frontal cortex was described, along with nuclear swelling, shrinkage of cell bodies, and defects of lipofuscin. Similar findings were subsequently described by others.

Dunlap, in 1928, in a critical analysis, repudiated all earlier interpretations of these alterations. He pointed out that many changes, such as the dark "sclerotic" nerve cell bodies and the fact that lipofuscin was increased, along with the age change described by Alzheimer was based on impression and could not be corroborated by quantitative methods. Similarly, the claim of Oscar Vogt of neuronal loss in the cortex was rejected by his contemporaries, Spielmeyer and Scholz, who were unable to find any consistent cellular abnormality in schizophrenia. Spielmeyer, in a critical study of the problem in 1930, concluded that such changes had actually been described up to that time could not be clearly distinguished from the normal, and that the more marked changes in some cases were likely due to coincidental causes (age, complicating disease, etc.). Corsellis, on the basis of yet another review of the neuropathologic data in 1976, found no reasons to deviate from Spielmeyer's view. The uncertain meaning of the neuropathologic findings was responsible for the enigmatic categorization of schizophrenia as a "functional" disorder, i.e., a disorder with no structural basis.

The advent of computed tomography and subsequently of magnetic resonance imaging of the brain provided a new stimulus to the anatomic study of schizophrenia. Johnstone et al were the first to describe ventricular enlargement and sulcal widening in 18 patients and correlate these findings with dulling of intellect and affect. In a study of 58 chronic schizophrenics under the age of 50 years, Weinberger and colleagues found enlargement of the lateral ventricles in 40 percent. In 9 of 11 CT studies, the third ventricle was found to be enlarged, and in 14 of 17 studies, the sulci were widened. In 15 pairs of monozygotic twins, one of whom had schizophrenia, the anterior hippocampi were found to be smaller and the lateral and third ventricles larger in the affected twin (Suddath et al). Shenton and colleagues have demonstrated a reduction in the volume of gray matter in the posterior part of the left superior temporal gyrus, which includes Heschl's gyr and the planum temporale. The reduction in volumetric reduction of the superior temporal gyrus points to acquired developmental disorders. The reduction in volume of the superior temporal gyrus has also been associated with the occurrence of auditory hallucinations (Barla et al). Other MRI studies have shown a volumetric change in the gray matter of the left hippocampus, parahippocampal gyrus, and amygdala (in right-handed patients). Equally compelling is the finding that young individuals having two or more relatives with the disease, and therefore being at risk for developing schizophrenia, have certain volumetric brain changes detected by imaging studies (Lawrie et al).

In unaffected relatives, the left hippocampal-amygdaloid region was smaller than in normals and slightly larger than in affected relatives. In summarizing the many cerebral changes observed in schizophrenics, Harrison concluded that some are quite consistent. These include mild enlargement of the lateral and third ventricles; decreased cortical volume, perhaps disproportionate in the temporal lobe; and—microscopically—diminution in size of cortical and hippocampal neurons; a diminished number of neurons in the dorsal thalamus; and a notable absence of gliosis. There has been a general sense that the number of neurons in the gray matter is normal, but the pyramidal cells are smaller and more densely packed, resulting in a thinning of laminae II and III. The cytoarchitectonic changes have been the most difficult to interpret and to confirm. Capricious methods such as the rapid Golgi stain indicate that density of dendritic spines is decreased in the frontal and temporal cortices of chronic schizophrenics. The observations of Benes et al, pointing to cytoarchitectonic developmental disorders in fetal life, have already been mentioned under "Developmental Abnormalities."

There are also a number of neurochemical changes in the striatum and cortex, mainly in dopaminergic and dopaminergic receptor density, but all are probably attributable to treatment with dopamine blocking drugs. The exception may be a decrease in 5-HT receptors in the cortex, which is found even in untreated patients.

Detailed neuropsychologic testing has disclosed deficits in attention and abnormalities of the P300 waves (cortical "event-related" potentials). These deficits correlate with reduced cognitive activation function in functional MRI. It is unclear, however, if these changes represent primary defects or are secondary to an inherent lack of motivation.

From these neuropsychodiagnostic findings, Murray and coworkers have asked whether there are at least two types of this disease—one with ventricular enlargement and a negative family history and the other (approximately two-thirds of the whole group) with normal ventricles and a positive family history. In the first group of sporadic, "acquired" schizophrenia, environmental factors, such as birth injury and EEG abnormalities (see below), were thought to be more frequent. A special problem in all morphologic studies relates to the accuracy of the clinical diagnosis and whether the study was made on the brains of patients in the early or late (deteriorated) stage of the disease. As pointed out by Davison and Bagley, many of the psychologic and behavioral characteristics of schizophrenia occur in Wilson disease, Huntington chorea, temporal lobe epilepsy, chronic alcoholism, and other metabolic encephalopathies, such as the neuronal storage diseases. Hence one may be observing a clinical syndrome of multiple etiologies, some with an identifiable morphologic substratum. Theoretically, true schizophrenia may be attributable to treatment with dopamine blocking drugs. The exception may be a decrease in 5-HT receptors in the cortex, which is found even in untreated patients.

In a special problem in all morphologic studies relates to the accuracy of the clinical diagnosis and whether the study was made on the brains of patients in the early or late (deteriorated) stage of the disease. As pointed out by Davison and Bagley, many of the psychologic and behavioral characteristics of schizophrenia occur in Wilson disease, Huntington chorea, temporal lobe epilepsy, chronic alcoholism, and other metabolic encephalopathies, such as the neuronal storage diseases. Hence one may be observing a clinical syndrome of multiple etiologies, some with an identifiable morphologic substratum. Theoretically, true schizophrenia may be affecting the same regions of the brain but presently without a consistent demonstrable cytopathology.

