PART 1 APPROACH TO THE PATIENT WITH NEUROLOGIC DISEASE

Chapter 1 The Clinical Method of Neurology
Chapter 2 Special Techniques for Neurologic Diagnosis

PART 2 CARDINAL MANIFESTATIONS OF NEUROLOGIC DISEASE:

SECTION 1 DISORDERS OF MOTILITY

Chapter 3 Motor Paralysis
Chapter 4 Abnormalities of Movement and Posture due to Disease of the Basal Ganglia
Chapter 5 Incoordination and Other Disorders of Cerebellar Function
Chapter 6 Tremor, Myoclonus, Focal Dystonias, and Tics
Chapter 7 Disorders of Stance and Gait

SECTION 2 PAIN AND OTHER DISORDERS OF SOMATIC SENSATION, HEADACHE, AND BACKACHE

Chapter 8 Pain
Chapter 9 Other Somatic Sensation
Chapter 10 Headache and Other Craniofacial Pains
Chapter 11 Pain in the Back, Neck, and Extremities

SECTION 3 DISORDERS OF THE SPECIAL SENSES

Chapter 12 Disorders of Smell and Taste
Chapter 13 Common Disturbances of Vision
Chapter 14 Disorders of Ocular Movement and Pupillary Function
Chapter 15 Deafness, Dizziness, and Disorders of Equilibrium

SECTION 4 EPILEPSY AND DISORDERS OF CONSCIOUSNESS

Chapter 16 Epilepsy and Other Seizure Disorders
Chapter 17 Coma and Related Disorders of Consciousness
Chapter 18 Faintness and Syncope
Chapter 19 Sleep and Its Abnormalities

SECTION 5 INCOORDINATION AND OTHER DISORDERS OF CEREBELLAR FUNCTION

Chapter 20 Delirium and Other Acute Confusional States
Chapter 21 Dementia and the Amnestic (Korsakoff) Syndrome
Chapter 22 Neurologic Disorders Caused by Lesions in Particular Parts of the Cerebrum
Chapter 23 Disorders of Speech and Language

SECTION 6 ANXIETY AND DISORDERS OF ENERGY, MOOD, EMOTION, AND AUTONOMIC AND ENDOCRINE FUNCTIONS

Chapter 24 Fatigue, Asthenia, Anxiety, and Depressive Reactions
Chapter 25 The Limbic Lobes and the Neurology of Emotion
Chapter 26 Disorders of the Autonomic Nervous System, Respiration, and Swallowing
Chapter 27 The Hypothalamus and Neuroendocrine Disorders

PART 3 GROWTH AND DEVELOPMENT OF THE NERVOUS SYSTEM AND THE NEUROLOGY OF AGING

Chapter 28 Normal Development and Deviations in Development of the Nervous System
Chapter 29 The Neurology of Aging

PART 4 THE MAJOR CATEGORIES OF NEUROLOGIC DISEASE

Chapter 30 Disturbances of Cerebrospinal Fluid and Its Circulation, Including Hydrocephalus, Pseudotumor Cerebri, and Low-Pressure Syndromes
Chapter 31 Intracranial Neoplasms and Paraneoplastic Disorders
Chapter 32 Infections of the Nervous System (Bacterial, Fungal, Spirochetal, Parasitic) and Sarcoid
Chapter 33 Viral Infections of the Nervous System and Prion Diseases
NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.
In the first edition of the Principles of Neurology, we remarked that the preface to a textbook is often an unnecessary appendage, doing little more than adding to the book's weight or distracting critics from its contents. The value of the book should be judged by its substance and composition. In his foreword to Cromwell, Victor Hugo expressed this sentiment more figuratively: one seldom inspects the cellar of a house after visiting its salons or examines the roots of a tree after eating its fruit.

Yet there has to be a place where authors can state the purpose of their work, the manner in which it was conceived, and the reasons for foisting yet another book on a medical public already overburdened with an immense literature. To sustain our analogy, although one seldom derives pleasure from inspecting the cellar of a house, one is not sorry to have done so, especially if one is to purchase it.

In writing the Principles of Neurology, we adopted a method that had for long been espoused on the Neurology Service of the Massachusetts General Hospital. Instead of the customary recitation of many diseases of the nervous system, we chose to introduce the subject with a consideration of the phenomenology, or cardinal manifestations, of neurologic disease. Thus the first part of this book consists of a detailed exposition of the symptoms and signs of disordered nervous function, their analysis in terms of anatomy and physiology, and their clinical implications. This is followed by an account of the natural clusterings of these phenomena, or syndromes, which are the lore of clinical neurology, and this, in turn, by a description of all the main categories and types of disease that express themselves by each syndrome. We believe this approach to neurologic disease to be a logical one, for in practice the patient presents with symptoms of disordered nervous function, from which the clinician reasons to a diagnosis. This sequence of symptom to syndrome to disease recapitulates the rational process by which this is achieved. In teaching students and residents, we have found this clinical method to be eminently successful.

The compass of our book differs in several other ways from most contemporary textbooks of neurology. We have included discussions of a number of subjects that form the core of pediatric neurology, which is heavily weighted with developmental anomalies and hereditary metabolic diseases. These are presented in the context of normal development and maturation of the nervous system. And the effects of aging and age-linked diseases (geriatric neurology) have been accorded a separate chapter. No distinction is drawn between neurosurgical pathology and medical neurology, since they differ only with reference to mode of therapy. A significant portion of the book has been allotted to psychiatric syndromes and the major psychiatric diseases. This has not been done in the belief that these diseases are neurologic in the strict sense. Further, it is our belief that all physicians, including neurologists, should be knowledgeable about the diagnosis of depressive states, neuroses, and eccentricities of personality which are commonly associated with all manner of medical illnesses. The neuropsychiatric effects of alcoholism and drug abuse are also included. Finally, we have consigned a section of the book to a description of muscle diseases, which increasingly are coming under the purview of neurologists. Thus our book provides information that is essential not only to the practice of neurology and neurosurgery, but also to the practice of internal medicine, pediatrics, and psychiatry. To aid readers from these various specialties in finding relevant material, we suggest they turn their attention to the following chapters: internists: 8, 10, 11, 16, 18, 32, 33, 34; pediatricians: 16, 17, 18, 34, 35; orthopedists: 8, 11, 44, 45; psychiatrists: 20, 21, 22, 24, 25, 56, 57, 58.

Throughout this text the emphasis is on the clinical aspects of disease. Of course, pertinent neurobiologic data are not disregarded, but always they are presented with the view of how they bear upon and explain neurologic phenomena and disease. One of our primary aims, in conformity with Oslerian tradition, is to present the clinical phenomena that we ourselves have observed. We persist in our belief that there are advantages to limited authorship. It enables the authors to select what they believe to be essential knowledge about common diseases and to view them from a particular perspective. Also it assuages an evenness and uniformity of style that is more likely to please the reader.

The warm reception accorded the first six editions of Principles of Neurology has led us to believe that our plan of exposition has filled a need and has emboldened us to carry this work forward. During the editing of the seventh edition, each of us has undertaken a deliberate and critical review of new ideas and developments in clinical neurology and has endeavored to incorporate them. Every chapter has thus been thoroughly revised. The newest discoveries of molecular genetics have been added where relevant. The clarification of physiologic function obtained by PET and SPECT scanning and functional MRI has been expanded. Considerably greater use has been made of tables and MRI illustrations as refinements of biopathology of disease. A special effort has been made to provide the most detailed and current information about the treatment of neurologic diseases.

It is hardly possible to enumerate and adequately thank our many colleagues who in one way or another have been instrumental in the development and growth of this textbook. Foremost is our indebtedness to colleagues and teachers who had an abiding influence in shaping our ideas—Derek Denny-Brown, C. M. Fisher, Paul Yakovlev, E. P. Richardson, and Mandel Cohen. A special debt is owed to Betty Banker for her assistance in revising the chapters on muscle disease and for her help on all matters, large and small, pertaining to this book, since its inception. We are grateful also to the many colleagues with whom we have repeatedly discussed the substantive material of previous editions—Robert Young, Jay Mohr, Hugo Moser, Edwin Kodolny, and Shirley Wray.

Individual chapters or parts of chapters for the current edition were graciously reviewed by Michael Worthington (Chap 32), David Weinberg (Chap 45), and Richard Blair (neuroimaging) of St. Elizabeth's Medical Center; and by Peter Williamson and Vijay Thadani (Chap 16) and James Filiano (Chap 39) of Dartmouth-Hitchcock Medical Center. Expert advice on particularly difficult topics was provided by Harvey Levy (inherited metabolic disorders), John Leigh (the anatomy of vertical eye movements), Pauline Filipak (autism), and Paul Chapman (arteriovenous malformations). Other colleagues too numerous to mention have been sources of constant reference and constructive criticism in this and previous editions.

Finally, we wish to express our gratitude to Richard Haver, librarian at Vermont Veterans Administration Medical Center, and to Sandra Ropper, both of whom were assiduous in searching out innumerable references; to Dolores Altavilla and Dorothy Sweet for their help in preparation of the manuscript; to Winnifred Quicke for her generous support of the Department of Neurology at St. Elizabeth's Medical Center; to Muza Navrozov of McGraw-Hill, whose dedication and editing skills have ensured repeated editions of readable text; and to Catherine Saggesse for her successful efforts in achieving the timely production of the book.

With the publication of the seventh edition of the Principles, readers will recognize a change in the book's format. Raymond D. Adams, who conceived the book and was its senior author through six editions, is relinquishing his role of active authorship and will henceforth have his name incorporated in the title of the book. Although no longer burdened with the day-to-day demands of editors and publishers, Dr. Adams has retained a keen interest in the book. He has read virtually the entire seventh edition, throughout which time we have had both the pleasure and the benefit of his guiding hand and his many suggestions and contributions.

Maurice Victor
Allan H. Ropper
Neurology is regarded by many as the most difficult and exacting medical specialty. Students and residents coming to the neurology ward or clinic for the first time are easily discouraged by what they see. Having had brief contact with neuroanatomy, neurophysiology, and neuropathology, they are already somewhat intimidated by the complexity of the nervous system. The ritual they then witness of putting the patient through a series of maneuvers designed to evoke certain mysterious signs, the names of which are difficult to pronounce, is hardly reassuring; in fact, the procedure often appears to conceal the very intellectual processes by which neurologic diagnosis is attained. Moreover, the students have had little or no experience with the many special tests used in neurologic diagnosis—such as lumbar puncture and electroencephalographic, angiographic, and imaging procedures—nor do they know how to interpret the results of such tests. Neurology textbooks only confirm their fears as they read the detailed accounts of the many rare diseases of the nervous system.

The authors believe that many of the difficulties in comprehension neurology can be overcome by adhering to the basic principles of clinical medicine. First and foremost, it is necessary to learn and acquire facility in the use of the clinical method. Without a full appreciation of this method, the student is virtually as helpless with a new clinical problem as a botanist or chemist who would undertake a research problem without understanding the steps in the scientific method.

The importance of the clinical method stands out more clearly in the study of neurologic disease than in certain other fields of medicine. In most cases, the clinical method will prove to consist of an orderly series of steps, as follows:

1. The symptoms and signs are secured by history and physical examination, respectively.
2. The symptoms and physical signs considered relevant to the problem at hand are interpreted in terms of physiology and anatomy—that is, one identifies the disorder(s) of function and the anatomic structure(s) implicated by such a disorder. Often one recognizes a characteristic clustering of symptoms and signs, constituting a syndrome. The formulation of symptoms and signs in syndromic terms is particularly helpful in ascertaining the locus and nature of the disease.
3. These correlations permit the physician to localize the disease process, i.e., to name the part or parts of the nervous system involved. This step is called the anatomic, or topographic, diagnosis.
4. From the anatomic diagnosis and other medical data—particularly the mode of onset, evolution, and course of the illness, the involvement of nonneurologic organ systems, the relevant past and family histories, and the laboratory findings—one deduces the pathologic diagnosis and, when the mechanism and causation of the disease can be determined, the etiologic diagnosis.
5. Finally, the physician should assess the degree of disability and determine whether it is temporary or permanent (functional diagnosis). This is important in managing the patient's illness and judging the potential for restoration of function, i.e., prognosis.

The foregoing approach to the diagnosis of neurologic disease is summarized in Fig. 1-1, a procedural diagram by which the clinical problem is solved in a series of sequential finite steps. This systematic approach, allowing the confident localization and often precise diagnosis of disease, is one of the intellectual attractions of neurology.

Figure 1-1 Steps in the diagnosis of neurologic disease.

Of course, the solution to a clinical problem need not always be schematized in this way. The clinical method offers a much wider choice in the order and manner by which information is collected and interpreted. In fact, in some cases, adherence to a formal sequence is not necessary at all. The clinical picture of Parkinson disease, for example, is usually so characteristic that the nature of the illness is at once apparent. In other cases it is not necessary to carry the clinical analysis beyond the stage of the anatomic diagnosis, which in itself may suggest the cause of a disease. For example, when a unilateral Horner syndrome, cerebellar ataxia, paralysis of a vocal cord, and analgesia of the face of acute onset are combined with loss of pain and temperature sensation in the opposite arm, trunk, and leg, the most likely cause is an occlusion of the vertebral artery, because all the involved structures can be localized to the lateral medulla, within the territory of this artery. Thus, the anatomic diagnosis determines and limits the disease possibilities. If the signs point to disease of the peripheral nerves, it is usually not necessary to consider the causes of disease of the spinal cord. Some signs themselves are almost specific, e.g., opsoclonus for paraneoplastic cerebellar degeneration, and Argyll Robertson pupils for neurosyphilitic or diabetic oculomotor neuropathy.

Irrespective of the intellectual process that one utilizes in solving a particular clinical problem, the fundamental steps in diagnosis always involve the accurate elicitation of symptoms and signs and their correct interpretation in terms of disordered function of the nervous system. Most often, when there is uncertainty or disagreement as to diagnosis, it will be found later that the symptoms of disordered function were incorrectly interpreted in the first place. Thus, if a complaint of dizziness is identified as vertigo instead of light-headedness or if partial continuous epilepsy is mistaken for an extrapyramidal movement disorder such as choreo-athetosis, then the clinical method is derailed from the beginning. Repeated examinations may be necessary to establish the fundamental clinical findings beyond doubt and to ascertain the course of the illness. Hence the aphorism that a second examination is the most helpful diagnostic test in a difficult neurologic case.
Different disease processes may cause identical symptoms, which is understandable in view of the fact that the same parts of the nervous system may be affected by any one of several diseases. For example, a spastic paraplegia may result from spinal cord tumor, a genetic defect, or multiple sclerosis. Conversely, one disease may present with different groups of symptoms and signs. However, despite the many possible combinations of symptoms and signs in a particular disease, a few constellations of findings are so frequently or so highly characteristic of that disease as to be diagnostic. The experienced clinician acquires the habit of attempting to categorize every case in terms of a characteristic symptom complex, or syndrome. One must always keep in mind that syndromes are not disease entities but rather abstractions set up by clinicians in order to facilitate the diagnosis of disease. For example, the symptom complex of right-left confusion and inability to write, calculate, and identify individual fingers constitutes the so-called Gerstmann syndrome, recognition of which determines the anatomic locus of the disease (region of the left angular gyrus) and at the same time narrows the range of possible etiologic factors.

In the initial analysis of a neurologic disorder, anatomic diagnosis takes precedence over etiologic diagnosis. To seek the cause of a disease of the nervous system without first ascertaining the parts or structures that are affected would be analogous in internal medicine to attempting an etiologic diagnosis without knowing whether the inflammation involved the lungs, stomach, or intestines. Diagnosis of a clinical syndrome (eliciting the clinical features of an entire disease) requires knowledge of the disease's entire clinical course. The examiner must therefore attempt to elicit the patient's trust and cooperation and make him realize the importance of the examination procedure.

In neurology more than any other specialty, the physician is dependent upon the cooperation of the patient for a reliable history, especially for a description of symptoms that are unobservable by any other means. Therefore, history taking should be regarded as an important and fundamental part of the examination procedure in these and other particular clinical circumstances.

The neurologic examination begins with observation of the patient while the history is being obtained. The manner in which the patient tells the story of his illness may betray confusion or incoherence in thinking, impairment of memory or judgment, or difficulty in comprehending or expressing ideas. Observation of such matters is an integral part of the examination and provides information as to the adequacy of cerebral function. The physician should learn to obtain this type of information without embarrassment to the patient. A common error is to pass lightly over inconsistencies in history and inaccuracies about dates and symptoms, only to discover later that these flaws in memory were the essential features of the illness. Asking the patient to give his own interpretation of the possible meaning of symptoms may sometimes expose unnatural concern, anxiety, suspiciousness, or even delusional thinking.

The remainder of the neurologic examination should be performed as the last part of the general physical examination, proceeding from an examination of the cranial nerves, neck, and trunk to the testing of motor, reflex, and sensory functions of the upper and lower limbs. This is followed by an assessment of the function of specific parts of the nervous system and suppleness of the neck and spine (meningeal irritation). Gait and station (standing position) should be observed before or after the rest of the examination. The neurologic examination is always performed and recorded in a sequential and uniform manner in order to avoid omissions and to facilitate the subsequent analysis of case records. In addition, it is often instructive to observe the patient in the course of his natural activities, such as walking or dressing; this may disclose subtle abnormalities of gait and movement that might not be evident in formal testing.

The thoroughness of the neurologic examination must of necessity be governed by the type of clinical problem presented by the patient. To spend a half hour or more testing cerebral, cerebellar, cranial nerve, and sensorimotor function in a patient seeking treatment for a simple compression palsy of an ulnar nerve is pointless and uneconomical. The examination must also be modified according to the condition of the patient. Obviously many parts of the examination cannot be carried out in a comatose patient; also, infants and small children as well as patients with psychiatric disease need to be examined in special ways. The following comments apply to patients who present symptoms of nervous system disease.

The neurologic examination begins with observation of the patient while the history is being obtained. The manner in which the patient tells the story of his illness may betray confusion or incoherence in thinking, impairment of memory or judgment, or difficulty in comprehending or expressing ideas. Observation of such matters is an integral part of the examination and provides information as to the adequacy of cerebral function. The physician should learn to obtain this type of information without embarrassment to the patient. The examination must also be modified according to the condition of the patient. Obviously many parts of the examination cannot be carried out in a comatose patient; also, infants and small children as well as patients with psychiatric disease need to be examined in special ways. The following comments apply to the examination procedure in these and other particular clinical circumstances.

PATIENTS WHO PRESENT SYMPTOMS OF NERVOUS SYSTEM DISEASE

Numerous guides to the examination of the nervous system are available. For a full account of the methods, the reader is referred to the monographs of DeMyer, Ross, Mancall, Bickerstaff and Spillane, Glick, and the staff members of the Mayo Clinic, each of which approaches the subject from a somewhat different point of view. The monograph of DeMyer is particularly recommended to students. An inordinately large number of tests of neurologic function have been devised, and it is not proposed to review all of them here. Some are described in subsequent chapters dealing with disorders of mentation, cranial nerves, and motor, sensory, and autonomic functions. Many tests are of doubtful value and should not be taught to students of neurology. Merely to perform all of them on one patient would require an inordinate amount of time. The following tests are relatively simple and provide the most useful information.

Testing of Higher Cortical Functions

These functions are tested in detail if the patient's history or behavior during the general examination has provided reason to suspect some cognitive defect. Questions should then be directed toward determining the patient's orientation in time (day and date) and place and insight into his current medical problem. Attention, speed of response, ability to give relevant answers to simple questions, and the capacity for sustained mental effort all lend themselves to straightforward observation. Useful bedside tests of attention, concentration, memory, and clarity of thinking include the repetition of a series of seven digits in forward and five in reverse order, serial subtraction of 3s and 7s from 100, recall of three items of information or a short story after an interval of 3 minutes, and naming the last five presidents or prime ministers. The patient's account of his recent illness, medical consultations, dates of hospitalization, and the day-to-day recollection of medical procedures, meals, and other incidents in the hospital are excellent tests of memory; the narration of how the tests were done and the patient's choice of words (vocabulary) provides information about his intelligence and coherence of thinking. Many other tests can be devised for this purpose. Often the examiner can obtain a better idea of the clarity of the patient's sensorium and soundness of intellect by using these few tests and noting the manner in which he deals with them than by relying on the score of a formal intelligence test.
If there is any suggestion of a speech or language disorder, the nature of the patient's spontaneous speech should be noted. In addition, his ability to read, write, and spell; execute spoken commands; repeat words and phrases spoken by the examiner; name objects and parts of objects; and solve simple arithmetical problems should be assessed. Bisecting a line, drawing a clock or the floor plan of one's home or a map of one's country, and copying figures are useful tests of visuospatial perception in cases of suspected cerebral disease. The testing of language, cognition, and other aspects of higher cerebral function are considered in Chap. 7, Chap. 22, and Chap. 23.

Testing of Cranial Nerves

The function of the cranial nerves must be investigated more fully in patients who have neurologic symptoms than in those who do not. If one suspects a lesion in the anterior fossa, the sense of smell should be tested in each nostril, and then it should be determined whether odors can be discriminated. Visual fields should be outlined by confrontation testing, in some cases by testing each eye separately; if any abnormality is suspected, it should be checked on a perimeter and scotomas sought on the tangent screen or, more accurately, by computed perimetry. Pupil size and reactivity to light and accommodation (during convergence), the range and rate of ocular movements, and the presence or absence of nystagmus should next be observed. Details of these test procedures and their interpretation are described in Chap. 12, Chap. 13, and Chap. 14.

Sensation over the face is tested with a pin and wisp of cotton; also, the presence or absence of the corneal reflexes should be determined. Facial movements should be observed as the patient speaks and smiles, for a slight weakness may be more evident in these circumstances than on movements to command. The auditory meati and tympanic membranes should be inspected with an otoscope. A 256 double-vibration tuning fork held next to the ear and on the mastoid discloses hearing losses and distinguishes middle ear (conductive) from neural deafness. The vocal cords need to be inspected with special instruments in cases of suspected medullary or vagus nerve disease, especially when there is hoarseness. Pharyngeal reflexes are meaningful if there is a difference on the two sides; bilateral absence of these reflexes is seldom significant. Inspection of the tongue, when protruded and at rest, is helpful; atrophy and fasciculations may be seen and weakness detected. Slight deviation of the protruded tongue as a solitary finding can usually be disregarded. Any abnormality in pronunciation should be noted. The jaw jerk and the snout, buccal, and sucking reflexes should be sought, particularly if there is a question of dysphagia, dysarthria, or dysphonia.