Despite the uncertainties that still surround this subject, there can be no doubt, from the anatomic data outlined above, that schizophrenia is a neurologic disease and has lost its status as a purely "functional psychosis."

Finally, attention should be drawn to the regional alterations of cerebral blood flow in chronic stable schizophrenic patients, as revealed by positron emission tomography (PET) and functional MRI. Weinberger and colleagues and Liddle and Barnes have reported a decrease in blood flow in the frontal and temporal regions, while delusions and hallucinations were associated with reduced flow in the cingulate, left frontal, and temporal areas. Silbersweig et al have performed PET studies in schizophrenics while they were experiencing auditory hallucinations. They found an increased blood flow mainly in both thalami, left hippocampus and the right striatum, but also in the parahippocampal, orbitofrontal, and cingulate areas. One drug-naive patient with visual and auditory hallucinations showed activation.
Diagnosis

From a neurologic standpoint, the main distinction to be made is between an acute schizophrenia-like psychosis (schizophreniform reaction; "good-prognosis" schizophrenia) and the chronic disease schizophrenia (nuclear or "process" schizophrenia). The acute schizophreniform illness takes the form of a delusional hallucinatory syndrome in which there is little if any disturbance of consciousness. Although such a syndrome is characteristic of schizophrenia, it may occur in the manic phase of manic-depressive disease, encephalitis, temporal lobe epilepsy, chronic amphetamine intoxication, withdrawal from alcohol after a sustained period of intoxication, phencyclidine (PCP), lysergic acid diethylamide (LSD), and other drug intoxications; it is rarely seen in certain endocrine and metabolic disorders, in which consciousness is not impaired. Whenever this syndrome is recognized, therefore, these several causes need to be differentiated. At our hospitals, less than one out of five of the acute schizophreniform psychoses has proved to be due to the disease schizophrenia. This distinction is made by the premorbid history and the course of the illness. If the patient had been reclusive, withdrawn and socially maladjusted and does not seem to recover fully from the acute psychosis, then the diagnosis of schizophrenia is appropriate. Lacking these features, and in particular with a full remission, one assumes the occurrence of hypomania or of a toxic-metabolic psychosis, which can usually be detected by laboratory screening for drugs and endocrine diseases. Only 10 percent of patients with classic schizophrenia will have such an acute episode.

It is the present authors' opinion that the status of acute schizophrenia and of the so-called schizothymic and schizoaffective states brings to light a crucial nosologic problem. Namely, is the traditional separation of depressive disease, manic-depressive disease, and schizophrenia biologically sound? The suggestion is that they are linked in some way by these transitional forms. Neurologists should keep an open mind about these and other theoretical problems that lack a firm genetic and neuropathologic basis.

The presence of a chronic delusional-hallucinatory syndrome always raises the possibility of schizophrenia, but it must be remembered that in either chronic schizophrenia or the remittent form of the disease, delusions and hallucinations may be either absent or too subtle to be detected during a brief examination. Other data are required for diagnosis. Feighner and colleagues, who first drew up a set of diagnostic criteria for research in the major psychiatric syndromes (which were subsequently incorporated in successive editions of the DSM), stated that the diagnosis of schizophrenia is tenable only in the presence of (1) a chronic illness of at least 6 months' duration and a failure (after an acute episode) to return to the premorbid level of psychosocial adjustment, (2) delusions or hallucinations without significant perplexity or disorientation (i.e., without clouding of consciousness), (3) verbal productions that are illogical and confusing as to make communication difficult (if the patient is mute, diagnosis should be deferred), and (4) at least three of the following manifestations: (a) among adults, the lack of a partner or spouse; (b) poor premorbid social adjustment or work history; (c) family history of schizophrenia; or (d) onset of illness prior to age of 40 years. Important negatives include the absence of a family history of manic-depressive disease, absence of an earlier illness with depressive or manic symptoms, and absence of alcoholism, drug abuse, or other organic disease within a year of the onset of the psychosis.

While the Feighner criteria are so strict as to exclude certain patients with a schizophrenic illness, those who are included will be found to constitute a fairly homogeneous group. Morrison and colleagues, who used these criteria, noted that after a 10-year period there was practically no change in diagnosis; they had reached a well-individualized schizophrenia, schizophreniform psychosis (in which only the acute delusional-hallucinatory syndrome was present), and manic-depressive psychosis.

In addition to the acute schizophreniform psychosis described above, the authors have encountered the greatest difficulties in the diagnosis of schizophrenia in the following clinical situations:

1. A patient with a normal family and premorbid history with an acute illness having many of the typical features of schizophrenia but associated with confusion, forgetfulness, and/or clouding of consciousness. Mood change may be prominent. Thus the illness combines the features of an affective disorder, schizophrenia, and a confusional state. This syndrome is characteristic of corticosteroid psychosis (drug-induced or Cushing disease), thyrotoxic psychosis, puerperal psychosis, phencyclidine intoxication, and so-called combat fatigue of wartime. Usually recovery is complete, and schizophrenia is excluded by the fact that the patient remains well.

2. Adolescents and young adults whose social relationships are disorganized and who are unusually sensitive, resentful, rebellious, fearful, discouraged, in trouble with school authorities and the law, using drugs, etc. The latter may have caused seizures, hallucinations, and withdrawal symptoms or may have resulted in addiction. Such patients are usually classified as having a borderline personality or "character disorder" that appears to go back several years; if they are incorrigible, unable to profit by experience, amoral, and in trouble with social agencies, they are called sociopaths. This type of personality disorder and social maladjustment usually turns out not to be schizophrenia. The most dependable means of determining this fact at the time the patient is first seen is the strict application of the Feighner criteria for the diagnosis of schizophrenia.

3. There is the opposite type of diagnostic problem, arising in an individual who has been only marginally competent because of personality problems and many vague neurotic and hypochondriacal symptoms, often requiring prolonged psychotherapy. Many such individuals will indeed be found to have simple schizophrenia (called "pseudoneurotic" at one time). Here also errors in diagnosis usually result from a failure to assess mental status carefully and to ascertain the life profile of the disorder.

4. A chronic delusional-hallucinatory state in a chronic alcoholic patient. Usually the history will disclose that the illness began when alcohol was withdrawn, after a period of sustained drinking, and at first took the form of an acute auditory hallucinosis, characterized by threatening, exteriorized auditory hallucinations to which the patient responds as if they were real. It is appropriate to say that a few of these patients drift into a quiet hallucinosis, mildly paranoid state, with rather bland affect. Evidence of the prespsychotic schizophrenia cannot be detected, and there is usually no family history of schizophrenia. Cases of this type that we have studied had their onset between 45 and 50 years of age, i.e., much later than the age of onset of schizophrenia. For these reasons, this alcoholic, schizophrenia-like illness should be differentiated from the paranoid type of schizophrenia.

5. A patient who is confused or stuporous and seemingly negativistic, refusing or unable to speak, to execute commands, or to be activated in any way. If signs of focal cerebral or brainstem disease are absent, one is tempted to make a diagnosis of catatonic schizophrenia, not appreciating that catatonia as a phenomenon may be indistinguishable from akinetic mutism (page 370) and may also appear with widespread disease of the associational cortices and with severe depression, certain toxic-metabolic psychoses, and with classic schizophrenia.

6. A patient with temporal lobe epilepsy who, apart from intermittent psychomotor seizures, has long periods (weeks or months) of hallucinations, delusions, bizarre behavior, and disorganization of thinking. Such a mental disturbance often reflects the presence of a persistent state of temporal lobe seizures (temporal lobe status), which in some cases have been demonstrated by depth electrodes to originate in the amygdaloid or other medial temporal areas. Other types of psychopathology, such as sexual deviations, may also be associated with temporal lobe epilepsy. The nature of the disturbances of emotionality and mental status in such patients is discussed in Chap. 16 and Chap. 25.

7. Schizophrenics with prominent depressive symptoms who have made repeated suicide attempts pose an exceptionally difficult problem in diagnosis. They were referred to in the past as schizothymic, and to this day it is not certain whether they have schizophrenia, a relatively mild chronic depressive illness (dysthymia), depressive disease, or the past as schizophrenia and depression ("schizoaffective"). When in remission, patients with affective disorders are usually normal, whereas those with schizophrenia and many with schizoaffective states are not.

8. One should always be hesitant to make the diagnosis of schizophrenia during childhood, although such a diagnosis has been entertained in children who have a variety of developmental and adjustment problems and who at some time become psychotic, i.e., they become excited, depressed, or hallucinatory and express bizarre ideas. There is no evidence that such children go on to have schizophrenia later in life. And although what are thought to be "schizoid" traits may be recognized in childhood, a frank psychosis is hardly ever recorded at this age. Of particular importance in such children is to exclude the presence of metabolic errors, mental retardation, or an early onset depressive illness. Similarly, childhood autism and particularly its milder forms (Asperger syndrome, page 199) should not be confused with schizophrenia. The fact that the incidence of schizophrenia is not increased in the families of autistic children supports the idea that the two are separate diseases.
The aims of treatment are to suppress psychotic symptoms, ameliorate the disorder of thinking and the apathetic state, prevent relapse, and optimize social adjustment. It is often possible, once the diagnosis of schizophrenia is established and the optimal regimen of medication decided upon, for a general physician to share the responsibility for following the patient with a psychiatric social worker or nurse. The physician soon becomes accustomed to the particular pattern of the patient's behavior and can help support the patient and his family during difficult periods. Relapse with psychotic decompensation demands drug therapy, and if there is a hazard of injury or suicide or difficulty in management at home, hospitalization becomes necessary. Many general hospitals and specialized psychiatric institutions have facilities for the management of such cases; state hospitals and other institutions are able to provide long-term treatment. The aim of hospitalization is to protect the patient, relieve the family of the need for constant vigilance and supervision, and assure the administration of drugs until the exacerbation spends itself. Later, instead of mere custodial care, the patient needs a supervised program of planned activities, vocational and milieu therapy, etc., in a "halfway house," which involves the patient as a contributing member during the more chronic phases of the disease. If medication is successful in preventing progressive decompensation, the patient can often return to the family and community. It is helpful to have a competent social worker maintain frequent contact with the patient and his family.

The modern era of treatment of schizophrenia began in 1952, with the demonstration of the antipsychotic properties of the dopaminergic blocking agent chlorpromazine. Treatment consists essentially of the administration of this drug or one of several similar antipsychotic medications.