Tests of Motor Function

In the assessment of motor function, it should be kept in mind that observations of the speed and strength of movements and of muscle bulk, tone, and coordination are usually more informative than the tendon reflexes. It is essential to have the limbs fully exposed and to inspect them for atrophy and fasciculations as well as to watch the patient maintain the arms outstretched in the prone and supine positions; perform simple tasks, such as alternately touching his nose and the examiner's finger; make drawing movements, particularly such movements that necessitate sudden acceleration and deceleration and changes in direction; rapidly touch the thumb to each fingertip and supinate and pronate the forearm; and accomplish simple tasks such as buttoning clothes, opening a safety pin, holding common tools. Estimates of the strength of leg muscles with the patient in bed are often unreliable; there may seem to be little or no weakness even though the patient cannot step up on a footstool without help or arise from a kneeling position. Running the heel down the front of the shin and rhythmically tapping the heel on the shin are the only tests of coordination that need be carried out in bed. The maintenance of the outstretched and supinated arms against gravity is a useful test; the weak one, tiring first, soon begins to sag, or, in the case of a corticospinal lesion, to resume the more natural pronated position. The strength of the legs can be similarly tested, either with the patient supine and the legs flexed at hips and knees, or with the patient prone and the knees bent. Also, abnormalities of movement and posture and tremors may be exposed (see Chap. 4 and Chap. 9).

Testing of Reflex Function

Testing of the biceps, triceps, supinator (radial-periosteal), patellar, Achilles, and cutaneous abdominal and plantar reflexes permits an adequate sampling of reflex activity of the spinal cord. Elicitation of tendon reflexes requires that the involved muscles be relaxed. Underactive or barely elicitable reflexes can be facilitated by voluntary contraction of other muscles (Jendrassik maneuver). The interpretation of the plantar response offers special difficulty because several different reflex responses can be evoked by stimulating the sole of the foot along its outer border from heel to toes. These are (1) the quick, high-level withdrawal-avoidance response; (2) the slower, spinal flexor noci-fensor reflex (flexion of knee and hip and dorsiflexion of toes and foot); (3) the Babinski response; (4) the plantar grasp reflex. Avoidance and withdrawal responses interfere with the interpretation of the Babinski sign and can sometimes be overcome by utilizing the several alternative stimuli that are known to elicit the Babinski response (squeezing the calf or Achilles tendon, flicking the fourth toe, downward scraping of the shin, lifting the straight leg, etc.). An absence of the superficial cutaneous reflexes of the abdominal, cremasteric, and other muscles is a useful ancillary test for detecting corticospinal lesions.

Testing of Sensory Function

This is undoubtedly the most difficult part of the neurologic examination. Usually sensory testing is reserved for the end of the examination and, if the findings are to be reliable, it should not be prolonged for more than a few minutes. Each test should be explained briefly; too much discussion of these tests with a meticulous, introspective patient may encourage the reporting of useless minor variations of stimulus intensity.

It is not necessary to examine all areas of the skin surface. A quick survey of the face, neck, hands, trunk, and feet with a pin takes only a few seconds. Usually one is seeking differences between the two sides of the body (it is preferable to ask whether stimuli on opposite sides of the body feel the same rather than to ask if they feel different), a level below which sensation is lost, or a zone of relative or absolute anesthesia. Regions of sensory deficit can then be tested more carefully and mapped out. Moving the stimulus from an area of diminished sensation into a normal area enhances the perception of a difference.

The finding of a zone of heightened sensation ("hyperesthesia") calls attention to a disturbance of superficial sensation. Variations in sensory findings from one examination to another most often reflect differences in technique of examination as well as inconsistencies in the responses of the patient.

Sensory testing is considered in greater detail in Chap. 9.

Testing of Stance and Gait

No examination is complete without watching the patient stand and walk. An abnormality of stance and gait may be the most prominent or the only neurologic abnormality, as in certain cases of cerebellar or frontal lobe disorder. Also, an impairment of posture and highly automatic adaptive movements in walking may provide the most definite diagnostic clues in the early stages of Parkinson disease and progressive supranuclear palsy (Chap. 7). Walking is the most effective way to bring out dystonic postures in the hands, feet, and trunk. And having the patient walk tandem or on the sides of the soles may disclose a lack of balance. Hopping or standing on one foot may also betray a lack of balance or weakness, and standing with feet together and eyes closed will bring out a disequilibrium that is due to impairment of labyrinthine-vestibular function or deep sensory loss (Romberg test).

THE MEDICAL OR SURGICAL PATIENT WITHOUT NEUROLOGIC SYMPTOMS

In this situation, brevity is desirable, but any test that is undertaken should be done carefully and recorded accurately and legibly. The patient's orientation, insight, and judgment and the integrity of speech and language functions are readily assessed in the course of taking the history. With respect to the cranial nerves, the size of the pupils and their reaction to light, ocular movements, visual and auditory acuity (by questioning), and movements of the face, palate, and tongue should be tested. Observing the bare outstretched arms for atrophy, weakness (pronating drift), tremor, or abnormal movements; checking the strength of hand grip and strength of the pupils and their reaction to light, ocular movements, visual and auditory acuity (by questioning), and movements of the face, palate, and tongue should be tested.
Accurate recording of negative data may be useful in relation to some future illness that requires examination.

THE COMATOSE PATIENT

Although subject to obvious limitations, careful examination of the stuporous or comatose patient yields considerable information concerning the function of the nervous system. The demonstration of signs of focal cerebral or brainstem disease or of meningeal irritation is particularly useful in the differential diagnosis of diseases that cause stupor and coma. The adaptation of the neurologic examination to the comatose patient is described in Chap. 17.

THE PSYCHIATRIC PATIENT

One is compelled in the examination of psychiatric patients to rely less on the cooperation of the patient and to be unusually critical of his statements and opinions. The depressed patient, for example, may claim to have impaired memory or weakness when actually there is neither amnesia nor diminution in muscular power, or the sociopathic or hysterical may feign paralysis. The opposite is sometimes true—a psychotic patient may make accurate observations of his own symptoms, only to have them ignored because of his mental state.

If the patient will speak and cooperate even to a slight degree, much may be learned about the functional integrity of different parts of the nervous system. Aphasia can be suspected in every instance, recognized by the manner in which the patient expresses ideas, reads and writes, and responds to spoken or written requests. Often it is possible to determine whether there are hallucinations or delusions, defective memory, or other recognizable symptoms of brain disease merely by watching and listening to the patient. Ocular movements and visual fields can be tested with fair accuracy by observing the patient's response to a moving stimulus or threat in all four quadrants of the fields. Cranial nerve, motor, and reflex functions are tested in the usual manner, but it must be remembered that the neurologic examination is never complete unless the patient will speak and cooperate in testing. On occasion, mute and resistive patients judged to be schizophrenic prove to have some widespread cerebral disease such as hypoxic or hypoglycemic encephalopathy, a brain tumor, a vascular lesion, or extensive demyelinating lesions.

INFANTS AND SMALL CHILDREN

The reader is referred to the methods of examination described by Gesell and Amatruda, Dubowitz et al, and textbooks of pediatric neurology (e.g., Berg), which are listed in the references and described in Chap. 28.

THE GENERAL MEDICAL EXAMINATION

Never to be overlooked in the assessment of a neurologic problem are the findings on general medical examination. Often they disclose evidence of an underlying systemic disease that has secondarily affected the nervous system. In fact, many of the most serious neurologic problems are of this type. A few common examples will suffice: the finding of adenopathy or a lung infiltrate implicates neoplasia or sarcoidosis as the cause of multiple cranial nerve palsies; the presence of low-grade fever, anemia, a heart murmur, and splenomegaly in a case of unexplained stroke points to a diagnosis of subacute bacterial endocarditis with embolic occlusion of brain arteries. Certainly no examination of a patient with stroke is complete without a search for hypertension, carotid bruits, heart murmurs, or irregular pulse.

IMPORTANCE OF A WORKING KNOWLEDGE OF NEUROANATOMY, NEUROPHYSIOLOGY, AND NEUROPATHOLOGY

Once the technique of obtaining reliable clinical data is mastered, students and residents may find themselves handicapped in the interpretation of the findings by a lack of knowledge of neuroanatomy and neurophysiology. For this reason, each of the later chapters dealing with the motor system, sensation, special senses, consciousness, language, etc., is introduced by a review of the anatomic and physiologic facts that are necessary for an understanding of their clinical disorders.

At a minimum, a physician should have a knowledge of the anatomy of the corticospinal tract; the motor unit (anterior horn cell, nerve, and muscle); the basal ganglionic and cerebellar motor connections; the sensory pathways; the cranial nerves; the hypothalamus and pituitary; the reticular formation of brainstem and thalamus; the limbic system; the functional areas of the cerebral cortex and their major connections; the visual, auditory, and autonomic systems; and the cerebrospinal fluid pathways. A working knowledge of neurophysiology should include an understanding of the nerve impulse, neuromuscular transmission, and the contractile process of muscle; spinal reflex activity; central neurotransmission; the processes of neuronal excitation, inhibition, and release; and cortical activation and seizure production.

From a practical diagnostic and therapeutic point of view, the neurologist is helped most by a knowledge of neuropathology—i.e., the changes that are produced by disease processes such as infarction, hemorrhage, demyelination, physical trauma, compression, inflammation, neoplasm, and infection, to name the more common ones. Experience with the gross and microscopic appearances of these disease processes greatly enhances one's ability to explain their clinical behavior. The ability to visualize the effects of disease on nerve and muscle, brain and spinal cord, meninges, and blood vessels gives one a strong sense of the clinical features that one might expect of a particular disease and which features are untenable or inconsistent with a particular diagnosis. An additional advantage of being exposed to neuropathology, of course, is that the clinician is better able to evaluate pathologic changes and reports of material obtained by biopsy.

LABORATORY DIAGNOSIS

From the foregoing description of the clinical method and its application, it is evident that the use of laboratory aids in the diagnosis of diseases of the nervous system is always preceded by rigorous clinical examination. Laboratory study can be planned intelligently only on the basis of clinical information. To reverse this process is wasteful of medical resources. However, in neurology, the ultimate goal is the prevention of disease, because the brain changes induced by many neurologic diseases are irreversible. In the prevention of neurologic disease, the clinical method in itself is inadequate, and of necessity one resorts to two other methods, namely, the use of genetic information and laboratory screening tests. Genetic information enables the neurologist to identify patients at risk of developing certain diseases and prompts the search for biologic markers before the advent of symptoms or signs. Biochemical screening tests are applicable to an entire population and permit the identification of neurologic disease in individuals who have yet to show their first symptom; in some such diseases, treatment can be instituted before the nervous system has suffered damage. In preventive neurology, therefore, laboratory methodology may take precedence over clinical methodology.

The laboratory methods that are available for neurologic diagnosis are discussed in the next chapter and in Chap. 45, on clinical electrophysiology. The relevant principles of genetic and laboratory screening methods that are presently available for the prediction of disease are presented in the discussion of the disease(s) to which they are applicable.

SHORTCOMINGS OF THE CLINICAL METHOD

If one adheres faithfully to the clinical method outlined here, neurologic diagnosis is greatly simplified. In most cases, one can reach an anatomic diagnosis. The cause of the disease may prove more elusive and usually entails the intelligent and selective employment of a number of the laboratory procedures described in the next chapter.

However, even after the most assiduous application of the clinical method and laboratory procedures, there are numerous patients whose diseases elude diagnosis. In such circumstances we have often been aided by the following rules of thumb: (1) Focus the clinical analysis on the principal symptoms and signs and avoid being distracted by minor signs and uncertain clinical data. (2) Avoid premature closure of diagnosis. Often this is the result of premature fixation on some item in the history or examination, closing the mind to alternative diagnostic considerations. The first diagnostic formulation should be regarded as only a testable hypothesis, subject to modification when new items of information are secured. Should the disease be in a stage of transition, time will allow the full picture to emerge and the diagnosis to be clarified. (3) When several of the main features of a disease under consideration are lacking, an alternative diagnosis should always be entertained. In general, however, one is more likely to encounter rare manifestations of common diseases than the typical manifestations of rare diseases (a paraphrasing of Bayes' theorem). (4) It is preferable to base diagnosis on one's experience with the dominant symptoms and signs and not on statistical analyses of the very large data base. For the most part, the methods of probability-based decision analysis have proved to be disappointing in relation to neurologic disease because of the impossibility of weighing the importance of each clinical datum. (5) Whenever reasonable and safe, obtain tissue for examination, for this adds
the dimension of histopathology to the clinical study.

As pointed out by Chimowitz, students tend to err in failing to recognize a disease they have not seen, and experienced clinicians may fail to recognize a rare variant of a common disease. There is no doubt that some clinicians are more adept than others at solving difficult clinical problems. Their talent is not intuitive, as sometimes is presumed, but is attributable to having paid close attention to the details of their experience with many diseases and having catalogued them for future reference. The unusual case is recorded in memory and can be resurrected when another one like it is encountered. Long experience also teaches one not to immediately accept the obvious explanation.

THE PURPOSE OF THE CLINICAL METHOD OF NEUROLOGY

Accurate diagnosis serves four main purposes: (1) it enables the physician to determine the proper treatment of the patient; (2) it is helpful in prognosis, i.e., in predicting the outcome of the illness; (3) if the disease is hereditary, it allows for genetic counseling; and (4) it is the essential initial step in the scientific study of clinical phenomena and disease. The medical profession is primarily concerned with the prevention and cure of illness, and all our knowledge is applied to this well-defined end. A major aim of the neurologist, therefore, is not to overlook a disease for which there is an effective treatment. Each of the treatable causes of a given syndrome must be carefully considered and excluded by clinical and laboratory methods. For example, in the study of a patient with disease of the spinal cord, one must take special care to exclude the presence of a tumor, subacute combined degeneration (vitamin B_12 deficiency), spinal syphilis, epidural abscess or hematoma, herniated disc, and cervical spondylosis, for these are all treatable. In this respect, failure to recognize amyotrophic lateral sclerosis is a less serious error.

THERAPEUTICS IN NEUROLOGY

Among medical specialties, neurology has traditionally occupied a somewhat anomalous position, being thought of by many as little more than an intellectual exercise concerned with making diagnoses of untreatable diseases. This disdainful view of our profession is no longer valid. There are a growing number of diseases, some medical and others surgical, for which specific therapy is now available, and—through advances in neuroscience—their number is steadily increasing. Matters pertaining to these therapies and to the dosages, timing, and manner of administration of particular drugs are considered in later chapters, in relation to the description of individual diseases.

There are, in addition, many diseases in which neurologic function can be restored to a varying degree by appropriate rehabilitation measures or by the judicious use of therapeutic agents that have not been fully validated. Claims for the effectiveness of a particular therapy, based on statistical analysis of large-scale clinical studies, must be treated circumspectly. Was the study well conceived, was there rigid adherence to the criteria for randomization and admission of cases into the study, were the statistical methods standardized, were the controls truly comparable? And most importantly, were the patients in a particular study strictly comparable to the clinical problem at hand? Also, it has been our experience, based on participation in a number of such multicenter trials, that the original claims must be accepted with caution. Since newly proposed therapeutic agents are often risky and expensive, it is often prudent to wait until further studies confirm the benefits that have been claimed for them or expose flaws in the design or fundamental assumptions of the original study.

Even when no treatment is possible, neurologic diagnosis is far more than an intellectual pastime. The first step in the scientific study of a disease process is its identification in the living patient. Until this is achieved, it is impossible to apply adequately the “master method of controlled experiment.” The clinical method of neurology thus serves both the physician in the practical matters of diagnosis, prognosis, and treatment and the clinical scientist in the search for the mechanism and cause of the disease.

*Throughout this text we follow the traditional English practice of using the pronoun he, his, or him in the generic sense whenever it is not intended to designate the gender of a specific individual.

Chapter 2
SPECIAL TECHNIQUES FOR NEUROLOGIC DIAGNOSIS

The analysis and interpretation of data elicited by a careful history and examination may prove to be adequate for diagnosis. Special laboratory examinations then do no more than corroborate the clinical impression. However, it happens more often that the nature of the disease is not discerned by “case study” alone; the diagnostic possibilities may be reduced to two or three, but the correct one is uncertain. Under these circumstances, one resorts to the ancillary examinations outlined below.

The aim of the neurologist is to arrive at a final diagnosis by artful analysis of the clinical data aided by the least number of laboratory procedures. Moreover, the strategy of laboratory study of disease should be based purely on therapeutic and prognostic considerations, not on the physician’s curiously or presumed medicolegal exigencies.

A few decades ago the only laboratory procedures available to the neurologist were lumbar puncture and examination of a sample of cerebrospinal fluid, radiology of the skull and spinal column, contrast myelography, pneumoencephalography, and electroencephalography. Now, through formidable advances in scientific technology, the physician’s armamentarium has been expanded to include a multitude of neuroimaging, biochemical, and genetic methods. Some of these new methods are so impressive that there is a temptation to substitute them for a careful, detailed history and physical examination. Use of the laboratory in this way should be avoided. It certainly does not guarantee a diagnosis. In fact, in a carefully examined series of 86 consecutively hospitalized neurologic patients, laboratory findings (including magnetic resonance imaging (MRI)) clarified the clinical diagnosis in 40 patients but failed to do so in the remaining 46 patients (Chimowitz et al).

The physician should always keep in mind the primacy of the clinical method and judge the relevance and significance of each laboratory datum only in the context of clinical findings. Hence the neurologist must be familiar with all laboratory procedures relevant to neurologic disease, their reliability, and their hazards.

Below is a description of laboratory procedures that have application to a diversity of neurologic diseases. Procedures that are pertinent to a particular symptom complex or category of disease—e.g., audiogram (deafness); electronystagmogram, or ENG (vertigo); electromyogram (EMG) and nerve conduction studies (neuromuscular disease)—are presented in the chapters devoted to these disorders.

LUMBAR PUNCTURE AND EXAMINATION OF CEREBROSPINAL FLUID

The information yielded by examination of the cerebrospinal fluid (CSF) is often crucial in the diagnosis of neurologic disease.

Indications for Lumbar Puncture (LP)

1. To obtain pressure measurements and procure a sample of the CSF for cellular, cytologic, chemical, and bacteriologic examination.
2. To aid in therapy by the administration of spinal anesthetics and occasionally antibiotics or antitumor agents, or by reduction of CSF pressure.
3. To obtain pressure measurements and procure a sample of the CSF for cellular, cytologic, chemical, and bacteriologic examination.
4. To aid in therapy by the administration of spinal anesthetics and occasionally antibiotics or antitumor agents, or by reduction of CSF pressure.

LP carries a certain risk if the CSF pressure is very high (evidenced by headache and papilledema), for it increases the possibility of a fatal cerebellar or transtentorial herniation. The risk is considerable when papilledema is due to an intracranial mass, but it is much lower in patients with subarachnoid hemorrhage or pseudotumor cerebri, conditions in which repeated lumbar punctures have actually been employed as a therapeutic measure. In patients with purulent meningitis, there is also a small risk of herniation, but this is far outweighed by the need for a definitive diagnosis and the institution of appropriate treatment at the earliest moment. With this exception, therefore, lumbar puncture should be preceded by computed tomography (CT) or magnetic resonance imaging (MRI) whenever an elevation of intracranial pressure is suspected. If the latter procedures do not disclose a mass lesion that causes displacement of tissue toward the tentorial opening or into the foramen magnum (the presence of a mass alone is of less concern) and it is considered essential to have the information yielded by CSF examination, the LP should be performed—with certain precautions. A fine-bore (no. 22 or 24) needle should be used, and if the pressure proves to be very high—over 400 mmHg— one should obtain the necessary sample of fluid and then, according to the suspected disease and patient’s condition, administer urea or mannitol and watch the manometer until the pressure falls. Dexamethasone or an equivalent corticosteroid should then be given in an initial intravenous dose of 10mg, followed by doses of 4 to 6 mg every 6 h in order to produce a sustained reduction in intracranial pressure.

Lumbar puncture is performed—with certain precautions. A fine-bore (no. 22 or 24) needle should be used, and if the pressure proves to be very high—over 400 mmHg—one should obtain the necessary sample of fluid and then, according to the suspected disease and patient’s condition, administer urea or mannitol and watch the manometer until the pressure falls. Dexamethasone or an equivalent corticosteroid should then be given in an initial intravenous dose of 10mg, followed by doses of 4 to 6 mg every 6 h in order to produce a sustained reduction in intracranial pressure.

Cisternal puncture and cervical subarachnoid puncture, although safe in the hands of an expert, are too hazardous to entrust to those without experience. Lumbar puncture is performed except in obvious instances of spinal block requiring a sample of cisternal fluid or myelography above the lesion.

Technique of Lumbar Puncture

Experience teaches the importance of meticulous technique. LP should always be done under sterile conditions. Local anesthetic is injected in and beneath the skin, which should render the procedure painless. Warming of the analgesic by rolling the vial between the palms seems to diminish the burning sensation that accompanies cutaneous infiltration. The patient is positioned on his side, preferably on the left side for right-handed physicians, with hips and knees flexed and his head as close to his knees as comfort permits. The patient's back should be aligned near the edge of the bed and a small pillow placed under the ear. The trocar should be removed slowly from the needle in order to avoid sucking a nerve rootlet into the lumen and causing radicular pain. Otherwise, sciatic pain during the procedure indicates that the needle is placed too far laterally. If the flow of CSF slows, the head can be elevated slowly. When drops of CSF contact the edge of a collecting tube, capillary action can also be utilized to speed up flow. Occasionally, one resorts to gentle aspiration with a small-bore syringe to overcome the resistance of proteinaceous and viscous CSF. The puncture is easiest to perform at the L3-L4 interspace, which corresponds to the axial plane of the iliac crests, or in the space above or below. In infants and young children, in whom the spinal cord may extend to the level of the L3-L4 interspace, lower spaces should be used. Failure to enter the lumbar subarachnoid space after two or three trials can usually be overcome by doing the puncture with the patient in the sitting position and then assisting him to lie on one side for pressure measurements and fluid removal. The “dry tap” is more often due to an improperly placed needle than to obliteration of the subarachnoid space by a compressive lesion of the cauda equina or chronic adhesive arachnoiditis.

There are few serious complications of lumbar puncture beyond the risk of inducing brain herniation. The most common is headache, the result of a reduction of CSF...
pressure and the tugging of cerebral and dural vessels as the patient assumes the erect posture. The syndrome of low CSF pressure and other complications of lumbar puncture are considered further in Chap. 30. Bleeding into the spinal meningeal spaces can occur in patients who are taking anticoagulants [prothrombin time >13.5 or an International Normalized Ratio (INR) >1.3], have low platelet counts (<30,000 to 50,000/mm$^3$), or have impaired platelet function (alcoholism, uremia).

Purulent meningitis and disc space infections have been known to complicate lumbar puncture, the result of imperfect sterile technique; and the introduction of particulate matter (e.g., talc) can produce a sterile meningitis. Diplopia, facial paresis, and tinnitus or deafness have reportedly complicated lumbar puncture on very rare occasions.

Examination Procedures

Once the subarachnoid space has been entered, the pressure and—in special cases—“dynamics” of the CSF are determined (see below) and samples of fluid obtained. The gross appearance of the fluid is noted, after which the CSF, in separate tubes, can be examined for (1) number and type of cells and presence of micro-organisms; (2) protein and glucose content; (3) tumor cells, using a Millipore filter or similar technique; (4) content of gamma globulin and other protein fractions and presence of oligoclonal bands; (5) pigments, lactate, NH$_3$, pHi, CO$_2$, enzymes, and radioactivity elaborated by tumors; and (6) bacteria and fungi (by culture), cryptococcal antigen, mycobacteria, herpesvirus and cytomegalovirus DNA (by polymerase chain reaction), and viral isolation.