The various classes of antipsychotic drugs, their mode of action, and neurologic ("neuroleptic") side effects have been discussed in Chap. 43 (pages 1263 to 1265).

In recent years several "atypical" antipsychotic agents that have complex effects on dopamine and serotonin systems (clozapine, risperidone, quetiapine, etc., as noted below) have been added to the standard dopaminergic antagonists such as the phenothiazines and butyrophenones. They all serve to calm the patient, blunt his emotional responses, reduce hallucinosis and aggressive and impulsive behavior, leaving cognitive functions relatively intact. The main side effects, pertaining mostly to the phenothiazine group, are summarized in Table 58-1, and on page 1264. The antipsychotic action of these drugs is more impressive in the short and intermediate term, although some data suggest that they are also of value in preventing relapses. Negative symptoms (apathy and withdrawal) respond less well than positive ones, and it is generally acknowledged that 10 to 20 percent of patients respond little or not at all to medication.

Table 58-1 Neuroleptic side effects of the neuroleptic-antipsychotic drugs

The optimal daily dose for treatment of an acute psychotic episode is in the range of 10 to 20 mg daily of haloperidol or the equivalent amount (400 to 800 mg) of a phenothiazine such as chlorpromazine. The administration of much higher doses is popular with some psychiatrists but entails serious risks, and the advantages of this practice have not been demonstrated in controlled trials (see Kane and Marder). The same dose or lower doses are used to maintain remission. Attempts are then made to individualize and eventually to lower the dosage until the patient's behavior suggests that a relapse is imminent. Long-acting piperazine phenothiazines, given subcutaneously every week or two, are used in patients who are unable to take oral medication or refuse to do so.

Clozapine, olanzapine, risperidone, and quetiapine are more recently introduced drugs with incompletely defined pharmacologic properties but with narrower affinities for certain receptors. They have been shown to produce clinical improvement in about half of patients who have proved to be unresponsive to other antipsychotic medications. The drugs bind to and inhibit serotonin receptors (Meltzer and Nest) but have a lower affinity for striatal dopamine receptors, thus providing a major advantage—the absence of immediate or tardive extrapyramidal side effects. This has led some psychiatrists to use one of these drugs, rather than a phenothiazine, as a first choice. About 1 percent of patients treated with clozapine develop leukopenia, which may prove fatal; there appears to be less risk with olanzapine, but leukopenia and agranulocytosis have been reported in rare instances. Orthostatic hypotension, tachycardia, fever, and hypersalivation may be troublesome in the first days and weeks of therapy. Risperidone, another of the newer antischizophrenic drugs, is a potent serotonin and dopamine receptor antagonist. Low doses of this drug reportedly attenuate the negative symptoms of schizophrenia (apathy, emotional withdrawal, lack of social interaction), and the incidence of extrapyramidal side effects is low provided that the dosage is kept below 6 mg daily. Dosages of these antipsychotic drugs are indicated in Table 58-2.

Table 58-2 Newer antipsychotic drugs with limited extrapyramidal side effects

Antidepressants and lithium have been used in schizophrenic patients with prominent affective symptoms. Electroconvulsive therapy (ECT) is now seldom used except in patients who are catatonic or severely agitated or who have prominent affective symptoms, or, in exceptional instances, where there has been no response to medication.

Many of the extrapyramidal side effects of haloperidol and the phenothiazines can be prevented or at least minimized by the simultaneous parenteral administration of antihistaminic drugs—e.g., diphenhydramine (Benadryl), 25 mg tid—and the anticholinergic drugs used in the treatment of Parkinson disease—e.g., benzphetamine mesylate (Cogentin), 0.2 mg tid. However, the latter drugs must be given cautiously, for they may interfere with the action of the antipsychotic drugs and, if given in large doses, may themselves induce a toxic confusional state. If it becomes necessary to treat the extrapyramidal side effects, it is usually possible to eliminate the anticholinergic drugs after 2 to 3 months without a return of symptoms. In chronically medicated patients, 20 to 40 percent of whom develop tardive dyskinasias, an increased dose of the antipsychotic drug may suppress the dyskinesia, but only temporarily. The most dreaded complication of pharmacotherapy is the neuroleptic malignant syndrome. The nature and management of this syndrome and other tardive dyskinasias have been discussed on page 1265.

Supportive psychotherapy (repeated explanation, reassurance, encouragement) is of course necessary, as in any prolonged illness, and the family needs the same type of help. The physician should be understanding and sympathetic but also firm and professional. The general purpose of psychotherapy is to help the patient get
a grasp on reality and to strengthen his self-esteem and psychologic defenses. Psychoanalytic therapy has little to offer as a primary mode of treatment.

Outcome
With modern drug therapy and supportive psychiatric management, fully 60 percent of schizophrenic patients will recover sufficiently to return to their homes and become socially adjusted to a varying degree (about half of this group can engage in some occupation). About 30 percent remain helpless and severely handicapped and 10 percent remain hospitalized.

DELFUSIONAL DISORDER (PARANOIA)
The term paranoid (para = beside, nous = mind) literally means a mind beside itself (Day and Manschreck). It designates patients who show fixed suspicions, persecution delusions, domineering ideas or grandiose ideas strongly elaborated and with due regard for reality once the false interpretation or premise has been accepted. Further characteristics are formally correct conduct, adequate emotional reactions, and coherence of the train of thought (Rosanoff).

In other words, in pure paranoia (delusional disorder in DSM-IV), there is supposed to be no mental defect other than the delusional system—no dementia, hallucinations, or emotional disturbance. In past years, a large group of the mentally ill were classified as paranoid. But with advancing knowledge of mental illness, fewer and fewer have been left in this category.

The trouble that psychiatrists have taken to couch this definition in negatives implies that paranoia is frequently a feature of other forms of mental illness, notably schizophrenia, manic-depressive disease, Alzheimer disease, Lewy-body disease, toxic or alcoholic psychosis, general paresis, etc. This fact about paranoia was known from the beginning, when Heinroth originally described it in 1818 and classified it as a limited disorder of the intellect. Kraft-Ebing, in his monograph on the subject, took pains to distinguish two syndromes: (1) “original paranoia,” developing about the time of puberty and attributable to heredity (surely paranoid schizophrenia by present-day criteria), and (2) acquired paranoia, developing in later life, particularly in the involutional period (the condition under discussion). Kraepelin, in agreement with the ideas of Kahlaibum, distinguished between paranoia and dementia praecox but remarked that approximately 40 percent of patients who developed paranoia early in life went on to become schizophrenic. The others represented true paranoia or a closely related condition which he called paraphrenia, a term no longer used. In DSM-IV, this disorder is classified as “delusional (paranoid) disorder” and defined as a persistent delusion that is not part of any other mental disorder. Furthermore, the delusions are nonbizarre, i.e., they involve situations that could occur in real life, such as being followed, poisoned, infected, loved at a distance, or deceived by a spouse, or having a disease.

Figures on the frequency of true paranoia are probably not reliable because they are of necessity based on hospital records. Doubtless there are many individuals with mild forms of the disorder who have never crossed the threshold of a mental hospital. They are relatively harmless and in their communities are judged to be mildly “cracked,” or monomaniacs. Males and females are about equally affected. Among psychiatric hospital patients, true isolated paranoia is rare (0.1 percent of admissions, according to Winokur).

Clinical Manifestations
It would be inappropriate in a neurology text to give an account of all the many ways in which paranoiaics behave. A simple paradigm will suffice—that of a man whose sense of personal worth is undermined, brooding, ascetic, eccentric, condition of the individual who gradually develops a dominating idea or belief of his own invention, of having in his possession special powers that make him the envy of others, who become bent on persecuting him. As the delusion grows, he becomes more preoccupied, less efficient, and increasingly suspicious of others, with a tendency to interpret every one of their words, gestures, or actions as having some reference to himself. Only when his behavior becomes noticeably bizarre or when he does something to annoy others does his condition come to medical attention. On examining such a person, one is impressed with his capacity for careful reasoning, which betrays good intelligence. Whatever the type of delusional theme—erotomanic (a delusion that another person, usually of higher status, is in love with the patient), grandiose, jealous, persecutory, or somatic, the lasting the most common—the patient's arguments are logical and buttressed cogently by evidence. The patients express their false beliefs with certainly and conviction and are totally unaccepting of all arguments that impugn their rationality. Also, the views of such patients about matters other than their delusions can be quite sensible.

As was said, the illness usually does not lead to hospitalization, and if admitted to hospital, the patient does not stay long. The querulous paranoiaics are the most annoying. They are usually not successful in the community, accusing people with copies of documents or incessantly writing to newspapers, and expressing their worthless opinions about anything and everything. As the years pass, the patient changes little, though a few such patients may later break down and begin to hallucinate and finally end in a deteriorated state much like that of schizophrenia. This trend supports Bleuler's opinion that the illness is a variant of schizophrenia.

Regarding causation, there have been several interesting but unverifiable ideas. The Freudian school attributed paranoia to repressed homosexuality and fixation at the narcissistic level. Meyer invoked a long-standing personality disorder, the paranoid constitution. He used the term to refer to persons with a lifelong tendency to hold biased views, to be overly concerned about what others think of them, and to attribute deliberate intentions to indifferent actions. This behavior seems but an exaggeration of a mild suspiciousness that is part of the personality makeup of many individuals. Manschreck has presented a detailed discussion of the proposed psychologic mechanisms of paranoia.

The authors' experience with pure paranoia in a general hospital has been rather limited. One sees deluded patients, to be sure, but usually their abnormal ideas have centered on personal persecution, health and bodily functions, inferiority of a spouse, theft of possessions, and the like. The claim that poisoning by carbon monoxide has left the person with ill-defined defects in concentration and other mental functions or the belief that there exists an unobservable parasitic infestation have been common delusions in our experience. One of our patients, functioning normally in every other way, carried the unshakable idea that people were sneaking into her house at night and when she was away and rearranging the furniture. Physicians under our care have seen wondrous delusions like around tenous scientific theories; these ideas have applied to personal life events as well as physical and psychologic symptoms, and in some cases have resulted in peculiar regimens of self-medication. Rarely, a patient comes to the hospital for some other medical reason and it is found that he or she has been living quietly in the community, preoccupied with a bizarre delusional system yet appearing neither depressed nor schizophrenic. Certainly one often sees delusions in depressed patients who compensate as their depression worsens.
lasts for only a few days ("postpartum blues"), being quelled by the return home, responsibility for the infant, nursing, etc. In some patients the depressive symptoms persist for months (see below).

The period after childbirth is also one in which there is a strong disposition to psychosis. Opinion varies as to whether there is a special puerperal psychosis. Most psychiatrists believe that the psychotic break that may occur at this time is either a confusional-delirious state or a schizophreniform or depressive psychosis, and that these illnesses do not differ from those occurring at other times in life.