Pressure and Dynamics With the patient in the lateral decubitus position, the CSF pressure is measured by a manometer attached to the needle in the subarachnoid space. The opening pressure is that of the fluid in the manometer at 100 mm H$_2$O. A pressure above 200 mm H$_2$O with the patient relaxed and legs straightened reflects the pressure of increased intracranial pressure. In an adult, a pressure of 50 mm H$_2$O or below indicates intracranial hypotension, generally due to leakage of spinal fluid or systemic dehydration. When measured with the needle in the lumbar sac and the patient in a sitting position, the fluid in the manometer rises to the level of the cisterna magna (pressure is approximately double that obtained in the recumbent position). It fails to reach the level of the ventricles because the latter are in a closed system under slight negative pressure, whereas the fluid in the manometer is influenced by atmospheric pressure. Normally, with the needle properly placed in the subarachnoid space, the fluid in the manometer oscillates through a few millimeters in response to the pulse and respiration and rises promptly with coughing, straining, or abdominal compression.

The presence of a spinal subarachnoid block can be confirmed by jugular compression. First one side of the neck is compressed, then the other, and then both sides simultaneously, with enough pressure to compress the veins but not the carotid arteries (Quenckenstedt test). In the absence of subarachnoid block, there is a rapid rise in pressure to 100 to 200 mm H$_2$O and a return to its original level within 10 s after release. Failure of the pressure to rise with this maneuver usually means that the needle is improperly placed. A rise in pressure in response to abdominal compression (or coughing or straining) but not to jugular compression indicates a spinal subarachnoid block, whereas the pressure rise in the reverse order indicates a lumbar puncture. (Jugular compression test) may indicate lateral sinus thrombosis. These tests are now rarely used, having been replaced by more precise and less hazardous imaging techniques, but they remain useful in appropriate circumstances. Jugular compression should never be performed when an intracranial tumor or other mass lesion is present or suspected.

Gross Appearance and Pigments Normally the CSF is clear and colorless, like water. Minor degrees of color change are best detected by comparing tubes of CSF and water against a white background (by daylight rather than fluorescent illumination) or by looking down into the tubes from above. The presence of red blood cells imparts a hazy or ground-glass appearance; at least 200 red blood cells (RBC) per cubic millimeter (mm$^3$) must be present to detect this change. The presence of 100 to 200 RBC per cubic millimeter imparts a hazy pink or red color, depending on the amount of blood; centrifugation of the fluid or allowing it to stand causes sedimentation of the RBC. Several hundred or more white blood cells in the fluid (pleocytoysis) may cause a slight opaque haziness.

A traumatic tap (in which blood from the epidural venous plexus has been introduced into the spinal fluid) may seriously confuse the diagnosis if it is incorrectly interpreted to indicate a pre-existent subarachnoid hemorrhage. To distinguish between these two types of “bloody tap,” two or three serial samples of fluid should be taken at the time of the LP. With a traumatic tap, there is usually a decreasing number of RBC in the second and third tubes. Also with a traumatic tap, the CSF pressure is usually normal, and if a large amount of blood is mixed with the fluid, it will clot or form fibrinous webs. These are not seen with pre-existent hemorrhage because the blood has been greatly diluted with CSF and defibrinated. With subarachnoid hemorrhage, the RBC begin to hemolyze within a few hours, imparting a pink-red discoloration (erythrocythemia) to the supernatant fluid; allowed to stand for a day or more, the fluid becomes yellow-brown (xanthochromia). Prompt centrifugation of bloody fluid from a traumatic tap will yield a colorless supernatant; only with large amounts of blood (RBC over 100,000/mm$^3$) will the supernatant fluid be faintly xanthochromic due to contamination with serum bilirubin and lipochromes.

The fluid from a traumatic tap should contain one or two white blood cells (WBC) per 1000 RBC assuming that the hematocrit is normal, but in reality this ratio varies widely. With subarachnoid hemorrhage, the proportion of WBC rises as RBC hemolyze, sometimes reaching a level of several hundred per cubic millimeter; but the vagaries of this reaction are such that it, too, cannot be relied upon to distinguish traumatic from pre-existent bleeding. The same can be said for determination of RBC, which occurs in both types of bleeding.

The reason that red corpuscles undergo rapid hemolysis in the CSF is not clear. It is surely not due to osmotic differences, insofar as the osmolality of plasma and CSF is essentially the same. Fishman suggests that the low protein content of CSF dis-equilibrates the red cell membrane in some way. The explanation for the rapid phagocytosis of RBC in the CSF, which begins within 48 h, is also obscure.

The pigments that discolor the CSF following subarachnoid hemorrhage are oxyhemoglobin, bilirubin, and methemoglobin; in pure form, these pigments are colored red (orange to orange-yellow with dilution), canary yellow, and brown, respectively. Mixtures of these pigments produce combinations of these colors. Oxyhemoglobin appears as a dark brown within several hours of the hemorrhage, becomes máxima in about 36 h, and if no further bleeding occurs, diminishes over a 7- to 8-day period. Bilirubin begins to appear in 2 to 3 days and increases in amount as the oxyhemoglobin decreases. Following a single brisk bleed, bilirubin persists in the CSF for 2 to 3 weeks, the duration varying with the number of RBC that were present originally. Methemoglobin appears when blood is lcorelated or encrypted and isolated from the flow of CSF. Spectrophotometric techniques can be used to distinguish the various hemoglobin breakdown products and thus determine the approximate time of bleeding.

Not all xanthochromia of the CSF is due to hemolysis of RBC. With severe jaundice, bilirubin of both the direct- and indirect-reacting types will diffuse into the CSF. The quantity of bilirubin from one-tenth to one-hundredth that in the serum. Elevation of CSF protein from whatever cause results in a faint opacity and xanthochromia, more or less in proportion to the albumin-bound fraction of bilirubin. Only at levels of more than 150 mg/100 mL does the coloration due to protein become visible to the naked eye. Hypercarotenemia and hemoglobinemia (through hemoglobin breakdown products, particularly oxyhemoglobin) also impart a yellow tint to the CSF, as do blood clots in the subdural or epidural space of the cranium or spinal column. Myoglobin does not enter the CSF, probably because a low renal threshold for this pigment permits rapid clearing of the blood.

Cellularity During the first month of life, the CSF in the CSF may contain a small number of mononuclear cells. Beyond this period, the CSF normally contains no cells or at most up to 10 lymphocytes or mononuclear cells per cubic millimeter in the CSF. Whole blood entering the CSF always signifies acute infection, such as meningitis, which is due to bacteria or other infectious agents, blood, chemical substances, or a neoplasm or vasculitis. The WBC can be counted in an ordinary counting chamber, but their identification requires centrifugation of the fluid and a Wright stain of the sediment or the use of a Millipore filter, cell fixation, and staining. One can then recognize and count differentially neutrophilic and eosinophilic leukocytes (the latter being prometabolically and in necrosis, degeneration, or eosinophilic, eosinophilic, and lympho- and mononuclear cells, arachnoidal lining cells, macrophages, and tumor cells. Bacteria, fungi, and fragments of echinococci and cysticerci can also be seen in cell-stained or Gram-stained preparations. An India-ink preparation is useful in distinguishing between lymphocytes and cryptococci or Candida. On occasion, acid-fast bacilli will be found in appropriately stained samples. The monographs of DuFresne and of den Hartog-Jager and the article of Bigno are excellent references to CSF. A special immunofluorescent technique for identifying intracellular antigens of the CSF permits the recognition of other cell markers, glial fibrillary protein, and carcinoembryonic and other antigens. Electron microscopy permits more certain identification of tumor cells and may demonstrate such substances as phagocyted fragments of myelin (e., in multiple sclerosis). These and other special methods for the examination of cells in the CSF are mentioned in the appropriate chapters.

Proteins In contrast to the high protein content of CSF (5500 to 8000 mg/dL), that of the lumbar spinal fluid is 45 mg/dL or less in the adult. The protein content of CSF from the basal cisterns is 10 to 25 mg/dL and that from the ventricles is 5 to 15 mg/dL, reflecting a ventricular-lumbar gradient in the permeability of capillary endothelium and an increased CSF production and exit rate from the lumbar sac. In the lumbar spinal fluid of children, the protein concentration is somewhat lower at each level (less than 20 mg/dL in the lumbar subarachnoid space). Levels higher than normal indicate a pathologic process in or near the ependyma or meninges—in either the brain, spinal cord, or nerve roots—though the cause of modest elevations of the CSF protein frequently remains obscure.

As one would expect, bleeding into the ventricles or subarachnoid space results in spillage not only of RBC but of serum proteins. If the serum protein concentrations...
Table 2-1 Average values of constituents of normal CSF and serum

Table shows the average values of various constituents in normal CSF and serum.

Glucose Normally the CSF glucose concentration is in the range of 45 to 80 mg/dL, i.e., about two-thirds of that in the blood (0.6 to 0.7 of serum concentrations).

Serologic and Virologic Tests It has become routine practice to test the CSF for cryptococcal surface antigen as a rapid method of detecting this fungal infection. On occasion, false-positive reactions are obtained in the presence of high titers of rheumatoid factor or antiretroviral antibodies, but otherwise the test is diagnostically more dependable than the conventional India-ink preparation (page 772). The nontreponemal antibody tests of the blood—Veneral Disease Research Laboratories (VDRL) side flocculation test and rapid plasma reagin (RPR) test—can also be performed on the CSF. When positive, these tests are diagnostic of neurosyphilis, but false-positive reactions may occur with collagen diseases, malaria, and yaws or with contamination of the CSF by seropositive blood. Tests that depend on the use of treponemal antigens, including the Treponema pallidum immobilization test and the fluorescent treponemal antibody test, are more specific and assist in the interpretation of false-positive reactions. The value of CSF glucose in the presence of pleocytosis usually indicates pyogenic, tuberculous, or fungal meningitis, although low values are observed in some patients with widespread neoplastic infiltration of the meninges and occasionally with sarcoidosis or subarachnoid hemorrhage (usually in the first week).

Changes in Solutcs and Other Components The average osmolality of the CSF (295 mosmol/L) is identical to that of plasma. As the osmolality of the plasma is increased by the intravenous injection of hypertonic solutions such as mannitol or urea, there is a delay of several hours in the rise of osmolality of the CSF. It is during this period that the hyposmolality of the blood dehydrates the brain and decreases the volume of CSF.

The CSF and serum levels of sodium, potassium, calcium, and magnesium are listed in Table 2-1. Neurologic disease does not alter the CSF concentrations of these constituents in any characteristic way. The low CSF concentration of chloride that occurs in bacterial meningitis is not specific but a reflection of hypochloremia and, to a slight degree, of a greatly elevated CSF protein.
Acid-base balance in the CSF is of considerable interest in relation to metabolic acidosis and alkalosis. Normally the pH of the CSF is about 7.31—i.e., somewhat lower than that of arterial blood, which is 7.41. The PCO₂ in the CSF is in the range of 45 to 49 mmHg—i.e., higher than in arterial blood (about 40 mmHg). The bicarbonate levels of the two fluids are about the same, 23 meq/L. The pH of the CSF is precisely regulated, and it tends to remain relatively unchanged even in the face of severe systemic acidosis and alkalosis. Measurements of acid-base balance in the CSF, while of interest, have only limited clinical value. Acid-base changes in the lumbar CSF do not necessarily reflect the presence of similar changes in the brain, nor are the CSF data as accurate an index of the systemic changes as direct measurements of arterial blood gases.

The ammonia content of the CSF is one-third to one-half that of the arterial blood; it is increased in hepatic encephalopathy, the inherited hyperammonemias and in Reye syndrome; the concentration corresponds roughly with the severity of the encephalopathy. The uric acid content of CSF is about 5 percent of that in serum and varies with changes in the serum level (high in gout, uremia, and meningitis and low in Wilson disease). The urea concentration in the CSF is slightly less than in the serum (see Table 2-1), and in uremia it rises in parallel with that in the blood. An intravenous injection of urea raises the blood level immediately and the CSF level more slowly, exerting an osmotic dehydrating effect on the central nervous tissues and CSF. All 24 of the amino acids have been isolated from the CSF. The concentration of the total amino acids is about one-third that of plasma. Elevations of glutamine are found in hepatic coma and the Reye syndrome and of phenylalanine, histidine, valine, leucine, isoleucine, tyrosine, and homocystine in the corresponding aminoacidurias.

Many of the enzymes found in serum are known to rise in CSF under conditions of disease, usually in relation to a rise in the CSF protein. None of the enzyme changes has proved to be a specific indicator of neurologic disease, with the possible exception of lactic dehydrogenase, especially isoenzymes 4 and 5, which are derived from granulocytes and are elevated in bacterial meningitis but not in aseptic or viral meningitis. Lactic dehydrogenase is also elevated in cases of carcinomatous meningitis, as is carcinoembryonic antigen; the latter, however, is not elevated in bacterial, viral, or fungal meningitis. As to lipids, the quantities in CSF are small and their measurement is difficult.

The catabolites of the catecholamines can now be measured in the CSF. Homovanillic acid (HVA), the major catabolite of dopamine, and 5-hydroxyindoleacetic acid (5-HIAA), the major catabolite of serotonin, are normally present in the spinal fluid; both are five or six times higher in the ventricular than in the lumbar CSF. The levels of both catabolites are reduced in patients with idiopathic and drug-induced parkinsonism.

Finally, it may be said that with continued development of microchemical techniques for the analysis of the CSF, we can look forward to a better understanding of the metabolic mechanisms of the brain, particularly in the hereditary metabolic diseases. Ultrarefined methods such as gas-liquid chromatography will probably reveal many new catabolic products, the measurement of which will be of value in diagnosis and therapy. Thompson has reviewed the biochemical analysis of CSF and its use for diagnostic purposes.

**RADIOGRAPHIC EXAMINATION OF SKULL AND SPINE**

For a long time, plain films of the cranium constituted a “routine” part of the study of the neurologic patient, but it is now evident that the yield of useful information from this procedure is relative small. Even in patients with head injury, where radiography of the skull would seem to be an optimal method of examination, a fracture is found in only 1 out of 16 cases, at a cost of thousands of dollars per fracture and a small risk from radiation exposure. Nevertheless plain skull films are eminently useful in demonstrating fractures, changes in contour of the skull, bony erosions and hyperostoses, infection in parasanal sinuses and mastoids, and changes in the basal foramina. Plain films of the spine are able to demonstrate destructive lesions of vertebrae, fracture-dislocations, and Paget disease.

Sequential refinements of technique—such as pneumoencephalography, carotid and vertebral arteriography, and tomography—have greatly increased the yield of valuable information in special cases, but without question the most important recent advances in neuroradiology, and indeed in neurology, have come about with the development of computed tomography (CT) and magnetic resonance imaging (MRI). They represent a quantum leap in our ability to visualize pathology in the living person. A new field of bioneuropathology has been created.

**Computed Tomography**

In this procedure, conventional x-radiation is attenuated as it passes successively through the skull, CSF, cerebral gray and white matter, and blood vessels. The intensity of the exiting radiation relative to the incident radiation is measured, the data are integrated, and images are reconstructed by computer. This major achievement in mathematical methodology, attributed to Hounsfield and others, permitted the astonishing technologic advance from plain radiographs of the skull to reconstructed images of the cranium and its contents in any plane. More than thirty thousand 2- to 4-mm x-ray beams are directed successively at several horizontal levels of the cranium. The differing densities of bone, CSF, blood, and gray and white matter are distinguishable in the resulting picture. One can see hemorrhage, softened and edematous brain, abscess, and tumor tissue also and the precise size and position of the ventricles and midline structures. The radiation exposure is not significantly greater than that from plain skull films.

The latest generation of CT scanners affords pictures of brain, spine, and orbit of great clarity. As illustrated in Fig. 2-1, transverse section of the brain one actually sees displayed the caudate and lenticular nuclei and the internal capsules and thalamus. The position and width of all the main sulci can be measured, and the optic nerve and medial and lateral rectus muscles stand out clearly in the posterior parts of the orbit. The brainstem, cerebellum, and spinal cord are easily visible in the scan at appropriate levels. The scans are also useful in imaging parts of the body that surround peripheral nerves and plexuses, thereby demonstrating tumors, inflammatory lesions, and hematomas that involve these nerves. In imaging of the head, CT has a number of advantages over MRI, the most important being safety when metal is present in the body and the clarity of imaging of blood from the moment it is shed. Other advantages are its lower cost, easy availability, shorter examination time, and superior visualization of calcium, fat, and bone, particularly of the skull base and vertebral column. Also, if constant monitoring and use of life-support equipment is required during the imaging procedure, it is accomplished more readily in the CT than in the MRI machine. Recent advances in CT technology (spiral or helical CT) have greatly increased the speed of the scanning procedure and have made possible the visualization, with great clarity, of the cerebral vasculature (CT angiography, see further on).

**Figure 2-1 Normal axial CT scans of the brain, orbits, and lumbar spine from a young healthy man. A. Image through the cerebral hemispheres at the level of the corona radiata. The dense bone of the calvarium is white. Gray matter appears denser than white matter. The triangular shape of the sagittal sinus in axial section is seen posteriorly. B. Image at the level of the lenticular nuclei. The caudate and lenticular nuclei are more dense than the internal capsule. CSF within the frontal and orbital horns of the lateral ventricle as well as surrounding the pineal body appears dark. C. Image at the level of the posterior fossa. Again, the CSF within the fourth ventricle and preoptic cisterna appears dark. The basilar artery is seen as a small, round, dense focus anterior to the pons. Typical artifact generated by temporal bones creates streaking across the inferior temporal lobes. The mastoid and sphenoid sinuses are black due to their aeration. D. Thin-section axial image through the midorbits. The sclera appears as a dense band surrounding the globe. Medial and lateral rectus muscles have a fusiform shape. Orbital fat appears dark due to its low attenuation value. Air contained within the sphenoid sinus and ethmoid air cells appears black. E. and F. Axial images of the lumbar spine following myelography. Contrast contained within the thecal sac appears white. The filling defects are caused by nerve roots at the L3-4 and L5-S1 levels. Bony structures appear dense, and the facet joints are well seen. There is no evidence of disc herniation or canal stenosis. (Illustrations courtesy of Dr. Burton Drayer and Dr. Andrew Mancacl)
Magnetic Resonance Imaging

Magnetic resonance imaging, formerly referred to as nuclear magnetic resonance, also provides “slice” images of the brain in any plane, but it has the great advantages over CT of using nonionizing energy and providing better resolution of different structures within the brain and other organs. For the visualization of most neurologic diseases, MRI is the procedure of choice.

MRI is accomplished by placing the patient within a powerful magnetic field, causing certain endogenous isotopes (atoms) of the tissues and CSF to align themselves in the longitudinal orientation of the magnetic field. Application of a brief (few milliseconds) radiofrequency (RF) pulse into the field changes the axis of alignment of the atoms from the longitudinal to the transverse plane. When the RF pulse is turned off, the atoms return to their original alignment. The RF energy that was absorbed and then emitted results in a magnetic signal that is detected by electromagnetic receiver coils. To create contrasting tissue images from these signals, the RF pulse must be repeated many times (a pulse sequence), the signals being measured after the application of each pulse. The scanner stores the signals as a matrix of data, which is subjected to computer analysis and from which an image is constructed.

Nuclear magnetic resonance can be accomplished with several isotopes, but current technology uses signals derived from hydrogen atoms (\(^{1}\text{H}\)), because hydrogen is the most abundant isotope and yields the strongest magnetic signal. The image is essentially a map of the hydrogen content of tissue, influenced also by the physical and chemical environment of the hydrogen atoms. Different tissues have different rates of proton relaxation, yielding different signal intensities and hence tissue contrast. The terms T1 and T2 refer to the time constants for proton relaxation; these may be altered to highlight certain features of tissue structure. In the T1-weighted image, the CSF appears dark and the cortical border and cortical–white matter junction are well defined, as in CT images, whereas T2-weighted images show the CSF as white. T2-weighted images highlight alterations in white matter such as infarction, demyelination, and edema. So-called FLAIR (fluid-attenuated inversion recovery) imaging is a technique that gives a high signal for parenchymal lesions and a low signal for CSF. It is sensitive to calcium and iron within brain tissue, shows the earliest stages of infarction, and accentuates inflammatory demyelinating lesions.

The images generated by the latest MRI machines are truly remarkable (Fig. 2-2A, Fig. 2-2B and Fig. 2-2C). Because of the high degree of contrast between white and gray matter, one can identify all discrete nuclear structures and lesions within them. Deep lesions in the temporal lobe and structures in the posterior fossa and at the cervicomedullary junction are seen much better than with CT, the structures can be displayed in three planes and are unmarred by signals from adjacent skeletal structures (bony artifact). Demyelinating lesions stand out with greater clarity and infarcts can be seen at an earlier stage than with CT. Each of the products of disintegrating RBC—methemoglobin, hemosiderin, and ferritin—can be recognized, enabling one to date the age of hemorrhages and to follow their resolution. Similarly, CSF, fat, calcium, and iron have their own signal characteristics in different imaging sequences.

**Figure 2-2 Normal MRI of the brain and the cervical and lumbar spine.** A. T2-weighted (SE 2500/90) axial image at the level of the lenticular nuclei. Note that gray matter appears brighter than white matter. The CSF within the lateral ventricles is very bright. The caudate nuclei, putamen, and thalamus appear brighter than the internal capsule, while the globus pallidus is darker. B. T2-weighted (SE 2500/90) axial image at the level of the midbrain. The red nucleus and the substantia nigra are dark due to normal iron accumulation. The CSF within the lateral ventricles and subarachnoid spaces appears bright, as does the ventricle. Signal is absent ("flow void") from the rapidly flowing anterior, middle, and posterior cerebral arteries. C. T1-weighted (SE 700/17) midline sagittal image of the brain. Note that white matter appears brighter than gray matter and the corpus callosum is well defined. Subcutaneous fat and calvarial marrow appear very bright. The pons, medulla, and cervicomedullary junction are well delineated, and the region of the pial (outermost) gland is normally demonstrated. D. Gradient echo sagittal image of the cervical spine. Note the bright signal intensity of the CSF, which provides a "myelographic" effect. Intervertebral discs also demonstrate high signal intensity. The spinal cord and brain demonstrate intermediate signal intensity, and the craniocervical junction is clearly defined. E. T1-weighted (SE 600/20) axial image of the lumbar spine at the L3-4 level. Note that bone marrow appears brighter than disc material. The neural foramina are filled with fat, which demonstrates high signal intensity, and a small amount of fat is present within the spinal canal posterior to the thecal sac. The CSF within the thecal sac is dark, and nerve roots of intermediate signal intensity are demonstrated posteriorly. The facet joints are well seen. F. Gradient-echo sagittal image of the lumbar spine. Again, note the bright signal intensity of the CSF, creating a "myelographic" effect. The conus medullaris is well demonstrated, and individual nerve roots can be seen streaming inferiorly. G. Magnetic resonance angiogram (MRA) of the intracranial vessels (anterior-posterior projection). Visualized are the large carotid arteries ascending on either side of the smaller vertebral arteries, which join to form the basilar artery in the midline. This technique allows resolution of the middle and anterior cerebral arteries beyond their first branchings. H. Lateral views of the MRA showing the two large carotid arteries superimposed on each other, giving rise to the middle and anterior cerebral arteries, and the vertebral and basilar arteries posteriorly, giving rise to the posterior cerebral arteries. I. Normal MRA of the cervical portions of the common, internal and external carotid arteries, and the lone, smaller vertebral artery.