Additionally there occurs a psychosis that cannot be categorized in this way. Usually it has its onset between 48 and 72 h after a delivery that may have been complicated by excessive bleeding or infection. As such cases have their early depressions attacks only after delivery. Also, as consultants we have had the Boston Lying-In Hospital, we had observed a number of patients with an acute postpartum schizophrenic episode. These patients were without family history or prepsychotic schizoid personality and seemed to have a better prognosis than one usually expects in schizophrenia, i.e., they had "good prognosis" schizophrenia. These are only impressions, however.

In the diagnosis of postpartum psychosis, one must also keep in mind the possibility of eclampsia, the consequences of puerperal infarction, cerebral vein thrombosis or transitory stroke of arterial type, ergot-induced psychosis, and hypotensive-hypoxic cerebral injury.

**THE ENDOCRINE PSYCHOSES**

One of the most provocative observations in contemporary psychiatry is that apparently normal individuals may become psychotic when they develop hyper- or hypothyroidism or the Cushing syndrome (or less often, adrenal insufficiency), or when they receive therapeutic doses of corticosteroids. If these conditions were no more than examples of drug-induced psychosis, they would be interesting enough. The fact is, however, that they differ considerably from the usual toxic deliria or confusional states. The syndrome, somewhat reminiscent of puerperal psychosis and some cases of "combat fatigue" seen in wartime, comprises features that are suggestive of manic-depressive psychosis or schizophrenia on the one hand and of confusional psychosis on the other. These endocrine psychoses have far-reaching medical significance, for they provide artificial models of psychoses created by the manipulation of metabolic and by exogenous factors.

**Corticosteroid and Adrenocorticotropic Hormone Psychosis** First described in arthritic patients being treated with cortisone, these syndromes are now occurring far less frequently than when this hormone was introduced into medical practice. Presumably, ACTH and cortisone are now more purified, and there are more reliable data as to safe dosage. The psychosis usually develops over a period of a few days after the patient has received the hormone for a week or more. The features are easily recognized as the classic signs of depression and inanition. Adrenocorticotropic hormone has two effects. One is a marked reduction in the level of cortisone, which is the main hormone of the pituitary-adrenal axis in the body. The other is a marked increase in the level of ACTH, which is the hormone that stimulates the adrenal cortex to produce cortisone. These changes lead to a rapid decrease in the level of cortisone in the blood, which causes the depression and inanition. The depression is often accompanied by agitation, excitement, and a generalized disinhibition. The inanition is usually associated with severe weight loss and anorexia. The patient may become extremely drowsy and disoriented, with a marked decrease in the level of consciousness. The psychosis may last for weeks or months, and it may recur when the hormone is reinstituted. In some cases, the psychosis may last for years, and it may recur when the hormone is reinstituted. In some cases, the psychosis may last for years, and it may recur when the hormone is reinstituted.

**Thyroid Psychosis** A great deal has been said about the pervasive effects of abnormal thyroid function on all organs, including the neuromuscular apparatus and central nervous system. These effects are discussed in Chapter 40, under acquired metabolic diseases of the nervous system (pages 1199 to 1202). The hyperthyroid patient often shows minor changes in emotions and mental activity. Restlessness, irritability, apprehension, emotional lability, and at times even agitation and a generalized choria may occur. Either of two trends may be observed in the relatively rare thyrotoxic patient who develops a psychosis. There may be a manic state, with its characteristic increase in psychomotor activity, overtalkativeness, and flight of ideas, or there may be depression, with its somber mood, weeping, and anxiety. Visual and auditory hallucinations may be present in both groups. The clinical picture is seldom clear. Usually the psychiatrist finds something more than a state, with its characteristic increase in psychomotor activity, overtalkativeness, and flight of ideas, or there may be depression, with its somber mood, weeping, and anxiety. Visual and auditory hallucinations may be present in both groups. The clinical picture is seldom clear. Usually the psychiatrist finds something more than a

**ADDITIONAL READING**

To understand mental disorders, one must know something of how the brain functions, know something of human psychology, and at the same time be sensitive to the other human beings and have a sincere desire to help them. The first two of these objectives require special study; the latter are more innate qualities, found in all good physicians. Indeed, the attributes that exalt our profession are sympathy for the sick and the willingness to put the patient's welfare ahead of our own—attributes that meet their greatest challenge in dealing with the mentally ill.

Mental disorders pose a number of special problems not met in other fields of medicine. In the first place, there are such wide variations in personality, character, and behavior that the point where normal ends and abnormal begins is often difficult to ascertain. Second, the methods of studying mental illness are quite subjective, depending mainly on the physician's perceptions of the inner secrets and purposes of the patient and on the patient's powers of description and narration in revealing his symptoms; these latter capacities vary with intelligence, personality, education, and cerebral function. Finally, and most vexing to the neuropathologist, the clinical entity must be a correlate in the following chapters are for the most part unverifiable; neither by laboratory test nor by postmortem examination can one reliably corroborate their existence.

In attempting to study mental disorder, one must be aware of another, more abstruse and essentially theoretical problem. Here, physicians find that there are two different and seemingly antithetical approaches to disordered nervous function—one proceeding along strictly medical or neurologic lines, the other psychologic. They must learn to utilize two types of data, one drawn from observations of the patient's behavior, the other from the patient's introspections. It must be emphasized that the terms neurologic and psychologic in this context do not necessarily refer to the activities of neurologists and psychiatrists. They are merely convenient terms for two distinct modes of approach to mental disorders; both may be and are frequently used by the neurologist and the psychiatrist, as will be made clear.

The neurologic approach begins with the premise that all clinical manifestations of a nervous disorder are expressions of a pathologic process (disease) within the nervous system. This process may be obvious (such as a tumor or cerebral infarct), or it may be impossible to detect with the light or even the electron microscope (e.g., the patient's current delirium tremens, the untoward and unexplainable state into which the individual may fall in a crisis). It is the function of the physician, the neurologist, to demonstrate the relationship of the patient's symptoms to abnormal behavior patterns and reactions, and, by a kind of re-education, i.e., psychotherapy, to assist in understanding the patient's current behavior in the light of past experiences and to use this understanding to effect change. By frank discussion, the physician endeavors to comprehend the patient's inner world, to understand the patient's current behavior in the light of past experiences, and to use this understanding to effect change. By frank discussion, the physician endeavors to comprehend the patient's inner world, to understand the patient's current behavior in the light of past experiences, and to use this understanding to effect change.

Pathologic considerations have no place in such a formulation. The purpose of this approach is not only to determine causality—namely, psychogenesis—but also to demonstrate the relationship of the patient's symptoms to abnormal behavior patterns and reactions, and, by a kind of re-education, i.e., psychotherapy, to assist in bringing about an understanding of the problems and improved ways of coping with them.

A HOLISTIC AND ECLECTIC POSITION

It seems to the present authors that both the neurologic and the psychologic concepts and approaches have their place in medicine. But the two methods operate at different levels and are of principal use in different types of nervous aberrations.

In the diagnosis of a disease of the nervous system, one begins always with a careful recording of the symptoms and signs and their temporal aspects, obtained through a detailed history and physical and ancillary examinations. The interpretation of such data by the use of anatomic and physiologic data leads to diagnosis. Here the psychologic method is of little value and the neurologic method stands as the only valid system of analysis. It permits one to approach the problem of nervous system disease as one does any other medical problem.

It must be acknowledged, however, that special difficulties attend the diagnosis of psychiatric diseases. These illnesses are expressed mainly by symptoms—complaints about disturbing thoughts or feelings, or behavior that is disturbing to others. Seldom are there objective signs. Often patients are not consistent in what they say, and their behavior may change with time. Symptoms are always more liable to varied interpretation than are signs. Nevertheless the
physician must rely on the methodology of medicine, with due allowance for these added difficulties.

In theorizing about disease and investigating its causes, this broad neurologic or medical approach is essential, for it accepts data from all the medical sciences and is able to incorporate all the biologic as well as psychologic facts. It is supported by the realization that every known psychiatric symptom is reproduced by known central nervous system disease, and every major neurologic disorder can be thought of as a condition in which there is a visible lesion or in which there is reasonable evidence of its existence on the basis of stereotypy of clinical expression and of genetic and collateral laboratory data. Goodwin and Guze offer a slightly different definition of psychiatric disease—as any cluster of symptoms and signs that occur with such consistency as to permit the prediction of their outcome. An abnormal psychologic reaction is defined as a disorder of psychic function and behavior caused by a maladjustment in social relations or a disordered response to life's difficulties not based directly on a known disease process or lesion.

Simple as this division might seem, it is not easily applied to every abnormal neuropsychiatric state. How does one interpret disturbances of impulse control, hyperactivity, timidity, seductiveness, suspiciousness, inability to learn at the accustomed pace, failure to read or master arithmetic at the usual age, criminality, and inadequacy in adjustment to school, work, marriage, and society? Some of these disturbances, as pointed out in Chap. 28, are due to specific retardations in development; others may be due to innate personality (genetically based) traits, lack of proper training and education, unstable home environment, etc. Obviously, with such a large number of phenomena, it may at times be impossible to separate cause and effect. An individual whose nervous system is affected by disease and who is unable to learn or to form stable social relationships may create an abnormal environment. Or a serious environmental stress may incapacitate a patient with underlying nervous system disease.

Also, certain mental abnormalities have an uncertain status vis-à-vis this division and are currently subject to double interpretations, depending on one's premises. A persistent anxiety state without obvious cause in a previously healthy adult would be viewed by some psychiatrists as a reaction to fear of some unconscious threat. Others would consider it a genetic disease closely allied to endogenous depression, in which some biochemical disturbance, as mysterious as was hyperthyroidism a century ago, has developed de novo. Since the nature of the condition is unsettled, it is treated by physicians using both psychologic methods and drugs. Anyone who proposes to investigate it, we would argue, should do so with a completely open mind and be prepared to review critically any reasonable hypothesis as to its cause.

As to the major psychiatric disorders—depression, mania, paranoia, and schizophrenia—they are regarded by most psychiatrists and neurologists as genetically determined diseases of the nervous system, the mechanism, anatomy, and biochemistry of which are still obscure. Environmental stress at times seems important in their evocation and exacerbation but is obviously not an essential or sufficient factor. Only a few psychiatrists still insist that such states represent deviant ways of living or abnormal psychologic reactions. It seems reasonable to assume that the more comprehensive methodology of the neurologic and medical sciences will eventually lead to their solution. Similarly, certain socially delicate issues such as gender identity and homosexuality will probably prove to have explanations in both psychologic and anatomic terms.