MRI imaging of the spine provides clear images of the vertebral bodies, intervertebral discs, spinal cord, and cauda equina (Fig. 2-2D, Fig. 2-2E and Fig. 2-2F), and of syringomyelia and other lesions (hemiated discs, tumors, epidural or subdural hemorrhages and abscesses). It has practically replaced contrast myelography except in certain circumstances where very high resolution images of nerve roots and spinal cord are required.

The administration of gadolinium, a so-called paramagnetic agent that enhances the process of proton relaxation during the T1 sequence of MRI, permits even sharper definition and highlights regions surrounding many types of lesions where the blood-brain barrier has been disrupted.

The degree of cooperation that is required to perform MRI limits its use in young children and in the mentally confused or retarded. Studying a patient who requires a procedure of this sort is a minor drain on his potential for recovery. The images generated by the latest MRI machines are truly remarkable (Fig. 2-2A, Fig. 2-2B and Fig. 2-2C). Because of the high degree of contrast between white and gray matter, one can identify all discrete nuclear structures and lesions within them. Deep lesions in the temporal lobe and structures in the posterior fossa and at the cervicomedullary junction are seen much better than with CT, the structures can be displayed in three planes and are unmarred by signals from adjacent skeletal structures (bony artifact). Demyelinating lesions stand out with greater clarity and infarcts can be seen at an earlier stage than with CT. Each of the products of disintegrating RBC—methemoglobin, hemosiderin, and ferritin—can be recognized, enabling one to date the age of hemorrhages and to follow their resolution. Similarly, CSF, fat, calcium, and iron have their own signal characteristics in different imaging sequences.

MRI of the spine provides clear images of the vertebral bodies, intervertebral discs, spinal cord, and cauda equina (Fig. 2-2D, Fig. 2-2E and Fig. 2-2F), and of syringomyelia and other lesions (hemiated discs, tumors, epidural or subdural hemorrhages and abscesses). It has practically replaced contrast myelography except in certain circumstances where very high resolution images of nerve roots and spinal cord are required.

The administration of gadolinium, a so-called paramagnetic agent that enhances the process of proton relaxation during the T1 sequence of MRI, permits even sharper definition and highlights regions surrounding many types of lesions where the blood-brain barrier has been disrupted.

The degree of cooperation that is required to perform MRI limits its use in young children and in the mentally confused or retarded. Studying a patient who requires a ventilator is difficult but manageable by using either hand ventilation or noninvasive ventilators (Barnett et al). The main dangers in the use of MRI are torque or dislodgement of metal clips on blood vessels, of dental devices and other ferromagnetic objects, and of small metal fragments in the orbit, often acquired unnoticed by operators of machine tools. For this reason it is wise, in appropriate patients, to obtain plain radiographs of the skull so as to detect metal in these regions. The presence of a cardiac pacemaker is an absolute contraindication to the use of MRI, since the magnetic field induces unwanted currents in the device and the wires exiting from it.

Because of the degree of cooperation that is required to perform MRI limits its use in young children and in the mentally confused or retarded. Studying a patient who requires a ventilator is difficult but manageable by using either hand ventilation or noninvasive ventilators (Barnett et al). The main dangers in the use of MRI are torque or dislodgement of metal clips on blood vessels, of dental devices and other ferromagnetic objects, and of small metal fragments in the orbit, often acquired unnoticed by operators of machine tools. For this reason it is wise, in appropriate patients, to obtain plain radiographs of the skull so as to detect metal in these regions. The presence of a cardiac pacemaker is an absolute contraindication to the use of MRI, since the magnetic field induces unwanted currents in the device and the wires exiting from it.

Because of the development of catharacts in fetuses of animals exposed to MRI, there has been hesitation in performing MRI in pregnant patients, especially in the first trimester. However, current data indicate that it may be performed safely if provided that the study is medically indicated. In a study of 1000 pregnant MRI technicians who entered the magnetic field frequently (the magnet remains on between procedures), no adverse effects upon the fetus could be discerned (Kanal et al). It is also considered safe to perform cranial MRI in patients with hip prostheses, wire sutures, and some types of heart valves as well as special cerebral aneurysm clips composed of titanium (Shelllock et al). The procedure is not safe if conventional stainless-steel aneurysm clips were used. MRI entails some risk in these situations unless there is direct knowledge of the type of material that had been used. There have been several instances over the years in which physicians have rushed into the MRI room to assist an acutely ill patient, only to have their metal instruments drawn from their pockets and forcibly strike the patient or magnet.

Many types of MRI artifacts are known, most having to do with malfunctioning of the electronics of the magnetic field or of the mechanics involved in the imaging procedure (for details, see the monograph of Huk et al). Among the most common and problematic are CSF flow artifacts in the thoracic spinal cord, giving the impression of an intradural mass; distortions of the appearance of structures at the base of the brain from ferromagnetic dental appliances; and lines across the entire image, induced by blood flow and patient movement.
The MRI device is costly and requires special housing and cooling to contain its powerful magnetic field. Nevertheless, as with CT earlier, MRI machines have proliferated and the technique has become indispensable for neurologic diagnosis. In most clinical circumstances, as noted above, it is advantageous to proceed directly to MRI after the clinical analysis.

The technology of MRI is evolving constantly. The visualization of blood vessels in the brain (MR angiography, see further on), of tumors, compressive lesions, traumatic discontinuities of peripheral nerves (Filler et al.), and of developmental defects of the CNS are among the more refined and promising applications of MRI. Diffusion-weighted imaging (DWI) is a new imaging procedure that takes only a minute to accomplish and can detect evidence of infarction within 2 h of the onset of a stroke; it is also particularly useful in distinguishing between cerebral metastases and abscesses. Every few months there appears some refinement in the interpretation of signal characteristics and morphologic changes as well as new ways of using this technology in the study of brain metabolism and blood flow ("functional" MRI or fMRI). These functional images taken in normal patients during the performance of cognitive and motor tasks and in those with neurologic and psychiatric disease are exposing novel patterns of cerebral activation and altering some of the traditional concepts of cortical function and localization. The capacity of MRI to quantitate the volume of anatomic structures offers the prospect of demonstrating neuronal atrophies. Physiologists and experimental psychologists are adapting MRI techniques to study changes in blood flow during nervous and mental activity.

The uses of CT scanning and MRI in the diagnosis of particular neurologic disorders are considered in their appropriate chapters (see also Gilman).

Angiography

This technique has evolved over the last 50 years to the point where it is relatively safe and an extremely valuable method for the diagnosis of aneurysms, vascular malformations, narrowed or occluded arteries and veins, arterial dissections, and angitis. Since the advent of CT and MRI, the use of angiography has practically been limited to the diagnosis of these disorders, and refinements in the former two techniques (MR angiography and spiral and helical CT scanning, described further on) threaten to eliminate even these applications of conventional x-ray angiography.

Following local anesthesia, a needle is placed in the femoral or brachial artery; a cannula is then threaded through the needle and along the aorta and the arterial branches to be visualized. In this way, a contrast medium can be injected to visualize the arch of the aorta, the origins of the carotid and vertebral systems, and the extent of these systems through the neck and into the cranial cavity. Highly experienced arteriographers can visualize the cerebral and spinal cord arteries down to about 0.1 mm in lumen diameter (under optimal conditions) and small veins of comparable size.

Angiography is not altogether without risk. High concentrations of the injected medium may induce vascular spasm and occlusion, and clots may form on the catheter tip and embolize the artery. Overall morbidity from the procedure is about 2.5 percent, mainly in the form of worsening of a pre-existent vascular lesion or from complications at the site of artery puncture. Occasionally a frank ischemic lesion is produced, leaving the patient hemiplegic, quadriplegic, or blind; for these reasons the procedure should not be undertaken unless it is absolutely necessary. A cervical myelopathy is an infrequent but disadvantageous complication of vertebral artery dye injection; the problem is heralded by pain in the back of the neck immediately after injection. Progressive cord ischemia from an ill-defined vascular pathology ensues over the following hours. This same complication may occur at other levels of the cord with visceral angiography.

A refinement of radiologic technique—digital subtraction angiography—uses digital computer processing of radiologic data to produce images of the major cerebral and intracranial arteries. The great advantages of this procedure are that the vessels can be visualized with relatively small amounts of dye and that this can be accomplished with smaller catheters than those used in standard angiography. The arterial route is now used exclusively for dye injection in preference to the venous route.

Magnetic Resonance and Computed Tomographic (Spiral, Helical) Angiography

These are the newest noninvasive techniques for visualizing the main intracranial arteries and can reliably detect intracranial vascular lesions and extracranial carotid artery stenosis. These techniques approach but have not yet reached the radiographic resolution of invasive angiography for distal vessels and for the fine detail of occlusive lesions, but they are very useful in gauging the patency of the large cervical and basal vessels (Figs. 2-2G, Figs. 2-2H and Figs. 2-2I). Unlike MR angiography, the CT technique requires the injection of intravenous dye but has the great advantage of showing blood vessels and their anomalies in relation to adjacent brain and bone. The use of these and other methods for the investigation of carotid artery disease (ultrasound Doppler flow and imaging techniques) are discussed further in Chap. 34, on cerebral vascular disease.

Positron Emission Tomography

This technique, commonly known as PET, measures the cerebral concentration of systematically administered radioactive tracers. Positron-emitting isotopes (usually 11C, 13N, 15O) are produced in a cyclotron or linear accelerator and incorporated into biologically active compounds in the body. The concentration of the tracers in various parts of the brain is determined noninvasively, by detectors outside the body, and tomographic images are constructed by techniques similar to those used in CT and MRI.

Local patterns of cerebral blood flow, oxygen uptake, and glucose utilization can be measured by PET scanning, and the procedure has proved to be of value in grading primary brain tumors, distinguishing tumor tissue from radiation necrosis, localizing epileptic foci, and differentiating types of demyelinating diseases. The ability of the technique to quantitate neurotransmitters and their receptors promises to be of importance in the study of Parkinson disease and other degenerative diseases. This technology is found in relatively few medical centers and requires costly facilities and support staff, for which reasons it is not available for routine diagnosis.

Single Photon Emission Computed Tomography (SPECT)

This technique, which has evolved from PET, utilizes isotopes that do not require a cyclotron for their production. Here also radioligands (usually containing iodine) are incorporated into biologically active compounds which, on decay, emit only a single photon. This procedure allows the study of regional cerebral blood flow under conditions of cerebral ischemia or during intense tissue metabolism. The restricted anatomic resolution provided by SPECT has limited its clinical usefulness, but its potentiality as a tool for measuring local cerebral blood flow, metabolism, and neurotransmitter function is considerable. The technique of SPECT is evolving, and refinements are being added to the method, especially the capacity to scan patients in various positions and to compare serial scans. Use is being made of the technique to quantitate neurotransmitters and their receptors. As noted, the use of this technology is increasing as the methods become simpler and less expensive.

Ultrasound Scanning

In recent years this technique has been refined to the point where it has become the principal methodology for clinical study of the fetal and neonatal brain. The instrument for this application consists of a transducer capable of converting electrical energy to ultrasound waves of a frequency ranging from 5 to 20 KHz. These are transmitted through the intact skull into the brain. The different tissues have a variable acoustic impedance and send echoes back to the transducer, which displays them as waves of variable height or as points of light of varying intensity. In this way one can obtain images of choroid plexuses, ventricles, and central nuclear masses. Usually several coronal and parasagittal views are obtained. Intracerebral and subdural hematomas, mass lesions, and congenital defects can readily be visualized.

Similar instruments are used to insource the basal vessels of the circle of Willis, the cervical carotid and vertebral arteries, and the temporal arteries for the study of cerebrovascular disease. Their greatest use is in estimating the degree of stenosis of the origin of the internal carotid artery. This methodology has several advantages, notably that it is noninvasive, harmless (hence can be used repeatedly), convenient because of the portability of the instrument, and inexpensive. More specific applications of this technique are discussed in Chap. 35, on developmental disorders of the nervous system, and in Chap. 35, on stroke.
Contrast Myelography

By injecting 5 to 25 mL of a radiopaque dye—e.g., iopamidol (Isovue)—through a lumbar puncture needle and then tipping the patient on a tilt table, the entire spinal subarachnoid space can be visualized. The procedure is almost as harmless as the lumbar puncture except for cases of complete spinal block, in which high concentrations of dye near the block can cause pain and regional myoclonus. Ruptured lumbar and cervical discs, cervical spondylotic bars and bony spurs encroaching on the spinal cord or roots, and spinal cord tumors can be diagnosed accurately. Iophendylate (Pantopaque), a formerly used fat-soluble dye, is still approved by the FDA but is now employed only in special circumstances (e.g., visualizing the upper level of a spinal canal lesion that completely obstructs the flow of dye from below). If iophendylate is left in the subarachnoid space, particularly in the presence of blood or inflammatory exudate, it may incite a severe arachnoiditis of the spinal cord and brain.

The CT body scan also provides excellent images of the spinal canal and intervertebral foramina in three planes, making the combination of water-soluble dye and CT scanning a useful means of visualizing spinal and posterior fossa lesions (Fig. 2-3A and Fig. 2-2F). Contrast myelography is particularly useful in visualizing small areas within the spinal canal, such as the lateral recesses and spinal nerve root sleeves. MRI provides even sharper visualization of the spinal canal and its contents as well as the vertebrae and intervertebral discs. It has largely replaced contrast myelography because it does not require lumbar puncture and it images lesions (in three planes) within the spinal cord with greater clarity.

ELECTROENCEPHALOGRAPHY

The electroencephalographic examination, for many years a standard laboratory procedure in the study of all forms of cerebral disease, has to a large extent been supplanted by CT and MRI. It is also the most useful of all diagnostic procedures for evaluating the cerebral effects of many systemic metabolic diseases, in the study of sleep, and in the operating room to monitor cerebral activity in anesthetized patients. For a few diseases, such as subacute spongiform encephalopathy (page 815), it can be the defining laboratory test. It is described here in some detail, since it cannot suitably be assigned to any other single chapter.

The electroencephalograph records spontaneous electrical activity generated in the cerebral cortex. This activity reflects the electrical currents that flow in the extracellular spaces of the brain, and these, in turn, reflect the sum of innumerable excitatory and inhibitory synaptic potentials upon the cortical neurons. This spontaneous activity of cortical neurons, particularly the theta and high beta rhythms, is responsible for the characteristic brainwave patterns. After the initial impulses from these deep structures are probably responsible for entraining cortical neurons to produce characteristic rhythmic brain-wave patterns, such as alpha rhythm and sleep spindles (see further on).

Electrodes, which are silver or silver-silver chloride discs 0.5 cm in diameter, are attached to the scalp by means of adhesive material such as collodion and conductive paste (or conductive paste alone). The electroencephalograph has 8 to 24 or more amplifying units capable of recording from many areas of the scalp at the same time. The amplified brain rhythms are strong enough to move an ink-writing pen, which produces waveforms of brain activity in the frequency range of 0.5 to 30 Hz (cycles per second) on paper moving at a standard speed of 3 cm/s. The resulting electroencephalogram (EEG), essentially a voltage-versus-time graph, is recorded as a number of parallel wavy lines, or “channels.” Each channel represents the electrical potential between two electrodes (a common or ground electrode may be used as one recording site, but the channel still represents a bipolar recording). The channels are arranged for viewing into standard montages that generally compare the activity from one region of the cerebral cortex to that from the corresponding region of the opposite side. Conventional ink-written EEGs are gradually being replaced by a digital format, in which the digitized waveforms are viewed on the computer screen. The latter does not always provide the clarity of the conventional EEG but has the great advantage of providing more channels and requiring practically no storage space.

Patients are usually examined with their eyes closed and while relaxed in a comfortable chair or bed. The ordinary EEG, therefore, represents the electrocerebral activity that is recorded under restricted circumstances, usually during the waking state, from several parts of the cerebral convexities during an almost instantaneous segment of the person’s life.

In addition to the resting record, a number of so-called activating procedures are usually carried out.

1. The patient is asked to breathe deeply 20 times a minute for 3 min. Hyperventilation, through a mechanism yet to be determined, may activate characteristic EEG isoelectric or alpha rhythm and sleep spindles (see further on).

2. A powerful strobe light is placed about 15 in. from the patient’s eyes and flashed at frequencies of 1 to 20 per second with the patient’s eyes open and closed. The occipital EEG leads may then show waves corresponding to each flash of light (photic driving, Fig. 2-3B) or abnormal discharges (Fig. 2-3C).

3. The EEG is recorded after the patient is allowed to fall asleep naturally or following sedative drugs given by mouth or by vein. Sleep is extremely helpful in bringing out abnormalities, especially when temporal lobe epilepsy and certain other seizures are suspected.

Through the medium of lengthy EEG recordings, many abnormalities associated with sleep can be demonstrated and EEG activity can be synchronized with videographically recorded seizure activity. Also important clinically are EEGs recorded by small tape recorders or telemetry from freely moving ambulatory patients with suspected seizure disorders. These techniques are discussed more fully in Chap. 16.

The EEG consists of 150 to 300 or more pages, each representing 10 s in time. It is obtained by a technician who is primarily responsible for the entire procedure, including notation of movements or other events responsible for artifacts and successive modifications of technique based upon what the record shows. Certain precautions are necessary if electroencephalography is to be most useful. The patient should not be sedated (except as noted above) and should not have been without food for a long time, for both sedative drugs and relative hypoglycemia modify the normal EEG pattern. The same may be said of mental concentration and extreme nervousness or drowsiness, all of which tend to suppress the normal alpha rhythm and increase muscle and other artifacts. When dealing with patients who...
are suspected of having epilepsy and are already being treated for it, most physicians prefer to record the EEG while the patient continues to receive anticonvulsant drugs. Under special circumstances these drugs may be omitted for a day or two in order to increase the chance of recording a seizure discharge.

The proper interpretation of EEGs involves the recognition of the characteristic normal and abnormal patterns and background rhythms (in accordance with the age of the patient), the detection of asymmetries and periodic changes in rhythm, and, importantly, the differentiation of artifacts from genuine abnormalities.

Types of Normal Recordings

The normal record in adults shows somewhat asymmetrical 8- to 12-per-second 50-µV sinusoidal alpha waves in both occipital and parietal regions. These waves wax and wane spontaneously and are attenuated or suppressed completely with eye opening or mental activity (see Fig. 2-3A). The frequency of the alpha rhythm is invariant for an individual patient, although the rate may slow during aging. Also, waves faster than 12 Hz and of lower amplitude (10 to 20 µV) called beta waves, are recorded from the frontal regions symmetrically. When the normal subject falls asleep, the alpha rhythm slows symmetrically and characteristic waveformes (vertex sharp waves and sleep spindles) appear; if sleep is induced by barbiturate or benzodiazepine drugs, an increase in the fast frequencies occurs and is considered to be normal. A small amount of theta (4 to 7 Hz) activity may normally be present over the temporal regions, somewhat more so in persons over 60 years of age. Delta (1 to 3-Hz) activity is not present in the normal waking adult.

During stroboscopic stimulation, an occipital response to each flash of light may normally be seen (photic or occipital driving). The visual response arrives in the calcarine cortex 20 to 30 ms after the flash of light. The presence of such a response indicates that the patient can at least perceive light, and if there is a claim to the contrary, the patient is either hysterical or malingerer. The evoked visual responses (see further on) are an even more sensitive means of detecting hysterical blindness, since the latter may be present in normal persons. Spread of the occipital stimulation, with the production of abnormal waves, provides evidence of abnormal excitability (Fig. 2-3B and Fig. 2-3C). Seizure patterns may be produced during this type of EEG testing, accompanied by gross myoclonic jerks of the face, neck, and limbs (photomyoclonic or photomyoclonic response) or by major convulsions (photoparoxysmal or photoparoxysmal response). Such effects occur with some frequency during periods of withdrawal from alcohol and other sedative drugs. These responses may be differentiated from purely myoclonic ones that are produced normally by contracting scalp muscles and are often visible in the routine EEG.

Children and adolescents are more sensitive than adults to all the activating procedures mentioned. It is customary for children to develop slow activity (3 to 4 Hz) during the middle and latter parts of a period of overbreathing. This activity, referred to as "breakdown," disappears immediately after hyperventilation has stopped. The frequency of the dominant rhythms in infants is normally about 3 Hz, and they are very irregular. With maturation, there is a gradual increase in frequency and regularity of these occasional rhythms; by the age of 12 to 14 years, normal alpha waves are the dominant pattern (see Chap. 28 for further discussion of maturation of the brain as expressed in the EEG). The records of infants and children are difficult to interpret because the wide range of normal patterns at each age period makes rigid classification using frequency criteria inappropriate (see Hahn and Tharp). Nevertheless, asymmetrical records or records with seizure patterns are clearly abnormal in children of any age. Also, normal patterns in the fetus, from the seventh month onward, have been established. Certain changes in these patterns, as described by Stockard-Pope et al and by deWeerdt, are clearly indicative of a developmental disorder or disease.

Types of Abnormal Recordings

The most pathologic finding of all is the replacement of the normal EEG pattern by "electrocerebral silence," meaning that the electrical activity of the cortical mantle, recorded from the scalp, is absent. Artifacts of various types should be seen as the amplifier gains are increased; if not, there is a risk that the leads are not connected to the machine. Acute intoxion with high levels of drugs such as barbiturates can produce this sort of isoelectric EEG (Fig. 2-3A). However, in the absence of nervous system depressants or extreme degrees of hypothermia, a record that is "flat" (less than 2 µV except for artifacts) over all parts of the head is almost always a result of profound cerebral hypoxia or ischemia or of trauma and raised intracranial pressure. Such a patient—without EEG activity, brainstem reflexes, and spontaneous respiratory or muscular activity of any kind for 6 h or more—is said to be "brain dead." The brain of such a patient is largely necrotic, and there is no chance of neurologic recovery. The topic of brain death is discussed further in Chap. 17.

Localized regions of absent brain waves may rarely be seen when there is a particularly large area of infarction, traumatic necrosis, or tumor or when an extensive clot lies between the cerebral cortex and the electrodes. With such a finding, the EEG localization of the abnormality is reasonably precise—but, of course, the nature of the lesion is not disclosed. However, most such lesions are not large enough, relative to the recording arrangement, to abolish the brain waves, and the EEG may then record abnormal waves arising from functioning though damaged brain at the borders of the lesion.

Two types of abnormal waves, already mentioned, are of lower frequency and higher amplitude than normal. Waves of fewer than 4 Hz with amplitudes from 50 to 350 µV are called delta waves (Fig. 2-3G and Fig. 2-3H); those with a frequency of 4 to 7 Hz are called theta waves. Fast (beta) activity tends to be prominent frontally and usually reflects the effects of sedative drugs or, if focal, an immediately underlying skull defect (bone filters the normally abundant fast activity of the cortex). Spikes or sharp waves are transient high-voltage waveforms that have a pointed peak at conventional paper speeds and a duration of 20 to 70 ms (Fig. 2-3D). Spikes or sharp waves that occur interictally in epileptics or in individuals with a genetic disposition to seizures are referred to as epileptiform discharges.

These abnormal fast and slow waves may be combined, and when some of them intermittently relieve normally quiet patterns in a paroxysmal fashion, they are highly suggestive of epilepsy. The ones associated with absence seizures are 3-second spike-and-wave complexes that characteristically appear in all leads of the EEG simultaneously and disappear almost as suddenly at the end of the seizure (Fig. 2-3E). This finding led to the theoretic localization of a pacemaker for primary generalized seizure discharges in the thalamus or other deep gray structures ("centrencephalic seizures"), but such a center has not been verified anatomically or physiologically.

Neurologic Conditions with Abnormal Electroencephalograms

Epilepsy

All types of generalized epileptic seizures (grand mal and typical and atypical absence—see Chap. 16) are associated with some abnormality in the EEG provided that it is being recorded at the time of the seizure. Also, the EEG is usually abnormal during more restricted types of seizure activity. Exceptions are seizure states that originate in deep temporal, mesial, or orbital frontal foci, from which the discharge fails to reach the scalp in sufficient amplitude to be seen against the normal background activity of the EEG, particularly if there is well-developed alpha rhythm. In these cases, extra scalp leads in the anterior frontal and temporal regions (which are the most free of alpha frequencies) may pick up the discharge, especially during sleep. In some such cases, the only way in which this deep activity can be sampled is by inserting an electrode into the substance of the brain or placing a grid of electrodes in the subdural space, but this procedure is applicable only to the relatively few patients who are undergoing craniotomy. Occasionally one may fail to record an EEG abnormality in the course of one of these types of focal seizure (seizure of Jacksonian type, partial complex, epilepsy partialis continua) or in polymyoclonus. Presumably this means that the neuronal discharge is too deep, discrete, fast, or asynchronous to be transmitted by volume conduction through the skull and recorded via the EEG electrode, which is some 2 cm from the cortex. More often, a completely normal EEG during a seizure indicates a "pseudoseizure." The different types of some seizure patterns are shown in Fig. 2-3C, Fig. 2-3D, and Fig. 2-3F. The absence, myoclonic, and grand mal patterns correlate closely with the clinical seizure type and may be present in milder form in the interictal EEG.

A fact of importance is that between seizures a single EEG recording will show a normal pattern in as many as 20 percent of patients with absence seizures and 40 percent of those with grand mal epilepsy (this percentage is less with repeated recordings). Anticonvulsant therapy also tends to diminish interictal EEG abnormalities. The records of another 30 to 40 percent of epileptics, though abnormal between seizures, are nonspecifically so; therefore the diagnosis of epilepsy can be made only by the correct interpretation of clinical data in relation to the EEG abnormality.

Brain Tumor, Ablues, Subdural Hematoma, and Encephalitis

Intracranial mass lesions are associated with characteristic abnormalities in the EEG, depending on their type and location, in some 90 percent of patients. In addition to diffuse changes, the classic abnormalities are focal or localized slow-wave activity (usually delta, as in Fig. 2-3F) or, occasionally, seizure activity and decreased amplitude and synchronization of normal rhythms. Although the EEG may be diagnostically helpful in cases of brain tumor or abscess, particularly when integrated with the other laboratory and clinical findings, reliance is now placed almost exclusively on CT and MRI.

However, EEG may be of considerable value in the diagnosis of herpes simplex encephalitis; periodic high-voltage sharp waves and slow-wave complexes at intervals of 2 to 3 per second in the temporal regions are characteristic. The other infectious encephalitides are often associated with sharp or spike activity, particularly if there
have been seizures. The highly characteristic pattern of Creutzfeldt-Jakob disease is shown in Fig. 2-3G.

Cerebrovascular Disease The EEG is now little used in the differential diagnosis of vascular hemiplegia. The main practical value of the EEG lies in its ability to distinguish an acute lesion in the distribution of the internal carotid or other major cerebral artery, which produces an area of slowing in the appropriate region. By contrast, with a lacunar infarction deep in the cerebrum or brainstem, the surface EEG is usually normal despite prominent clinical abnormalities. After 3 to 6 months, roughly 50 percent of patients with infarction in the territory of the middle cerebral artery have a normal EEG. Perhaps half these patients will have had normal EEGs even in the week or two following the stroke. A persistent abnormality is associated with a poor prognosis for further recovery. Large lesions of the diencerephalon or midbrain produce bilaterally synchronous slow waves, but those of the pons and medulla (i.e., below the mesencephalon) are usually associated with a normal or near-normal EEG pattern despite catastrophic clinical changes.

Cerebral Trauma A brief episode of cerebral concussion in animals is accompanied by a transitory disturbance in the EEG, but in humans this is usually no longer evident by the time a recording can be made. Large cerebral contusions produce EEG changes similar to those described for cerebral infarction. Diffuse changes often give way to focal ones, especially if the lesions are on the supratentorial surfaces of the brain, and these, in turn, usually disappear over a period of weeks or months. Sharp waves or spikes sometimes emerge as the focal slow-wave abnormality resolves and may precede the occurrence of posttraumatic epilepsy; serial EEGs may be of prognostic value in this regard. They may also aid in evaluating patients for subdural hematoma.

Diseases That Cause Coma and States of Impaired Consciousness The EEG is abnormal in almost all conditions in which there is impairment of consciousness. There is a fairly close correspondence between the severity of acute anoxic damage from cardiac arrest and the degree of EEG slowing. The mildest forms are associated with generalized theta activity, intermediate forms with widespread delta waves and the loss of normal background activity, and the most severe forms with "burst suppression," in which the recording is almost isoelectric for several seconds, followed by high-voltage sharp and irregular delta activity.

The term alpha coma refers to a unique EEG pattern in which an apparent alpha activity in the 8- to 12-Hz range is distributed widely over the hemispheres rather than posteriorly. When analyzed carefully, this apparent alpha, unlike the normal rhythm, is found not to be monorhythmic; instead, it varies in frequency in a narrow band. This is usually a transitional pattern after global anoxia; less often, alpha coma may be seen with acute large pontine lesions. Both burst suppression and alpha coma are usually transitional patterns leading to severe generalized slowing and voltage reduction or to electrocerebral silence. With severe hypothyroidism, the brain waves are normal in configuration but usually of decreased frequency.

In altered states of consciousness, the more profound the depression of consciousness, in general, the more abnormal the EEG recording. In states of deep stupor or coma, the slow (delta) waves are bilateral and of high amplitude and tend to be more conspicuous over the frontal regions (Fig. 2-3H). This persists in such differing conditions as acute meningitis or encephalitis and disorders that severely derange blood gases, glucose, electrolytes, and water balance; uremia; diabetic coma; and infection. A prominent accompanying or complicating abnormality in the EEG is the degree of confusion, stupor, or coma. Characteristic of hepatic coma are paroxysms of bilaterally synchronous large, sharp "triphasic waves" (Fig. 2-3H), although such waveforms may also be seen with encephalopathies related to renal or pulmonary failure and with acute hydrocephalus.

An EEG may also be of help in the determination of coma when the pertinent history is unavailable. Perhaps its greatest value in this situation is the disclosure of status epilepticus in the absence of obvious convulsions ("spike-wave stupor," epileptic fugue state). It may also point to an otherwise unexpected cause, such as hepatic encephalopathy, intoxication with barbiturates or other sedative-hypnotic drugs, the effects of diffuse anoxia-ischemia, or hysteria (in which case the EEG is normal).

Diffuse Degenerative Diseases Alzheimer disease and other degenerative diseases that cause serious impairment of cerebrocortical function are accompanied by relatively slight degrees of diffuse slow-wave abnormality in the theta (4- to 7-Hz) range. More rapidly progressive disorders—such as subacute sclerosing panencephalitis (SSPE), Creutzfeldt-Jakob disease, and to a lesser extent the cerebral lipidoses—usually have, in addition, very characteristic and almost pathognomonic EEG changes consisting of periodic bursts of high-amplitude sharp waves, usually bistrormy and symmetrical (Fig. 2-3G). In a negative sense, a normal EEG in a patient who is profoundly apathetic is a point in favor of the diagnosis of catatonia, an affective disorder, or schizophrenia (see below).

Other Diseases of the Cerebrum Many disorders of the brain cause little or no alteration in the EEG. Multiple sclerosis and other demyelinating diseases are examples, though as many as 50 percent of advanced cases will have an abnormal record of nonspecific type (focal or diffuse slowing). Delirium tremens and Wernicke-Korsakoff disease, despite the dramatic nature of the clinical picture, cause little or no change in the EEG. Some degree of slowing usually accompanies confusional states that have been designated by some clinicians as hypokineti delirium (Chap. 20). Interestingly, the neuroses, psychoses (such as manic-depressive disorders or schizophrenia), intoxication with hallucinogenic drugs such as LSD, and the majority of cases of mental retardation are associated either with no modification of the normal record or with only minor nonspecific abnormalities unless seizures are present.

Clinical Significance of Minor EEG Abnormalities The gross EEG abnormalities discussed above are by themselves clearly abnormal, and any formulation of the patient's clinical state should attempt to account for them. These abnormalities include seizure discharges, generalized and extreme slowing, definite slowing with a clear-cut asymmetry or a focus, and absence of normal rhythms. Lesser degrees of these abnormalities form a continuum between the undoubtedly abnormal and the completely normal and are of correspondingly minor significance. Findings such as 14- and 6-per-second positive spikes, small sharp waves, scattered 5- or 6-per-second slowing, voltage asymmetries, and persistence of "breakdown" for a few minutes after hyperventilation are interpreted as borderline. The latter abnormalities may be meaningful, but only if correlated with particular clinical phenomena. Whereas borderline deviations in an otherwise entirely normal person have no clinical significance, the same EEG findings associated with particular clinical signs and symptoms—even if they, too, are of minimal severity—become important. The significance of a normal or "negative" EEG in certain patients suspected of having a cerebral lesion has been discussed above.

In summary, the results of the EEG, like those of the EMG and electrocardiogram, are meaningful only in relation to the clinical state of the patient at the time the recordings were made.

Evoked Potentials The stimulation of sense organs or peripheral nerves evokes a response in the appropriate cortical receptive areas and a number of subcortical relay stations as well. However, one cannot place a recording electrode near the relay stations, nor can one detect tiny potentials of only a few microvolts among the much larger background activity in the EEG or EMG. The use of averaging methods, introduced by Dawson in 1954, and the subsequent development of computer techniques have provided the means of overcoming these problems. Initially, emphasis was on the study of late waves (over 75 ms after the stimulus) because they are of high amplitude and easy to obtain. However, there is more clinical utility in recording the much smaller, so-called short-latency waveforms, which are modified at each nuclear relay station and recorded by distant electrodes ("far-field recording"). These waveforms are maximized by the computer to a point where their latency and voltage can easily be measured. One of the most remarkable properties of evoked potentials is their resistance to anesthesia, sedative drugs, and—in comparison with other evoked potentials—their resistance to the effects of the cerebral hemispheres. This permits their use for monitoring the integrity of the cerebral pathways in situations that render the EEG useless. The details of these techniques are reviewed in the monograph edited by Chiappa. The interpretation of afferent evoked potentials (visual, auditory, and somatosensory) is based on the prolongation of the latencies of the waveforms after the stimulus, the interwave latencies, and asymmetries in timing. Norms have been established, but it is still advisable to confirm these in each laboratory. Typically 2.5 or 3 standard deviations above the mean latency for any measurement is taken as the definition of abnormality (Table 2-3). The amplitudes of the waves are less informative.
Visual Evoked Potentials For many years it had been known that a light stimulus flashing on the retina often initiates a discernible waveform over the occipital lobes. In the EEG, such responses to fast rates of stimulation are referred to as the occipital driving response (Fig. 2-3B and Fig. 2-3C). In 1969, Regan and Heron observed that a visual evoked response could be produced by the sudden change of a viewed checkerboard pattern. The responses produced in this way, by rapidly repeating the pattern reversal, were easier to detect and measure than flash responses and more consistent in waveform from one individual to another. It became apparent that this type of stimulus, applied first to one eye and then to the other, could demonstrate conduction delays in the visual pathways of patients who had formerly suffered a disease of the optic nerve—even though in some instances there were no residual signs of reduced visual acuity, visual field abnormalities, alterations of the optic nerve head, or changes in pupillary reflexes.

This procedure, called pattern-shift visual evoked responses (PSVER) or pattern-reversal visual evoked potentials, has been widely adopted as one of the most delicate tests of lesions in the visual system. Figure 2-4 illustrates the normal PSVER and two types of delayed responses. Usually, abnormalities in the amplitude and duration of PSVER accompany the abnormally prolonged latencies, but they are difficult to quantify. The expected latency for the positive polarity PSVER is near 100 ms (thus the term “P 100”), an absolute latency over approximately 118 ms or a difference in latencies of greater than 9 ms between the two eyes signifies involvement of one optic nerve (Table 2-2). Bilateral prolongation of latencies, demonstrated by separate stimulation of each eye, can be due to lesions in both optic nerves, in the optic chiasm, or in the visual pathways posterior to the chiasm.

As indicated above, PSVER is especially valuable in proving the existence of active or residual disease of an optic nerve. Examinations of large numbers of patients who were known to have had retrobulbar (optic) neuritis showed that among 51 such patients, only 4 had normal latencies (Shahrokhi and coworkers). These authors found similar abnormalities of PSVER in about one-third of multiple sclerosis patients who had no history or clinical evidence of optic nerve involvement. The finding of abnormal PSVER in a patient with a clinically apparent lesion elsewhere in the CNS may usually be taken as evidence of multiple sclerosis.

A compressive lesion of an optic nerve will have the same effect as a demyelinating one. Many other diseases of the optic nerves—including toxic and nutritional ambiopias, ischemic optic neuropathy, and the Leber type of hereditary optic neuropathy—show abnormalities of the PSVER. Glaucoma and other diseases involving structures anterior to the retinal ganglion cells may also produce increased latencies. Impaired visual acuity has little effect on the latency but does correlate well with the amplitude of the PSVER. By presenting the pattern-shift stimulus to one hemifield, it is sometimes possible to isolate a lesion to an optic tract or radiation, or one occipital lobe, but with less precision than that provided by the usual monocular test.

Brainstem Auditory Evoked Potentials The effects of auditory stimuli can be studied in the same way as visual ones by a procedure called brainstem auditory evoked responses or potentials (BAERs or BAEPs). Between 1000 and 2000 clicks, delivered first to one ear and then to the other, are recorded through scalp electrodes and maximized by computer. A series of seven waves appears at the scalp within 10 ms after each stimulus. On the basis of depth recordings and the study of lesions produced in cats as well as pathologic studies of the brainstem in humans, it has been determined that each of the first five waves is generated by the brainstem structures indicated in Fig. 2-5. The generators of waves VI and VII are uncertain. Clinical interpretations of BAERs are based mainly on latency measurements of waves I, III, and V. The most important are the interwave latencies between I and III and III and V (see Table 2-2). The presence of wave I and its absolute latency are of particular value in testing the integrity of the auditory nerve.

A lesion that affects one of the relay stations or its immediate connections manifests itself by a delay in its appearance and an absence or reduction in amplitude of subsequent waves. These effects are more pronounced on the side of the stimulated ear than contralaterally. This is difficult to understand, since a majority of the cochlear-superior olivary-lateral lemniscal-medial geniculate fibers cross to the opposite side. It is also surprising that a severe lesion of one relay station would allow impulses, even though delayed, to continue their ascent and be recordable in the cerebral cortex. As indicated above, BAEPs are a particularly sensitive means of detecting lesions of the eighth cranial nerve (acoustic neuroma and other tumors of the cerebellopontine angle) and of the auditory pathways of the brainstem. Almost one-half of patients with definite multiple sclerosis and a lesser number with a possible or probable diagnosis of this disease will show abnormalities of the BAEPs (usually a prolongation of interwave latencies I-III or II-V), even in the absence of clinical symptoms and signs of brainstem disease. The BAEPs are also useful in assessing hearing in infants who have been exposed to ototoxic drugs, in young children, and in hysterical patients who feign deafness.

Somatosensory Evoked Potentials Somatosensory evoked potentials (SEPs) are used in most clinical neurophysiology laboratories to confirm lesions in the somatic sensory systems. The technique consists of applying 5-per-second painless transcutaneous electrical stimuli to the median, peroneal, and tibial nerves and
recording the evoked potentials (for the upper limb) over Erb’s point above the clavicle, over the C-2 spine and over the opposite parietal cortex, and (for the lower limb) over the lumbar and cervical spines and the opposite parietal cortex. The impulses generated in large touch fibers by 500 or more stimuli and averaged by computer can be traced through the peripheral nerves, spinal roots, and posterior columns to the nuclei of Burdach and Goll in the lower medulla, through the medial lemniscus to the contralateral thalamus, and thence to the sensory cortex of the parietal lobe. Delay between the stimulus site and Erb’s point or lumbar spine indicates peripheral nerve disease; delay from Erb’s point (or lumbar spine) to C-2 implies an abnormality in the appropriate nerve roots or more frequently in the posterior columns; the presence of lesions in the medial lemniscus and thalamoparietal pathway can be inferred from delays of subsequent waves recorded from the parietal cortex (Fig. 2-6). The normal waveforms are designated by the symbol P (positive) or N (negative), with a number indicating the interval of time in milliseconds from stimulus to recording (e.g., N 11, N 13, P 13, P 22, etc.). As shorthand for the polarity and approximate latency, the summated wave that is recorded at the cervicomedullary junction is termed “N/P 13,” and the cortical potential from median nerve stimulation is seen in two contiguous waves of opposite polarity, called “N 19–P 22.” The corresponding cortical wave after tibial or peroneal nerve stimulation is called “N/P 37.”

**Figure 2-6** Short-latency SSEPs produced by stimulation of the median nerve at the wrist. The set of responses shown at left is from a normal subject; the set at right is from a patient with multiple sclerosis who had no sensory symptoms or signs. In the patient, note the preservation of the brachial-plexus component (EP), the presence of the cervical component, and the persistence of the thalamocortical (N and P) potential. The latency of the cervical component is increased and the amplitude is markedly above the normal mean ± 3 SD for the separation from the brachial plexus. Unilateral stimulation occurred at a frequency of 5 per second. Each trace is the average response to 1024 stimuli; the superimposed trace represents a repetition to demonstrate waveform consistency. Recording-electrode locations are as follows: FZ denotes midfrontal; EP, Erb’s point (the shoulder); C2, the middle back of the neck over the C2 cervical vertebrae; and Cc, the scalp overlying the sensorimotor cortex contralateral to the stimulated limb. Relative negativity at the second electrode caused an upward trace deflection. Amplitude calibration marks denote 2 μV. (Reproduced by permission from Chiappa and Ropper.)

**Transcranial Motor Cortex Stimulation**

It is now possible, by using single-pulse high-voltage magnetic stimulation, to directly activate the motor cortex and cervical spine segments and to detect delays or lack of conduction in descending motor pathways. This technique, introduced by Marsden and associates, painlessly stimulates only the largest motor neurons. It is used to test the rapidity with which the impulses are conducted from the motor cortex to the periphery. By comparing the latency of response to electrical stimulation of the motor cortex (the P 300) with that of magnetic stimulation (the N 300), it is possible to determine if an abnormality exists and to locate it. The latency of the magnetic response is of the order of 10–20 ms longer than that of the electric response. The accuracy of the magnetic response is comparable to that of the conventional evoked potentials.

**Endogenous Event-Related Evoked Potentials**

Among the very late brain electrical potentials (>100 ms latency), which can be extracted from background activity by computer methods, are a group that cannot be classified as sensory or motor but rather as psychophysical responses to environmental stimuli. These responses are of very low voltage, often fleeting and inconsistent, and of unknown anatomic origin. The most studied types occur approximately 300 ms (P 300) after an attentional subject identifies an unexpected or novel stimulus that has been inserted into a regular train of stimuli. Almost any modality can be used and the potential occurs even when a stimulus has been omitted from a regular pattern. The amplitude of the response depends on the difficulty of the task and has an inverse relationship to the frequency of the unexpected or “odd” event; the latency depends on the task difficulty and other features of testing. There is therefore no single P 300; instead, there are numerous components, depending on the experimental paradigm. A prolongation of the latency is found with aging and in dementia as well as with degenerative diseases such as Parkinson disease, progressive supranuclear palsy, and Huntington chorea, and the amplitude is depressed in schizophrenia and depression. The potential has been interpreted by some as a reflection of the subject's orienting behavior or attention, and by others, including Donchin, who discovered the phenomenon, as related to updating the brain's representation of the environment. The P 300 remains a curiosity for the clinical neurologist because abnormalities are detected only when large groups are compared to normals, and the technique is hardly as standardized as the conventional evoked potentials. A review of the subject can be found in sections by Altenmüller and Gerloff and by Polich in the Niedermeyer and Lopes DaSilva text on electroencephalography.

**Electromyography and Nerve Conduction Studies**

These are discussed in Chap. 45.

**Psychometry, Perimetry, Audiometry, and Tests of Labyrinthine Function**

The methods are used in quantitating and defining the nature of the psychologic or sensory deficits produced by disease of the nervous system. The indications for doing these tests are (1) to obtain confirmation of a disorder of function in particular parts of the nervous system and to ascertain its nature or (2) to quantitate the disorder and to determine, by subsequent examinations, the course of the underlying illness. A description of these methods and their clinical use will be found in the chapters dealing with developmental disorders of the cerebrum (Chap. 28), dementia (Chap. 21), and disorders of vision (Chap. 15) and of hearing and equilibrium (Chap. 15).

**Biopsy of Muscle, Nerve, Skin, Temporal Artery, Brain, and Other Tissue**

The application of light, phase, and electron microscopy to the study of these tissues may be highly informative. The findings are discussed in Chap. 45 (muscle), Chap. 46 (nerve), and Chap. 37 (skin and conjunctivum in the diagnosis of storage diseases). Temporal artery biopsy is indicated when giant cell arteritis is suspected. Brain biopsy, aside from the direct sampling of a suspected neoplasm, is often diagnostic in cases of granulomatous angiitis, some forms of encephalitis, subacute spongiform encephalopathy (biopsy performed infrequently because of the risk of transmitting the infectious agent), and a number of other rare diseases. An important advance in recent years has been the use of CT-guided stereotactic biopsy, which is particularly valuable in tumor diagnosis and exposes the patient to less...
risk than does a craniotomy and open biopsy. In choosing to perform a biopsy in any of these clinical situations, the paramount issue is the likelihood of establishing a definitive diagnosis—one that would permit successful treatment or otherwise enhance the management of the disease.