When the clinical specialties of psychiatry and neurology are viewed in terms of these theories about disease and psychosocial reactions, it is obvious that they have overlapping interests. Diseases such as schizophrenia and manic-depressive psychosis, while of interest to neurologists, will remain indubitably in the province of psychiatrists. The latter have the training in psychotherapeutic methods and expertise in neuropharmacology that are needed in the care of such patients. Also, the psychiatrist must stand as the spokesman for the medical position on the countless ills related to social and behavioral maladjustments in modern life. The vast array of well-defined cerebrospinal diseases is the prerogative of the neurologist, but he, too, must be sensitive to their psychologic aspects.

Psychosomatic Medicine It is difficult to appreciate the evolution of psychiatry, particularly in America, without mentioning psychosomatic medicine. Beginning in the 1930s there was great interest in a large category of disease referred to for decades as psychosomatic. Included here were peptic ulcer, mucous and ulcerative colitis, hay fever, bronchial asthma, urticaria, angioneurotic edema, essential hypertension, hyperthyroidism, rheumatoid arthritis, amenorrhea, and many other stress-tolerant and non-tolerant etiologic factors. Often associated with their occurrence was the exacerbation of coronary atherosclerosis. More than 70 years have passed since these ideas were first proclaimed, and an enormous literature followed, with the establishment of pathetically few unassailable facts. It became clear that the so-called psychosomatic diseases are not neuroses in that they have different symptoms, and in most instances there is a known and easily demonstrable disease process. Even peptic ulcer, an old psychosomatic favorite, is now traced to a bacterial infection. No complete proof of psychic causation of any of the psychosomatic diseases has been found. Treatment has been concerned mainly with the relief of symptoms and has been directed for the most part by nonpsychiatric specialists. There is no evidence that the therapeutic results obtained by psychiatrists are better than those of a competent internist.

This extended application of the concept of psychosomatic disorders is still extant. The psychiatric literature is permeated with references to personality types that predispose to disease. Our criticism is that it tends to overemphasize the psychologic aspects out of all proportion to the somatic. One must concede that anxiety and related states raise the blood pressure and probably are associated with other physiologic changes, but the majority of assertions regarding personality types and psychologic states in relation to physical diseases remain unproven. The current societal preoccupation with "stress" as a cause or trigger for all manner of medical and neurologic disease, including disorders function of the immune system, is an extension of this still tenuous concept. As pointed out by Wolff in his scholarly exposition of the "mind-body" relationship, the fallacy of "psychogenic" or "psychosomatic" concepts is that they imply a mind acting in opposition to the body. Nevertheless, interest in the psychosomatic diseases has focused attention on the importance of psychosocial factors in the diseased patient and not merely on the disease in isolation. As has had a salutary effect. Berne and ably espoused and elaborated by Walter Cannon and Adolph Meyer is the view that the patient must always be regarded as a complex psychobiologic unit functioning in relation to the immediate physical and social environment. Disease represents a faulty or inadequate adaptation of the organism to the environment. Interestingly, the terms psychosomatic and psychophysiological are not listed in the fourth edition of the American Psychiatric Association's official diagnostic manual, the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV), and the disorders originally called psychosomatic now appear under the categories of "somatoform disorders" or "psychological factors affecting physical conditions"; these are discussed in subsequent chapters.

The reader seeking further information as to the status of psychosomatic or psychophysiological disorders is referred to the review by Rogers and Reich.

PLAN OF PSYCHIATRY SECTION

In the chapters that follow there will be a consideration of the neuroses, the affective disorders, the sociopathies, the schizophrenias, and the paranoid states. The major neurotic and psychotic disorders and their clinical aspects will be the focus of all important case material. Some 20 to 30 percent of all individuals at one time or another experience psychiatric symptoms and seek medical help for them. The headings that guide our exposition of neuropsychiatric illnesses might be questioned, but the justification for their selection is that each can be diagnosed by a competent physician and each diagnosis, once made, has been validated by follow-up studies. All physicians should know something about these categories of psychiatric disease. Neurologists in particular need to be familiar with them, if only for the purposes of differentiating them from other neurologic diseases and initiating intelligent management.

Emphasis throughout these chapters will be on the biologic characteristics and the diagnosis of each state. This approach is in keeping with a significant change in American psychiatry since the development of rigorous criteria for the diagnosis of psychiatric disorders. The stimulus for this development can be largely traced to the work of Feighner, Robins, Guze, and their colleagues (see also the monographs of Goodwin and Guze and of Rakoff et al.). Many of the diagnostic formulations proposed by these workers were adopted, in 1980, by DSM-III (and later its revised form, DSM-III-R, and DSM-IV).
The prevention of suicide, the choice of appropriate therapy, communication with the patient's family and physician, predictions about the course of the illness (prognosis)—all begin with accurate diagnosis. In addition to their practical clinical value, strict diagnostic criteria are important in psychiatric research.

Mainly, in the chapters that follow, we adhere to conventional psychiatric terms, since they are the ones most widely used in psychiatry and are familiar to most physicians. The DSM has introduced a plethora of new terms, and these will be alluded to where they may possibly be preferable to the older and better-known ones.

In adhering to the bias of neurologic medicine, we do not wish to depreciate the importance of psychologic medicine or of psychiatry. Our position on this matter has been fully stated in the preceding pages and needs no further elaboration. Theoretic aspects of personality and psychopathology and symptom formation will be given little space because of our ignorance of such psychologic mechanisms. Although many of these psychiatric conditions are regarded as diseases of the nervous system, because of their ubiquity and chronicity they should be treated by psychiatrists. The reader will find them well presented in the references at the end of each chapter.