CHAPTER REFERENCES

The term paralysis is derived from the Greek words para, “beside, off, amiss,” and yasis, a “loosening” or “breaking up.” In medicine it has come to refer to an abolition of function, either sensory or motor. When applied to motor function, paralysis means loss of voluntary movement due to interruption of one of the motor pathways at any point from the cerebrum to the muscle fiber. A lesser degree of paralysis is spoken of as paresis, but in everyday medical parlance paralysis may stand for either partial or complete loss of function. The word plegia comes from a Greek word meaning “to strike,” and the word palsy from an old French word that has the same meaning as paralysis. All these words are used interchangeably, though generally one uses paralysis or plegia for severe or complete loss of motor function and paresis for partial loss.

**THE LOWER MOTOR NEURON**

**Anatomic and Physiologic Considerations**

Each spinal and cranial motor nerve cell, through the extensive arborization of the terminal part of its efferent fiber, comes into contact with only a few or up to 100 or more muscle fibers; together, they constitute the motor unit. All variations in the force, range, rate, and type of movement are determined by the number and size of motor units called into action and the frequency and sequence of firing of each motor unit. Freible movements involve relatively few small motor units; powerful movements recruit many more units of increasing size. When a motor neuron becomes diseased, as in progressive spinal muscular atrophy, it may manifest increased irritability, i.e., the axon is unstable and capable of ectopic impulse generation, and all the muscle fibers that it controls may discharge sporadically, in isolation from other units. The result of contraction of one or several such units is a visible twitch, or fasciculation, which can be recognized in the electromyogram (EMG) as a large spontaneous muscle action potential. Simultaneous or sequential spontaneous contractions of multiple motor units cause a rippling of muscle, a condition known as myokymia. If the motor neuron is destroyed, all the muscle fibers that it innervates undergo profound atrophy—namely, denervation atrophy. Within a few days after interruption of a motor nerve, the individual denervated muscle fibers begin to contract spontaneously. This isolated activity of individual muscle fibers is called fibrillation. Inability of the isolated fiber to maintain a stable membrane potential is a more likely explanation. Fibrillation is so fine that it cannot be seen through the intact skin, but it can be recorded as a small, repetitive, short-duration potential in the EMG (Chap. 45).

The motor nerve fibers of each ventral root intermingle with those of neighboring roots to form plexuses, and although the muscles are innervated roughly according to segments of the spinal cord, each large muscle comes to be supplied by two or more roots. In contrast, a single peripheral nerve usually provides the complete motor innervation of a muscle or group of muscles. For this reason, paralysis due to disease of the anterior horn cells or anterior roots usually has a different pattern than paralysis following interruption of a peripheral nerve.

All motor activity, even the most elementary reflex type, requires the synchronous activity of many muscles. Analysis of a relatively simple movement, such as clenching the fist, conveys some idea of the complexity of the underlying neuromuscular arrangements. In this act the primary movement is a contraction of the flexor muscles of the fingers, the flexor digitorum sublimis and profundus, the flexor pollicis longus and brevis, and the abductor pollicis brevis. In the terminology of Beevor, these muscles act as agonists, or prime movers. In order for flexion to be smooth and forceful, the extensor muscles (antagonists) must relax at the same rate as the flexors contract (reciprocal innervation, or Sherrington's law). The muscles that flex the fingers also flex the wrist; since it is desired that only the fingers flex, the extensors of the wrist must be brought into play to prevent its flexion. In this particular act, the wrist extensors function as synergists. Last, during this action of the hand, appropriate flex and extensor muscles stabilize the wrist, elbow, and shoulder; muscles that accomplish this serve as fixators. The coordination of agonists, antagonists, synergists, and fixators is effectuated mainly by segmental spinal reflexes under the guidance of proprioceptive sensory stimuli. In general, the more delicate the movement, the more precise must be the coordination between agonist and antagonist muscles.

All movements are effectuated by the activation of motor neurons, large ones supplying large motor units and small ones, small motor units. The latter are more efficiently activated by sensory affrements from muscle spindles, more tonically active, and more readily recruited in reflex activities, postural maintenance, walking, and running.

All the large motor units participate mainly in phasic movements, which are characterized by an initial burst of activity in the agonist muscles, then a burst in the antagonists, followed by a third burst in the agonists. The strength of the initial agonist burst determines the speed and distance of the movement, but there is always the same triphasic pattern of agonist, antagonist, and agonist activity (Hallett et al). The basal ganglia and cerebellum set the pattern and timing of the muscle action in any projected motor performance. These points are discussed further in Chap. 4 and Chap. 5.

Unlike phasic movements, certain basic motor activities do not involve reciprocal innervation. In support of the body in an upright posture, when the legs must act as rigid pillars, and in shivering, agonists and antagonists contract simultaneously. Locomotion requires that the extensor pattern of reflex standing be inhibited and that the coordinated pattern of alternating stepping movements be substituted; the latter is accomplished by multisegmental spinal and brainstem reflexes, the so-called locomotor centers. Suprasegmental control of the axial and proximal limb musculature (antigravity postural mechanisms) is mediated primarily by the reticulospinal and vestibulospinal tracts and manipulatory movements of the distal extremity muscles, by the rubrospinal and corticospinal tracts. These aspects of motor function are also elaborated further on.

Tendon reflex activity and muscle tone depend on the status of the large motor neurons of the anterior horn (the alpha motor neurons), the muscle spindles and their afferent fibers, and the small anterior horn cells (gamma neurons) whose axons terminate on the small intrafusal muscle fibers within the spindles. Each anterior horn cell has on its surface membrane approximately 10,000 synaptic terminals (boutons). Some of these terminals are excitatory, others inhibitory; in combination, they determine the activity of the neuron. The largest neurons, in Rexed layer IX (see Fig. 8-19), innervate large muscles with large motor units. Smaller anterior horn cells innervate small muscles and control more delicate movements, particularly those in the fingers and hand.
The term caudal course in the lateral funiculus of the spinal cord—hence the alternative name white matter (corona radiata), internal capsule, cerebral peduncle, basis pontis, and pyramid of the upper medulla; decussates in the lower medulla; and continues its

Acute and profound spinal cord lesions and, to a lesser extent, corticospinal lesions in the brainstem and cerebrum temporarily abolish spinal myotatic reflexes. Combination of a flaccid, areflexic paralysis and sensory changes usually indicates involvement of mixed motor and sensory nerves or of both anterior and posterior roots. If sensory changes are absent, the lesion must be situated in the anterior gray matter of the spinal cord, in the anterior roots, in a purely motor branch of a sensory nerve, or in a purely sensory branch of a mixed nerve. In the lower extremity, involvement of the S1 spinal segment and passing to the hamstring muscles demonstrate the disynaptic pathway by which inhibitory influences are exerted upon an antagonistic muscle group during the reflex. The small diagram below illustrates the gamma loop. Gamma effferent fibers pass to the polar portions of the muscle spindle. Contractions of the intrafusal fibers in the polar parts of the spindle stretch the nuclear bag region and thus cause an afferent impulse to be conducted centrally. The afferent fibers from the spindle synapse with many alpha motor neurons, the peripheral processes of which pass to extrafusal muscle fibers, thus completing the loop. Both alpha and gamma motor neurons are influenced by descending fiber systems from supraspinal levels. (Adapted by permission from Carpenter MB, Sutin J: Human Neuroanatomy, 8th ed. Baltimore, Williams & Wilkins, 1983.)

Thus the setting of the spindle fibers and the state of excitability of the alpha and gamma neurons (influenced greatly by descending fiber systems) determine the level of activity of the tendon reflexes and muscle tone (the responsiveness of muscle to stretch). Other mechanisms, of an inhibitory nature, involve the Golgi tendon organs, for which the stimulus is tension produced by active contraction of muscle. These encapsulated receptors, which lie in the tendinous and aponeurotic insertions of muscle, activate afferent fibers that end on interneuronal cells, which, in turn, project to alpha motor neurons, thus forming a disynaptic reflex arc. Golgi tendon receptors are silent in relaxed muscle and during passive stretch; they serve, together with muscle spindles, to monitor or calibrate the length and force of muscle contraction under different conditions. They also play a role in naturally occurring limb movements, particularly in locomotion.

The alpha neurons of the medial parts of the anterior horn supply trunk or axial muscles, and neurons of the lateral parts supply the appendicular muscles. Both groups of alpha neurons receive projections from neurons in the intermediate Rexed layers (V to VIII) and from propriospinal neurons in the fasciculi proprii of adjacent spinal segments (see Fig. 8-1B). All the facilitatory and inhibitory influences supplied by cutaneous and proprioceptive afferent and descending suprasegmental neurons are coordinated at segmental interneuronal levels in such activities as phasic and tonic reflexes, flexor withdrawal and crossed extensor reflexes, postural support, tonic neck and lumbar reflexes, and more complex synergies such as rhythmic stepping (e.g., the reflex stepping of neonates). For details, see Burke and Lance and also Davidoff (1962).

There is also considerable information concerning the pharmacology of motor neurons. The large neurons of the anterior horns of the spinal cord contain high concentrations of choline acetyltransferase and utilize acetylcholine as their transmitter. Glycine is the neurotransmitter released by Renshaw cells, which are responsible for recurrent inhibition, and by interneurons that mediate reciprocal inhibition during reflex action. Gamma-aminobutyric acid (GABA) serves as the inhibitory neurotransmitter of interneurons in the posterior horn. L-glutamate and L-aspartate are released by primary afferent terminals and interneurons and act specifically on excitatory amino acid receptors. There are also descending cholinergic, adrenergic, and dopaminergic axons, which play a less well defined role in reflex functions.

Paralysis Due to Lesions of the Lower Motor Neurons

If all or practically all peripheral motor fibers supplying a muscle are interrupted, all voluntary, postural, and reflex movements of that muscle are abolished. The muscle becomes lax and soft and does not resist passive stretching, a condition known as flaccidity. Muscle tone—the slight resistance that normal relaxed muscle offers to passive movement—is reduced (hypotonia or atonia). The denervated muscle undergoes extreme atrophy, being reduced to 20 or 30 percent of its original bulk within 3 to 4 months. The reaction of the muscle to sudden stretch, as by tapping its tendon, is lost (areflexia). Affection of only a portion of the motor fibers supplying the muscle results in partial paralysis, or paresis, and a proportionate diminution in the speed of contraction. The atrophy will be less and the tendon reflex will be reduced instead of lost. The electrodiagnosis of denervation depends upon finding fibrillations, fasciculations, and other abnormalities on needle electrode examination. These abnormalities appear several days or a week or two after nerve injury (see Chap. 45).

Lower motor neuron paralysis is the direct result of loss of function or destruction of anterior horn cells or their axons in anterior roots and nerves. The signs and symptoms vary according to the location of the lesion. In any individual case, the most important clinical question is whether sensory changes coexist. The combination of a flaccid, areflexic paralysis and sensory changes usually indicates involvement of mixed motor and sensory nerves or of both anterior and posterior roots. If sensory changes are absent, the lesion must be situated in the anterior gray matter of the spinal cord, in the anterior roots, in a purely motor branch of a peripheral nerve, or in motor axons alone. At times it may be impossible to distinguish between nuclear (spinal) and anterior root (radicular) lesions.

Acute and profound spinal cord lesions and, to a lesser extent, corticospinal lesions in the brainstem and cerebrum temporarily abolish spinal myotatic reflexes (“spinal shock”). This is due to the interruption of descending tonic excitatory impulses, which normally maintain a sufficient level of excitation in spinal motor neurons to permit the peripheral activation of segmental reflexes. Preserved and often heightened tendon reflexes and spasticity in muscles weakened by lesions of the corticospinal systems attest to the integrity of the spinal segments below the level of the lesion.

THE UPPER MOTOR NEURONS

Anatomic and Physiologic Considerations

The terms pyramidal, corticospinal, and upper motor neuron are often used interchangeably, although they are not altogether synonymous. The pyramidal tract, strictly speaking, designates only those fibers that course longitudinally in the pyramid of the medulla oblongata. Of all the fiber bundles in the brain, the pyramidal tract has been known for the longest time, the first accurate description having been given by Turck in 1851. It descends from the cerebral cortex; traverses the subcortical white matter (corona radiata), internal capsule, cerebral peduncle, basis pontis, and pyramid of the upper medulla; decussates in the lower medulla; and continues its caudal course in the lateral funiculus of the spinal cord—hence the alternative name corticospinal tract. This is the only direct long-fiber connection between the cerebral cortex and the spinal cord (Fig. 3-2). The indirect pathways through which the cortex influences spinal motor neurons are the corticorubrospinal, corticoreticulospinal, corticovestibulospinal, and corticocerebellar; these tracts do not run in the pyramid. All of these pathways, direct and indirect, are embraced by the term upper motor neuron.
A major source of confusion about the pyramidal tract stems from the traditional view, formulated at the turn of the century, that it originates entirely from the large motor cells of Betz in the fifth layer of the precentral convolution, or area 4 of Brodmann (Fig. 3-3 and Fig. 22-1). However, there are only some 25,000 to 35,000 Betz cells, whereas the medullary pyramids contains about 1 million axons (Lassèe). The pyramidal tract, therefore, contains many fibers that arise from cortical neurons other than Betz cells, particularly those in Brodmann areas 4 and 6 (the frontal cortex immediately rostral to area 4, including the posterior portion of the superior frontal gyrus, i.e., the supplementary motor area); in the primary somatosensory cortex (Brodmann’s areas 3, 1, and 2); and in the superior parietal lobule (areas 5 and 7). Data concerning the origin of the pyramidal tract in humans are scanty, but in the monkey, by counting the pyramidal axons that remained after cortical excisions and long survival periods, Russell and DeMyer found that 40 percent of the descending axons arose in the parietal lobe, 31 percent in area 4, and the remaining 29 percent in area 6. Studies of retrograde transport of tracer substance in the monkey have confirmed these findings.

Fibers from the motor and premotor cortices (Brodmann areas 4 and 6, Fig. 22-1), supplementary motor cortex, and portions of parietal cortex (areas 1, 3, 5, and 7) converge in the corona radiata and descend through the posterior limb of the internal capsule, basis pedunculi, basis pontis, and medulla. The corticospinal tracts and other upper motor neurons terminate mainly in relation to nerve cells in the intermediate zone of spinal gray matter (internuncial neurons), lying next to the gray matter. The corticospinal tracts decussate at the lower end of the medulla, although some of their fibers may cross above this level. The proportion of crossed and uncrossed fibers varies to some extent from one person to another. Most textbooks state that 75 to 80 percent of the fibers cross and that the remainder descend ipsilaterally, mostly in the uncrossed ventral corticospinal tract. In exceptional cases, these tracts cross completely; equally rarely, they remain uncrossed. These variations are probably of functional significance in determining the amount of neurologic deficit that results from a unilateral lesion such as capsular infarction.

Beyond their decussation, the corticospinal pathways descend as well-defined bundles in the anterior and posterior lateral columns of white matter (funiculi) of the spinal cord (Fig. 3-2). The course of the noncorticospinal motor pathways (vestibulospinal, reticulospinal, and descending propriospinal) have been traced in man by Nathan and his colleagues. The lateral vestibulospinal tract lies at the periphery of the cord, where it occupies the most anterolateral portion of the anterior funiculus. The medial vestibulospinal fibers mingle with those of the medial longitudinal fasciculus. Reticulospinal fibers are less compact; they descend bilaterally, and most of them come to lie just anterior to the lateral corticospinal tract. The descending propriospinal pathway consists of a series of short fibers (one or two segments long) lying next to the gray matter.

The somatotopic organization of the corticospinal system is of importance in clinical work, especially in relation to certain stroke syndromes. As the descending axons subserving limb and facial movements emerge from the cortical motor strip, they maintain the anatomic specificity of the overlying cortex; therefore, a discrete cortical-subcortical lesion will result in a restricted weakness of the hand and arm or the foot and leg. More caudally the descending motor fibers converge and are collected in the posterior limb of the internal capsule, so that even a small lesion there may cause a "pure motor hemiplegia," in which the face, arm, leg, and foot are affected to more or less the same degree (page 851). The axons subserving facial movement are situated rostrally in the posterior limb of the capsule, those for hand and arm in the central port and those for foot and leg, caudally (see Brodai).

This topographic distribution is more or less maintained in the cerebral peduncle, where the corticospinal fibers occupy approximately the middle of the peduncle, the fibers destined to innervate the facial nuclei lying most medially. More caudally, in the basis pontis, the descending motor tracts separate into bundles that are interspersed with masses of pontocerebellar neurons and their cerebellopetal fibers. A somatotopic organization can be recognized here as well, exemplified by selective weakness of the face and hand with dysarthria, or of the leg, which may occur with pontine lacunar infarctions. Anatomic studies in nonhuman primates indicate that arm-leg distribution of fibers in the rostral pons is much the same as in the basis pedunculi; in the caudal pons this distinction is less well defined. In man, a lack of systematic study leaves the precise somatotopic organization of corticospinal fibers in the pons uncertain.

The descending pontine bundles, now devoid of their corticopontine fibers, reunite to form the medullary pyramid. The brachial-crustral pattern may persist in the pyramids and is certainly reconstituted in the lateral columns of the spinal cord (Fig. 8-3), but it should be emphasized that the topographic separation of motor fibers at cervical, thoracic, and lumbar levels is not as discrete as usually shown in schematic diagrams of the spinal cord. The corticospinal tracts and other upper motor neurons terminate mainly in relation to nerve cells in the intermediate zone of spinal gray matter (intermuncial neurons), from which motor impulses are then transmitted to the anterior horn cells. Only 10 to 20 percent of corticospinal fibers (presumably the thick, rapidly conducting axons derived from Betz cells) establish direct synaptic connections with the large motor neurons of the anterior horns.

The Motor, Premotor, and Supplementary Motor Cortex and the Control of Movement

The motor area of the cerebral cortex is defined physiologically as the region of electrically excitable cortex from which isolated movements can be evoked by stimuli...
of minimal intensity (Fig. 3-3). The muscle groups of the contralateral face, arm, trunk, and leg are represented in the primary motor cortex (area 4), those of the face being in the most inferior part of the precentral gyrus on the lateral surface of the cerebral hemisphere and those of the leg in the paracentral lobule on the medial surface of the cerebral hemisphere. The parts of the body capable of the most delicate movements have, in general, the largest cortical representation.

Area 6, the premotor area, is also electrically excitable but requires more intense stimuli than area 4 to evoke movements. Stimulation of its caudal aspect (area 6aa) produces responses that are similar to those elicited from area 4. These responses are probably effected by transmission of impulses from area 6a to area 4 (since they cannot be obtained after ablation of area 4) and discharge via the corticospinal tract. Stimulation of the rostral premotor area (area 6ab) elicits more general movement patterns, predominantly of proximal limb musculature. The latter movements are effected via pathways other than those derived from area 4 (hence, “extrapyramidal”). Very strong stimuli elicit movements from a wide area of premotor frontal and parietal cortex, and the same movements may be obtained from several widely separated points. From this it may be assumed, as Alexander and DeLong point out, that the premotor cortex includes several anatomically distinct subregions with different afferent and efferent connections. In general, it may be said that the motor-premotor cortex is capable of synthesizing agonist actions into an infinite variety of finely graded, highly differentiated patterns. These are directed by visual (area 7) and tactile (area 5) sensory information and supported by appropriate postural mechanisms.

The supplementary motor area is the most anterior portion of area 6 on the medial surface of the cerebral hemisphere. Stimulation of this area may induce relatively gross homolateral or contralateral movement, bilateral tonic contractions of the head and eyes with tonic contraction of the contralateral arm, and sometimes inhibition of voluntary motor activity and vocal arrest.

In primates, lesions limited to area 4 of Brodmann, the motor cortex, cause only hypotonia and weakness of the distal limb muscles. Lesions of the premotor cortex...
Fulton

There have been many investigations of the biochemical changes that underlie spasticity and the mechanisms of action of antispasticity drugs. These clinical effects have not been as clearly defined in humans as in monkeys. Resection of cortical areas 4 and 6 and subcortical white matter causes complete and permanent paralysis and spasticity (Laplane et al.).

The one place where corticospinal fibers are entirely isolated is the pyramidal tract in the medullary pyramid. In humans there are a few documented cases of a lesion more or less confined to this location (Rooper et al.). The result of such lesions has been an initial flaccid hemiplegia (with sparing of the face), from which there is considerable recovery. Similarly in monkeys—as shown by Turner in 1940 and subsequently by Lawrence and Kuyper and by Gilman and Marco—interruption of both pyramidal tracts results in a hypotonic paralysis; ultimately, these animals regain a wide range of movements, though slowness of all movements and loss of individual finger movements remain as permanent deficits. Also, the cerebral peduncle has been sectioned in patients in an effort to abolish involuntary movements (Bucy et al.), in some of these patients, a slight degree of weakness or only a Babinski sign was produced but no spasticity developed. These observations and those in monkeys indicate that a pure pyramidal tract lesion does not result in spasticity and that control over a wide range of voluntary movements depends at least in part on nonpyramidal motor pathways. Animal experiments suggest that the corticospinal pathways are partially involved in this respect, since their fibers are arranged somatotopically and are able to influence stretch reflexes. Further studies in humans are necessary to settle problems related to volitional movement and spasticity. The motor organization of the cat and even of the monkey is so different from that of humans, and the range of volitional activity and motor skills is so much less in animals, that direct comparisons are not justified.

The distribution of the paralysis due to upper motor neuron lesions varies with the locale of the lesion, but certain features are characteristic of all of them. A group of muscles is always involved, never individual muscles, and if any movement is possible, the proper relationships between agonists, antagonists, synergists, and fixators, and the distribution of paralysis never involves all of the muscles, even in the several forms of the hemiplegia. Movements that are invariants—such as those of the eyes, jaw, pharynx, larynx, neck, thorax, diaphragm, and abdomen—are little or not at all affected. This comes about because the muscles involved in bilateral movements are bilaterally innervated; i.e., stimulation of either the right or left motor cortex results in contraction of these muscles on both sides of the body. Upper motor neuron paralysis is rarely complete for any long period of time; in this respect it differs from the absolute paralysis due to destruction of anterior horn cells or interruption of their axons.

Upper motor neuron lesions are characterized further by certain implications of residual movement. There is decreased voluntary drive on spinal motor neurons (fewer motor units are recruitable and their firing rates are slower). There is an increased degree of cocontraction of antagonistic muscles, reflected in a decreased rate of rapid alternating movements. These abnormalities probably account for the greater sense of effort and the manifest fatigability in effecting voluntary movement of the muscles of the upper motor neurons. When the pyramidal tract is usually involved as well. If the latter tract is spared, only paresis, loss of support reflexes, and possibly release of flexor reflexes (Babinski phenomenon) occur. In spinal cord lesions that involve the corticospinal tract, the dorsal reticulospinal and rubro-olivary systems are also damaged; thus the spinothalamic and reticulothalamic systems are in part involved; and a Babinski sign is usually present.

Spatiasticity

A prediction for involvement of certain muscle groups, a specific pattern of response of muscles to passive stretch (where resistance increases linearly in relation to velocity of stretch), and a manifest exaggeration of tendon reflexes are the identifying characteristics of spasticity. The antagonistic muscles—those of the flexors of the limb—may become a flexed and plantar-flexed position and the extensors and adductors, one indicating that certain spinal reflexes are more reactive than others. At rest, with the muscles shortened to midposition, they are flexed at the patella and the hip and knee are usually partially flexed or extended. In flexed and plantar-flexed pose, the hip and knee may be flexed or extended. If the limb is extended or the leg flexed very slightly, there may be a little or no change in muscle tone. By contrast, if the muscles are briskly stretched, the limb moves freely for a very short distance (free interval), beyond which there is an abrupt catch and then a rapidly increasing muscular resistance up to a point; then, as passive extension of the arm or flexion of the leg continues, the resistance melts away. This sequence constitutes the classic clasp-knife phenomenon. With the limb in the extended or flexed position, a new passive movement may not encounter the same sequence; this entire pattern of responses constitutes the lengthening and shortening reaction. Thus the essential feature of spasticity is a velocity-dependent increase in the resistance of muscles to a passive stretch stimulus.

Although a clasp-knife relaxation following peak resistance is highly characteristic of cerebral hemiplegia, it is by no means found consistently. In some cases, the arm flexors show an increase in spasticity, while the antagonistic muscles show an apparent decrease. This phenomenon, known as the clasp-knife phenomenon, is observed in spastic hemiplegia. In spinal cord lesions that involve the corticospinal tract, the dorsal reticulospinal tract is usually involved as well. If the latter tract is spared, only paresis, loss of support reflexes, and possibly release of flexor reflexes (Babinski phenomenon) occur. In spinal cord lesions that involve the corticospinal tract, the dorsal reticulospinal and rubro-olivary systems are also damaged; thus the spinothalamic and reticulothalamic systems are in part involved; and a Babinski sign is usually present.

Until recently, it was taught that the heightened myotatic or stretch reflexes (tendon jerks) of the spastic state are “release” phenomena—the result of interruption of descending inhibitory pathways. This appears to be only a partial explanation. Animal experiments have demonstrated that this aspect of the spastic state is also mediated through spinal afferents (increased tonic activity of gamma motor neurons) and, centrally, through reticulospinal and vestibulospinal pathways that act on alpha motor neurons. The clasp-knife phenomenon appears to derive at least partly from a lesion (or presumably a change in central control) of a specific portion of the reticulospinal system.

Brown, in a discussion of the pathophysiology of spasticity, has emphasized the importance of two systems of fibers: (1) the dorsal reticulospinal tract, which has inhibitory effects on stretch reflexes, and (2) the medial reticulospinal and vestibulospinal tracts, which together facilitate extensor tone. He postulates that in cerebral and capsular lesions, cortical inhibition is weakened, resulting in spastic hemiplegia. In spinal cord lesions that involve the corticospinal tract, the dorsal reticulospinal tract is usually involved as well. If the latter tract is spared, only paresis, loss of support reflexes, and possibly release of flexor reflexes (Babinski phenomenon) occur. In spinal cord lesions that involve the corticospinal tract, the dorsal reticulospinal and rubro-olivary systems are also damaged; thus the spinothalamic and reticulothalamic systems are in part involved; and a Babinski sign is usually present.

The hyperreflexic state that characterizes spasticity often takes the form of clonus, a series of rhythmic involuntary muscular contractions occurring at a frequency of 5 to 7 Hz in response to an abruptly applied and sustained stretch stimulus. It is usually designated in terms of the part of the limb to which the stimulus is applied (e.g., patella, ankle). The frequency is constant within 1 Hz and is not appreciably modified by altering peripheral or central nervous system activities. Clonus depends for its elicitation on an appropriate degree of muscle relaxation, integrity of the spinal stretch reflex mechanisms, sustained hyperexcitability of alpha and gamma motor neurons (supraspinal effects), and synchronization of the contraction-release cycle of muscle spindles. The cutaneous abdominal and cremasteric reflexes are usually diminished as a result of spasticity, which is invariably present.

Irradiation, or spread of reflexes, is regularly associated with spasticity, although the former phenomenon may be observed in normal persons with brisk tendon reflexes. Tactile stimuli of the radial peristem, for example, may elicit a reflex contraction not only of the trachiodialis but also of the biceps, triceps, or finger flexors. This spread of reflex activity is probably due not to an irradiation of impulses in the spinal cord, as is often taught, but to the propagation of a vibration wave from bone to muscle, stimulating the excitible muscle spindles in its path (Lance). The same mechanism is probably operative in other manifestations of the hyperreflexic state, such as the Hoffmann sign and the crossed adductor reflex of the thigh muscles. Also, reflexes may be “inverted,” as in the case of a lesion of the fifth or sixth cervical nerve, where biceps and finger flexors, when the proximal nerves are intact, respond to a tap over the distal radius.

There have been many investigations of the biochemical changes that underlie spasticity and the mechanisms of action of antispasticity drugs. These have been reviewed by Davidoff. Since glutamic acid is the neurotransmitter of the corticospinal tracts, one would expect its action on inhibitory interneurons to be lost. As...
mentioned earlier, gamma-aminobutyric acid (GABA) and glycine are the major inhibitory transmitters in the spinal cord; GABA functions as a presynaptic inhibitor, suppressing sensory signals from muscle and cutaneous receptors. Baclofen, a derivative of GABA, as well as diazepam and progabide, are thought to act by reducing the release of excitatory transmitter from the presynaptic terminals of primary afferent terminals. Actually, none of these agents is particularly effective in the treatment of spasticity when administered orally; the administration of baclofen intrathecally may have a beneficial effect. Glycine is the transmitter released by inhibitory interneurons and is measurably reduced in quantity, uptake, and turnover in the spastic animal. There is some evidence that the oral administration of glycine reduces experimentally induced spasticity, but its value in patients is uncertain. Interruption of descending noradrenergic, dopaminergic, and serotonergic fibers is undoubtedly involved in the genesis of spasticity, although the exact mode of action of these neurotransmitters on the various components of spinal reflex arcs remains to be defined.

In addition to hyperactive phasic myotatic reflexes ("tendon jerks"), certain lesions, particularly of the cervical segments of the spinal cord, may result in great enhancement of tonic myotatic reflexes. These are stretch reflexes in which a stimulus produces a prolonged asynchronous discharge of motor neurons, causing sustained muscle contraction. As the patient stands or attempts voluntary movement, the entire limb may become involved in intense muscular spasm, sometimes lasting for several minutes. During this period the limb is quite useless. Presumably there is both an interruption of lateral reticulospinal inhibitory influences on the anterior horn cells and a release of the medial reticulospinal facilitatory effects needed in antigravity support (Henneman).

The nociceptive spinal flexion reflexes, of which the Babinski sign is a part, are not essential components of spasticity. They, too, are exaggerated because of disinhibition or release in cases of paraparesis or paraplegia of spinal origin. Important characteristics of these responses are their capacity to be induced by weak superficial stimuli (such as a series of pinpricks) and their tendency to persist after the stimulation ceases. In their most complete form, a nocifensive flexor synergy occurs, involving flexion of the knee and hip and dorsiflexion of the foot and big toe (triple flexion response). With incomplete suprasegmental lesions, the response may be fractionated; for example, the hip and knee may flex but the foot may not dorsiflex, or vice versa. In the more chronic stages of hemiplegia the upper limb is characteristically held stiffly in partial flexion.

With bilateral cerebral lesions, exaggerated stretch reflexes can be elicited in cranial as well as limb and trunk muscles because of interruption of the corticobulbar pathways. These are seen as easily triggered masseter contractions in response to a brisk downward tap on the chin (jaw jerk) and brisk contractions of the orbicularis oris muscles in response to tapping the philtrum or corners of the mouth. In advanced cases, weakness or paralysis of voluntary movements of the face, tongue, larynx, and pharynx are added (bulbar spastic or "pseudobulbar" palsy; see pages 517 and 541).

Table 3-1 summarizes the main attributes of upper motor neuron lesions and contrasts them with those of the lower motor neuron.

**Motor Disturbances due to Lesions of the Parietal Lobe**

As indicated earlier in this section, a significant portion of the pyramidal tract originates in neurons of the parietal cortex. Also, the parietal lobes are important sources of visual and tactile information necessary for the control of movement. Pause and colleagues have described the motor disturbances due to lesions of the parietal cortex. The patient is unable to maintain stable postures of the outstretched hand when his eyes are closed and cannot exert a steady contraction. Exploratory movements and manipulation of small objects are impaired, and the speed of tapping is diminished. Posterior parietal lesions (involving areas 5 and 7) are more detrimental in this respect than anterior ones (areas 1, 3, and 5), but in patients with the most severe deficits both regions are affected.

**APRAXIA AND OTHER NONPARALYTIC DISORDERS OF MOTOR FUNCTION**

All that has been said about the cortical and spinal control of the motor system gives one only a limited idea of human motility. Viewed objectively, the conscious and sentient human organism is continuously active—fidgeting, adjusting posture and position, sitting, standing, walking, running, speaking, manipulating tools, or performing the intricate sequences of movements involved in athletic or musical skills. Some of these activities are relatively simple, automatic, and stereotyped. Others have been learned and mastered through intense conscious effort and with long practice have become habitual—i.e., reduced to an automatic level—a process not at all understood physiologically. Still others are complex and voluntary, parts of a carefully formulated plan, and demand continuous attention and thought. What is more remarkable, one can be occupied in several of these variably conscious and habitual activities simultaneously, such as driving through heavy traffic while lighting a cigarette and engaging in animated conversation. Moreover, when an obstacle prevents a particular sequence of movements from accomplishing its goal, a new sequence can be undertaken automatically for the same purpose. As stated above, these activities, in the scheme of Hughlings Jackson, represent the third and highest level of motor function.

How is all this made possible? Neuropsychologists, on the basis of studies of large numbers of patients with lesions of different parts of the cerebrum, believe that the planning of complex activities, conceptualizing their final purpose, and continuously modifying the individual components of a motor sequence until the goal is achieved are initiated and directed by the frontal lobes. Lesions of the frontal lobes have the effect of reducing the impulse to think, speak, and act (i.e., abulia or reduced "cortical tone," to use Luria's expression), and a complex activity will not be initiated or sustained long enough to permit its completion.

The term apraxia is applied to a state in which a clear-minded patient with no weakness, ataxia, or other extrapyramidal derangement and no defect of the primary modes of sensation loses the ability to execute highly complex and previously learned skills and gestures. This was the meaning given to apraxia by Liepmann, who introduced the term in 1900. It was his view, on the basis of subsequent case studies, that apraxia could be subdivided into three types—ideational, ideomotor, and kinetic. His anatomic data indicated that planned or commanded action is normally developed not in the frontal lobe but in the parietal lobe of the dominant hemisphere, where visual, auditory, and somesthetic information is integrated. Presumably the formation of engrams of skilled movements depends on the integrity of this part of the brain; if it is damaged, the engrams cannot be activated at all or the movements are faltering and inappropriate. The failure to conceive or formulate an action, either spontaneously or to command, was referred to by Liepmann as ideational apraxia. From sensory areas 5 and 7 in the dominant parietal lobe there are connections with the supplementary and premotor cortices of both cerebral hemispheres, wherein reside the innervatory mechanisms for patterned movement. The patient may know and remember the planned action, but because these connections are interrupted, he cannot execute it with either hand. This was Liepmann's concept of ideomotor apraxia. Kinetic limb apraxia refers to clumsiness and maladroitness of a limb in the performance of a skilled act that cannot be accounted for by paresis, ataxia, or sensory loss (see also Chap. 22).

These high-order abnormalities of learned movement patterns have several unique features. Seldom are they evident to the patient himself, and therefore they are not sources of complaint; or, if they are appreciated by the patient, he has difficulty describing the problem except in narrow terms of the activity that is impaired, such as using a phone or dressing. For this reason they are often overlooked by the examining physician. Their evocation requires special types of testing that may be difficult because of the presence of other neurologic deficits. Obviously, if the patient is confused or aphasic, spoken or written requests to perform an act will not be understood and one must find ways of persuading him to imitate the movements of the examiner. Moreover, the patient must be able to recognize and name the articles that he attempts to manipulate; i.e., there must not be an agnosia.

In a practical sense, the lesions responsible for ideomotor apraxia of both arms usually reside in the left parietal region. Kertesz and colleagues have provided
evidence that separate lesions are responsible for aphasia and apraxia, though the two conditions are frequently associated. Surprisingly, there are but a few cases of ideomotor apraxia with proven premotor lesions. The exact location of the premotor lesion, whether in the supramarginal gyrus or in the superior parietal lobe (areas 5 and 7) and whether subcortical or cortical, is still uncertain. Geschwind accepted Liepmann’s proposition that a lesion of a subcortical tract (presumably the arcuate fasciculus) disconnects the premotor from the left frontal cortex, accounting for the ideomotor apraxia of the right limbs, and that the left limb apraxia is due to a caudal disconnection of the left and right premotor association cortices. In a right-handed person, the lesion that gives rise to a left limb apraxia is usually in the left frontal lobe and includes Broca's area, the left motor cortex, and the deep underlying white matter. Clinically there is a motor speech disorder, a right hemiparesis, and apraxia of the nonparalyzed hand—i.e., “sym pathetic apraxia.” If the lesion in the deep white matter separates the language areas from the right motor cortex but not from the left, the patient can write with the right hand but not with the left, or he may write correctly with the right hand and aphatically with the left. That such a syndrome is attributable to interruption of a pathway that traverses the genu of the corpus callosum, as depicted by Geschwind, is questionable, insofar as sympathetic apraxia has not been observed in patients with lesions (or surgical sections) confined to the anterior third of the corpus callosum (see page 494). The disconnection syndromes are discussed further in Chap. 22 and Chap. 23.

Facial-oral apraxia is probably the most common of all apraxias. It may occur with lesions that undercut the left supramarginal gyrus or the left motor association cortex and may be associated with apraxia of the limbs. Such patients are unable to carry out facial movements to command (like the lips, blow out a match, etc.), although they may do better when asked to imitate the examiner or when holding a lighted match. With lesions that are restricted to the facial area of the left motor cortex, the apraxia is limited to the facial musculature and may be associated with a verbal apraxia and cortical dysarthria (page 555). So-called apraxia of gag is considered in Chap. 7. The terms dressing apraxia and constructional apraxia are sometimes used to describe certain manifestations of parietal lobe disease. These abnormalities are not apraxias in the strict sense as defined above but are symptoms of contralateral extinction or neglect of the body and extrapersonal space (anosognosia, page 484).

Testing for apraxia is carried out in several ways. First, one observes the actions of the patient as he engages in such tasks as dressing, washing, shaving, and using eating utensils. Second, the patient is asked to carry out familiar symbolic acts—wave good-bye, shake his fist as though angry, salute, or blow a kiss. Third, if he fails, he is asked to imitate such acts made by the examiner. Finally, he is asked to show how he would hammer a nail, brush his teeth, comb his hair, cross himself, and so forth, or to execute a more complex act, such as lighting and smoking a cigarette or opening a bottle of soda, pouring some into a glass, and drinking it. These last actions, involving more complex sequences, are said to be tests of ideational apraxia, and the simpler acts, tests of ideomotor apraxia. To perform these tasks in the absence of the tool or utensil is always demanding because the patient must generically formulate a plan of action. Nature has provided a habitual motor sequence. The patient may fail to carry out a commanded or suggested activity (e.g., to take a pipe out of his pocket), yet a few minutes later he may perform the same motor sequence automatically. One may think of such an ideomotor deficit, if it can be singled out (no confusion or defect in comprehension), as a kind of amnesia for certain learned patterns of movement, analogous to the amnesia for words in aphasia.

Children with cerebral diseases that retard mental development are often unable to learn the sequences of movement required in hopping, jumping over a barrier, hitting or kicking a ball, or dancing. They suffer a developmental motor apraxia. Certain tests quantitate failure in these age-linked motor skills (see Chap. 28).

In the authors’ opinion, the time-honored division of apraxia into ideational, ideomotor (idiokinetik), and kinetic types is unsatisfactory. It is more helpful to think of the apraxias in an anatomic sense, as disorders of association between different parts of the cerebral cortex, as described above. We have been unable to confidently separate ideomotor from ideational apraxia. The patient with a severe ideomotor apraxia nearly always has difficulty at the ideational level. Furthermore, in view of the complexity of the motor system, we are frequently uncertain whether a clumsiness or ineptitude of a hand in performing a motor skill represents a kinetic apraxia or some other fault in the intrinsic organization of hand control.

A related but poorly understood disorder of movement has been termed the alien hand. In the absence of volition, the hand and arm undertake complex and seemingly purposeful movements such as reaching into a pocket or handbag, placing the hand behind the head, and lugging on the opposite hand or other body part, and these activities may occur even during sleep. The patient has the sense that the actions are beyond his control, and there is often an impression that the hand is estranged as if controlled by an external agent (although the limb is recognized as one’s own—there is no anosognosia); a grasp reflex and a tendency to grope are sometimes used to describe certain manifestations of parietal lobe disease. These abnormalities are not apraxias in the strict sense as defined above but are symptoms of contralateral extinction or neglect of the body and extrapersonal space (anosognosia, page 484).

PATTERNS OF PARALYSIS AND THEIR DIAGNOSIS

The diagnostic considerations for paralysis may be simplified by utilizing the following subdivision, based on the location and distribution of the muscle weakness.

1. Monoplegia refers to weakness or paralysis of all the muscles of one leg or arm. This term should not be applied to paralysis of isolated muscles or groups of muscles supplied by a single nerve or motor root.

2. Hemiplegia, the commonest form of paralysis, involves the arm, the leg, and sometimes the face on one side of the body. With rare exceptions, mentioned further on, hemiplegia is attributable to a lesion of the corticospinal system on the side opposite to the paralysis.

3. Paraplegia indicates weakness or paralysis of both legs. It is most often the result of spinal cord disease, rarely of the medial frontal motor cortices, cauda equina, or peripheral nerves.

4. Quadriplegia (tetraplegia) denotes weakness or paralysis of all four extremities. It may result from disease of the peripheral nerves, muscles, or myoneural junctions; gray matter of the spinal cord; or the upper motor neurons bilaterally in the cervical cord, brainstem, or cerebrum. Diplegia is a special form of quadriplegia in which the legs are affected more than the arms. Triplegia occurs most often as a transitional condition in the development of or partial recovery from tetraplegia.

5. Isolated paralysis of one or more muscle groups.

6. Nonparalytic disorders of movement (apraxia, ataxia, etc.).

7. Muscle incoordination without visible changes in motor neurons, roots, or nerves.

8. Hysterical paralysis.

Monoplegia

The examination of patients who complain of weakness of one limb often discloses an asymptomatic weakness of another, and the condition is actually a hemiparesis or paraparesis. Or, instead of weakness of all the muscles in a limb, only isolated groups are found to be affected. Ataxia, sensory disturbances, or reluctance to move the limb because pain must not be misinterpreted as weakness. The presence of parkinsonism may give rise to the same error, as can rigidity or bradykinesia of other causation, or a mechanical limitation due to arthritis and bursitis. The presence or absence of atrophy of muscles in a monoplegic limb is of particular diagnostic help, as indicated below.

Monoplegia without Muscular Atrophy

This is most often due to a lesion of the cerebral cortex. Only infrequently does it result from a subcortical lesion that interrupts the motor pathways. A cerebral vascular lesion (thrombotic or embolic infarction) is the commonest cause; a circumscribed tumor or abscess may have the same effect. Multiple sclerosis and spinal cord tumor, early in their course, may cause weakness of one limb, usually the leg. Monoplegia due to a lesion of the upper motor neuron is usually accompanied by spasticity, increased reflexes, and an extensor planter reflex (Babinski sign); exceptionally, a small lesion of the motor cortex will not result in spasticity. In either event, nerve conduction studies are normal. In acute distal spasticity, the lower motor neurons, the tendon reflexes are reduced or abolished, but atrophy may not appear for several weeks. Hence, before reaching an anatomic diagnosis, one must take into account the mode of onset and duration...
of the disease.

**Monoplegia with Muscular Atrophy** This is more frequent than monoplegia without muscular atrophy. Long-continued disease of one limb may lead to atrophy, but it is usually of lesser degree than atrophy due to lower motor neuron disease (denervation atrophy). In disease atrophy, the tendon reflexes are retained and nerve conduction studies are normal. With denervation of muscles, there may be visible fasciculations and reduced or abolished tendon reflexes in addition to paralysis. If the limb is partially denervated, the electromyogram shows reduced numbers of motor unit potentials (often of large size) as well as fasciculations and fibrillations. The location of the lesion (in nerves, spinal roots, or spinal cord) can usually be determined by the pattern of weakness, by the associated neurologic symptoms and signs, and by special tests—magnetic resonance imaging (MRI) of the spine, examination of the cerebrospinal fluid (CSF), and electrical studies of nerve and muscle.

A complete atrophic brachial monoplegia is uncommon; more often, only parts of a limb are affected. When present in an infant, it should suggest brachial plexus trauma from birth; in a child, poliomyelitis or other viral infection of the spinal cord; and in an adult, poliomyelitis, syringomyelia, amyotrophic lateral sclerosis, or a brachial plexus lesion. *Cural* (leg) monoplegia is more frequent than brachial monoplegia and may be caused by any lesion of the thoracic or lumbar cord—i.e., traumatic, tumor, myelitis, multiple sclerosis, progressive muscular atrophy, late radiation effect, etc. These disorders rarely cause severe atrophy; neither does infarction in the territory of the anterior cerebral artery. A prolapsed intervertebral disc and the several varieties of mononeuropathy almost never paralyze all or most of the muscles of a limb. The effects of a centrally prolapsed disc or other compressive lesion of the cauda equina are rarely confined to one leg. However, a unilateral retropitoneal tumor or hematoma may paralyze the leg by compressing the lumbosacral plexus. The mode of onset and temporal course differentiate these diseases.

**Hemiplegia** This is the most frequent form of paralysis. With rare exceptions (a few unusual cases of poliomyelitis or motor system disease), this pattern of paralysis is due to involvement of the corticospinal pathways.

**Location of Lesion Producing Hemiplegia** The site or level of the lesion—i.e., cerebral cortex, corona radiata, capsule, brainstem, or spinal cord—can usually be deduced from the associated neurologic findings. Diseases localized to the cerebral cortex, cerebral white matter (corona radiata), and internal capsule usually manifest themselves by weakness or paralysis of the leg, arm, and lower face on the opposite side. The occurrence of seizures or the presence of a language disturbance (dysphasia, discrimination loss) suggests a contralateral cortical or subcortical location.

Damage to the corticospinal and corticobulbar tracts in the upper portion of the brainstem also causes paralysis of the face, arm, and leg of the opposite side (see 

As indicated above, muscle atrophy that follows upper motor neuron lesions never reaches the proportions seen in diseases of the lower motor neuron. The atrophy in the former cases is due to deus. When the motor cortex and adjacent parts of the paretic muscle are damaged in infancy or childhood, normal development of the muscle is arrested, as well as the skeletal system in the region supplied by the tract is retarded. The limbs are often small in proportion to the trunk. In adults, muscle atrophy is most evident if the paralysis occurs after puberty, by which time the greater part of skeletal growth has been attained. In hemiplegia due to spinal cord lesions, muscles at the level of the lesion may atrophy as a result of damage to anterior horn cells or ventral roots. In the causation of hemiplegia, hemorrhagic and ischemic vascular diseases of the cerebrum and brainstem exceed all others in frequency. Trauma (brain contusion, epidural and subdural hemorrhage) ranks second. Other important causes, less acute in onset, are, in order of frequency, brain tumor, brain abscess, demyelinating diseases, and the vascular complications of meningitis and encephalitis. Most of these diseases can be recognized by their mode of evolution and characteristic clinical and laboratory findings, which are presented in the chapters on neurologic diseases. Alternating transient hemiparesis may be due to a special type of migraine (see discussion in Chap. 10).

**Paraplegia** Paralysis of both lower extremities may occur with diseases of the spinal cord, nerve roots, or, less often, the peripheral nerves. If the onset is acute, it may be difficult to distinguish spinal from neuropsychiatric paralysis because of the element of spinal shock, which results in abolition of reflexes and flaccidity. In acute spinal cord diseases involving cortexicospinal tracts, the paralysis or weakness affects all muscles below a given level; usually, if the white matter is extensively damaged, sensory loss below a particular level is conjoined (loss of pain and temperature sense due to spinothalamic tract damage, and loss of vibratory and position sense due to posterior column involvement). Also, in bilateral disease of the spinal cord, the bladder and bowel and their sphincters are usually affected. These abnormalities may be due to an intrinsic lesion of the cord or to an extrinsic mass that narrows the spinal canal, both types of lesion being evident on MRI. In peripheral nerve diseases, motor loss tends to involve the distal muscles of the legs more than the proximal ones (exceptions are certain varieties of the Guillain-Barré syndrome and diabetic neuropathy); sphincteric function is usually spared or impaired only transiently. Sensory loss, if present, is also more prominent in the distal segments of the limbs and the degree of loss is often more for one modality than for another.

For clinical purposes it is helpful to separate the acute paraplegias from the chronic ones and to divide the latter into two groups: those beginning in adult life and those occurring in infancy.

The most common cause of acute paraplegia (or quadriplegia, if the cervical cord is involved) is spinal cord trauma, usually associated with fracture-dislocation of the spine. Less common causes are hematomyelia due to a vascular malformation, an arteriovenous malformation of the cord that causes ischemia via an obscure mechanism, or infarction of the cord due to occlusion of the anterior spinal artery or, more often, to occlusion of segmental branches of the aorta (due to dissecting aneurysm or atheroma, vasculitis, and nucleus pulposus embolism).

Paraplegia or quadriplegia due to postinfectious myelitis, demyelinating or necrotizing myelopathy, or epidural abscess or tumor with spinal cord compression tends to develop somewhat more slowly, over a period of hours or days or longer. Epidural or subdural hemorrhage from bleeding diseases or warfarin therapy causes an acute or subacute paraplegia; in a few instances the bleeding has followed a lumbar puncture. Paralytic poliomyelitis and acute polyneuritis (Guillain-Barré—the former, a purely motor disorder with mild meningeals (now rare), the latter predominantly motor but often with sensory disturbances—must be distinguished from the acute and subacute myelopathies and from each other.

In adult life, multiple sclerosis and tumor account for most cases of subacute and chronic spinal paralysis, but a wide variety of extrinsic and intrinsic processes may produce the same effect: protruded cervical disc and cervical spondylosis (often with a congenitally narrow canal), epidural abscess and other infections (tuberculous, fungal, and other granulomatous diseases), syphilitic meningomyelitis, motor system disease, subacute combined degeneration (vitamin B12 deficiency), syringomyelia, and degenerative disease of the lateral and posterior columns of unknown cause. (See Chap. 44 for discussion of these spinal cord diseases.) Several varieties of polyneuropathy and polyneuromyelitis must also be considered in the differential diagnosis of paraplegia or paraparesis.

In pediatric practice, delay in starting to walk and difficulty in walking are common problems. These conditions may indicate a systemic disease (such as rickets), mental deficiency, or, more commonly, some muscular or neurologic disease. Congenital cerebral disease from periventricular leukomalacia accounts for a majority of cases of infantile diplegia (weakly predominating of the legs, with minimal affection of the arms). Present at birth, it becomes manifest in the first months of life and
may appear to progress, but actually the disease is stationary and the progression is only apparent, being exposed as the motor system develops; later there may
seem to be slow improvement as a result of the normal maturation processes of childhood. Congenital malformation or birth injury of the spinal cord are other
possibilities. Friedreich ataxia and familial paraplegia, muscular dystrophy, tumor, and the chronic varieties of polynuropathy tend to appear later, during childhood
and adolescence, and are slowly progressive. Acute transverse (demyelinating) myelitis is a rare condition of childhood.

**Quadruplegia (Tetraplegia)**

All that has been said about the spinal causes of paraplegia applies to quadriplegia, the lesion being in the cervical rather than the thoracic or lumbar segments of the
spinal cord. If the lesion is situated in the thoracic or lumbar segments, it involves the anterior half of the spinal cord, as typified by the anterior spinal artery syndrome (but
occurring also in some cases of myelitis and fracture-dislocations of the cervical spine), the paralysis of the arms may be flaccid and areflexic in type and that of the
legs, spastic. There is usually pain in the neck and shoulders and numbness of the hands; elements of ataxia from posterior column lesions accompany the
paraparesis. Dislocation of the odontoid process with compression of the C1 and C2 spinal cord segments may occur with rheumatoid arthritis and Morquio disease;
in the latter there may also be pronounced dural thickening.

A progressive syndrome of monoparesis, biparesis, and then triaparesis is caused by tumors and a variety of other compressive lesions in the region of the foramen
magnum and high cervical cord. Bilateral infarction of the mediulla pyramids from occlusion of the vertebral arteries or their anterior spinal branches is a very rare
cause of quadriplegia. Repeated cerebrovascular accidents may lead to bilateral hemiplegia, usually accompanied by pseudobulbar palsy. In infants and young
children, aside from developmental abnormalities and anoxia of birth, certain metabolic cerebral diseases (metachromatic and other forms of leukoencephalopathy,
lipid storage disease) may be responsible for a quadriplegia or paraplegia, but always with severe psychomotor retardation. Congenital forms of muscular
dystrophy and muscular atrophy (Werdnig-Hoffmann disease) may be recognized soon after birth or later and progress slowly.

**Triplegia**

Paralysis that remains confined to three limbs is observed only rarely; more often the fourth limb is weak or hyporeflexic, and the syndrome is really an
incomplete tetraplegia. Also, as indicated earlier, this pattern of involvement is important, because it may signify an evolving lesion of the upper cervical cord or
cervicomedullary junction. A meningioma of the foramen magnum, for example, may begin with spastic weakness of one limb, followed by sequential involvement of the
other limbs in an “around the clock” pattern. There are usually bilateral Babinski signs early in the process, but there may be few sensory findings. We have also
seen this pattern in patients with multiple sclerosis and other intrinsic inflammatory and neoplastic lesions. These same diseases may produce triplegia (or triaparesis)
by a combination of paraplegia from a thoracic spinal cord lesion and a separate unilateral lesion in the cervical cord or higher that results in a hemiparesia.

**Paralysis of Isolated Muscle Groups**

This condition usually indicates a lesion of one or more peripheral nerves or of several adjacent spinal roots. The diagnosis of an individual peripheral nerve lesion
is made on the basis of weakness or paralysis of a particular muscle or group of muscles and impairment or loss of sensation in the distribution of the nerve. Complete
or extensive interruption of a peripheral nerve is followed by atrophy of the muscles it innervates and by loss of tendon reflexes of the involved muscles; abnormalities
of vasomotor and sudomotor functions and trophic changes in the skin, nails, and subcutaneous tissue may also occur.

Knowledge of the motor and sensory innervation of the peripheral nerve in question is needed for a satisfactory diagnosis. It is not practical to memorize the precise
sensorimotor distribution of each peripheral nerve, and special manuals, such as *Aids to the Examination of the Peripheral Nervous System*, should be consulted (see
also Chap. 46). In addition, it is important to decide whether the lesion is a temporary one of conduction alone or whether there has been a structural interruption of nerve
fibers, requiring nerve regeneration or corrective surgery for recovery. Electromyography and nerve conduction studies are of great value here.

If there is no evidence of upper or lower motor neuron disease but certain movements are nonetheless imperfectly performed, one should look for a disorder of
position sense or cerebellar coordination, or for rigidity with abnormalities of posture and movement due to disease of the basal ganglia (Chap. 4). In the absence of
these disorders, the possibility of an apraxic disorder should be investigated by the methods outlined earlier.

**Hysterical Paralysis**

Hysterical paralysis may involve one arm or leg, both legs, or all of one side of the body. Tendon reflexes are retained and severe atrophy is lacking in hysterical
paralysis, features that distinguish it from chronic lower motor neuron disease. Diagnostic difficulty arises only in certain acute cases of upper motor neuron disease
that lack the usual changes in reflexes and muscle tone. The hysterical gait is often diagnostic (page 131). Sometimes there is loss of sensation in the paralyzed parts
and loss of light, hearing, and smell on the paralyzed side—a pattern of sensory changes that is never seen in organic brain disease. When the hysterical patient is
asked to move the affected limbs, the movements tend to be slow, hesitant, and jerky, often with contraction of agonist and antagonist muscles simultaneously and
intermittently. Lack of effort is usually obvious, despite facial and other expressions to the contrary. Power of contraction improves with encouragement. The
weakness is inconsistent; some movements are performed tentatively and moments later another movement involving the same muscles is performed naturally.

Hoover's sign and the trunk-thigh sign of Babinski are helpful in distinguishing hysterical from organic hemiplegia. To elicit Hoover's sign, the examiner places both
hands under the heels of the recumbent patient, who is asked to press the heels down forcefully. With organic hemiplegia, pressure will be felt entirely or almost
entirely from the nonparalyzed leg. The examiner then removes his hand from under the nonparalyzed leg, places it on top of the nonparalyzed foot, and asks the
patient to raise that leg. In true hemiplegia, no added pressure will be felt by the hand that remained beneath the heel of the paralyzed leg. In hysteria, the heel of the
supposedly paralyzed leg will press down on the examiner's hand. To carry out Babinski's trunk-thigh test, the examiner asks the recumbent patient to sit up while
keeping his arms crossed in front of his chest. In the patient with organic hemiplegia, there is an involuntary flexion of the paretic lower limb; in paraplegia, both limbs
are flexed as the trunk is flexed; in hysterical hemiplegia, only the normal leg may be flexed; and in hysterical paraplegia, neither leg is flexed.

**Muscular Paralysis and Spasm Unattended by Visible Changes in Nerve or Muscle**

A discussion of motor paralysis would not be complete without some reference to a group of diseases in which muscle weakness may be profound but there are no
over structural changes in motor nerve cells or nerve fibers. This group comprises myasthenia gravis; myotonia congenita (Thomsen disease); familial periodic
paralysis; disorders of potassium, sodium, calcium, and magnesium metabolism; tetany; tetanus; poisoning by *Clostridium botulinum*, black widow spider bite; and the
thyroid and other endocrine myopathies. In these diseases, each with a fairly distinctive clinical picture, the abnormality is essentially biochemical, and their
investigation requires special biochemical and histochemical tests and electron microscopic study. These subjects are discussed in the section on muscle disease.

Section 1

DISORDERS OF MOTILITY

The control of motor function, to which much of the human nervous system is committed, is accomplished through the integrated action of a vast array of segmental and suprasegmental motor neurons. As originally conceived by Hughlings Jackson in 1858, purely on the basis of clinical observations, the motor system is organized hierarchically in three levels, each higher level controlling the one below. It was Jackson's concept that the spinal and brainstem neurons represent the lowest, simplest, and most closely organized motor centers; that the motor neurons of the posterior frontal region represent a more complex and less closely organized second motor center; and that the prefrontal parts of the cerebrum are the third and highest motor center. This scheme is still regarded as being essentially correct, though Jackson failed to recognize the importance of the parietal lobe and basal ganglia in motor control.

Since Jackson's time, physiologists have repeatedly analyzed these three levels of motor organization and have found their relationships to be remarkably complex. Motor and sensory systems, although separated for practical clinical purposes, are not independent entities but are closely integrated. Without sensory feedback, motor control is ineffective. And at the higher cortical levels of motor control, motivation, planning, and other frontal lobe activities that subserve volitional movement are always preceded and modulated by activity in the parietal sensory cortex.

Motor activities include not only those that alter the position of a limb or other part of the body (isotonic contraction) but also those that stabilize posture (isometric contraction). Movements that are performed slowly are called ramp movements. Very rapid movements, too fast for sensory control, are called ballistic. Another way of classifying movements, stressed by Hughlings Jackson, is in terms of their automaticity: reflex movements are the most automatic, willed movements the least. Physiologic studies, cast in their simplest terms, indicate that the following parts of the nervous system are engaged primarily in the control of movement and, in the course of disease, yield a number of characteristic derangements.

1. The large motor neurons in the anterior horns of the spinal cord and the motor nuclei of the brainstem. The axons of these nerve cells comprise the anterior spinal roots, the spinal nerves, and the cranial nerves, and they innervate the skeletal muscles. These nerve cells and their axons constitute the primary, or lower, motor neurons, complete lesions of which result in a loss of all movement—voluntary, automatic, postural, and reflex. The lower motor neurons are the final common path by which all neural impulses are transmitted to muscle.

2. The motor neurons in the frontal cortex adjacent to the rolandic fissure connect with the spinal motor neurons by a system of fibers known, because of their collective shape in transverse sections through the medulla, as the pyramidal tract. Since the motor fibers that extend from the cerebral cortex to the spinal cord are not confined to the pyramidal tract, they are more accurately designated as the corticospinal tract, or, alternatively, as the upper motor neurons, to distinguish them from the lower motor neurons.

3. Several brainstem nuclei project to the spinal cord, notably the pontine and medullary reticular nuclei, vestibular nuclei, and red nuclei. These nuclei and their descending fibers subserve the neural mechanisms of posture and movement, particularly when movement is highly automatic and repetitive. Certain of these brainstem nuclei are influenced by the motor or premotor regions of the cortex, e.g., via corticoreticulospinal relays.

4. Two subcortical systems, the basal ganglia (striatum, pallidum, and related structures, including the substantia nigra and subthalamic nucleus) and the cerebellum. Each system plays an important role in the control of muscle tone, posture, and coordination of movement by virtue of its connections, via thalamocortical fibers, with the corticospinal system and other descending cortical pathways.

5. Several other parts of the cerebral cortex, particularly the premotor and supplementary motor cortices. These structures are involved in the programming (i.e., the sequencing and modulation) of voluntary movement.

6. The prefrontal cortex, which is involved in the planning and initiation of willed movement. Fibers from the prefrontal cortex project to the supplementary and premotor cortex and provide the motor signals to these more strictly motor areas. Similarly, certain parietal cortical areas (superior parietal lobule) supply the somatic sensory information that activates the premotor and supplementary motor cortices and leads to directed movement. In addition, other parts of the nervous system concerned with tactile, visual, and auditory sensation are connected by fiber tracts with the motor cortex. These association pathways provide their own sensory regulation of motor function.

The impairments of motor function that result from lesions in these various parts of the nervous system may be subdivided into (1) paralysis (or paresis) due to affection of lower motor neurons, (2) paralysis due to affection of upper motor (corticospinal) neurons, (3) apraxic or nonparalytic disturbances of purposive movement due to involvement of association pathways in the cerebrum, (4) involuntary movements and abnormalities of posture due to disease of the basal ganglia, and (5) abnormalities of coordination (ataxia) due to lesions in the cerebellum. The first two types of motor disorder and the apraxic disorders of movement are discussed in Chap. 3; extrapyramidal motor abnormalities are discussed in Chap. 4; and disorders of coordination in Chap. 5. A miscellaneous group of movement disorders—tremor, myoclonus, spasms, and tics—and disorders of stance and gait are considered in Chap. 6 and Chap. 7. Impairment or loss of motor function due to primary disease of peripheral nerves and striated muscle or to a failure of neuromuscular transmission forms the subject matter of Chap. 48, Chap. 49, Chap. 50, Chap. 51, Chap. 52, Chap. 53, Chap. 54, and Chap. 55.

Chap. References

In this chapter, the disorders of the automatic, static, postural, and other less modifiable motor activities of the nervous system are discussed. They are believed, on good evidence, to be an expression of the extrapyramidal motor system, meaning—according to S. A. K. Wilson, who introduced this term—the motor structures of the basal ganglia and certain related thalamic and brainstem nuclei.

In health, the activities of the basal ganglia and the cerebellum are blended with and modulate the corticospinal and corticobrainstem-spinal systems. The static postural activities of the former are indispensable to the voluntary movements of the latter. The close association of these two systems also becomes evident in the course of neurologic disease. Cerebral lesions that involve the corticospinal tracts predominantly result not only in a contralateral paralysis of volitional movements but also in a fixed posture or attitude in which the arm is flexed and the leg extended (predilection type of Wernicke-Mann or hemiplegic dystonia of Denny-Brown). As noted in Chap. 3, interruption of the motor projection pathways by a lesion in the upper pons or midbrain may release another posture in which all four limbs or the arm and leg on one side are extended and the cervical and thoracolumbar portions of the spine are hyperextended (decerebrate rigidity). In these released motor patterns, one has evidence of labyrinthine, tonic neck, and other postural reflexes that are mediated through descending nonpyramidal bulbospinal and other brainstem motor systems. Observations such as these and the anatomic data presented in Chap. 3 have blurred the classic distinctions between pyramidal and extrapyramidal motor systems. Nevertheless, this division remains a useful if not an essential concept in clinical work, since it compels us to distinguish several motor syndromes from one another—one that is characterized by a loss of volitional movement and spasticity; a second by akinesia, rigidity, and tremor without loss of voluntary movement; a third by involuntary movements (chorea, athetosis, and dystonia); and yet another by incoordination (ataxia). The clinical differences between corticospinal and extrapyramidal syndromes are summarized in Table 4-1.

Much of the criticism of the pyramidal-extrapyramidal concept derives from the terms themselves. The ambiguity related to the term pyramidal was discussed in Chap. 3, in which it was pointed out that pure pyramidal lesions do not cause total paralysis; when the latter exists, there is always involvement of other descending pathways as well. The term extrapyramidal is equally imprecise. Strictly interpreted, it refers to all the motor pathways except the pyramidal one, making this term so all-embracing as to be practically meaningless. The concept of an extrapyramidal motor system becomes more meaningful if it is subdivided into two parts: (1) the striatopallidonoigral system (basal ganglia) and (2) the cerebellum. These parts function very differently in the control of movement and posture, and disease in each of them results in particular disturbances of movement and posture without paralysis. The basal ganglia and the symptoms that result when they are diseased are described in the pages that follow. The disorders of movement and posture due to cerebellar disease are described in Chap. 5.

THE STRIATOPALLIDONOIGRAL SYSTEM (BASAL GANGLIA)

Anatomic and Physiologic Considerations

As an anatomic entity, the basal ganglia have no precise definition. Principally they include the caudate nucleus and the lentiform nucleus with its two subdivisions, the putamen and globus pallidus. Insofar as the caudate nucleus and putamen are really a continuous structure (separated only incompletely by fibers of the internal capsule) and are cytologically and functionally distinct from the pallidum, it is more meaningful to divide these nuclear masses into the striatum (or neostriatum), comprising the caudate nucleus and putamen, and the paleostriatum or pallidum, which has a medial (internal) and a lateral (external) segment. The putamen and pallidum lie on the lateral aspect of the internal capsule, which separates them from the caudate nucleus, thalamus, subthalamic nucleus, and substantia nigra on its medial side (Fig. 4-1 and Fig. 4-2). By virtue of their close connections with the caudate and lenticular nuclei, the subthalamic nucleus (nucleus of Lysy) and the substantia nigra are usually considered as parts of the basal ganglia. The cauastrium and amygdaloid nuclear complex, because of their largely different connections and functions, are usually excluded.

Figure 4-1 Diagram of the striatal afferent pathways. Corticostriate fibers from broad cortical areas project to the putamen; fibers from the cortex on the medial surface project largely to the caudate nucleus. Nigrostrial fibers arise from the pars compacta of the substantia nigra. Thalamostriate fibers arise from the centromedian-parafascicular complex of the thalamus. CM, centromedial nucleus; DM, dorsomedial nucleus; GP, globus pallidus; IC, internal capsule; PUT, putamen; RN, red nucleus; SN, substantia nigra; VPL, ventral posterolateral nucleus; VPM, ventral posterior medial nucleus. (Redrawn by permission from Carpenter MB, Sutin J: Human Neuroanatomy, 8th ed. Baltimore, Williams & Wilkins, 1983.)
For reasons indicated further on, some physiologists have expanded the list of basal ganglionic structures to include the red nucleus, the intralaminar thalamic nuclei, and the reticular formations of the upper brainstem. These structures receive direct cortical projections and give rise to rubrospinal and reticulospinal tracts which run parallel to the corticospinal (pyramidal) ones; hence they were referred to as extrapyramidal. However, these nongyralid linkages are structurally independent of the major extrapyramidal circuit that includes the striatum, pallidum, thalamus, and premotor and supplementary motor cortices. Insofar as the final links in this circuit—the premotor and supplementary motor cortices—ultimately project onto the motor cortex, this circuit is more aptly referred to as prepyramidal (Thach and Montgomery).

Earlier views of basal ganglionic organization emphasized the serial connectivity of the basal ganglionic structures and the funneling of efferent projections to the ventrolateral thalamus and thence to the motor cortex (Fig. 4-3). This concept was based largely on the seminal experimental work of Whittier and Mettler and of Carpenter, in the late 1940s. These investigators demonstrated, in monkeys, that a characteristic movement disorder, which they termed choreoid dyskinesia, could be produced consistently in the limbs of one side of the body by a lesion localized to the opposite subthalamic nucleus. They also showed that for such a lesion to provoke dyskinesia, the adjacent pallidum and pallidofugal fibers had to be preserved. Furthermore, a secondary lesion—placed in the medial segment of the pallidum, in the fasciculus lenticularis, or in the ventrolateral thalamic nuclear group—could abolish the dyskinesia. This experimental hyperkinesia could be abolished permanently by interruption of the lateral corticospinal tract but not by interruption of the other motor or sensory pathways in the spinal cord. These observations were interpreted to mean that the subthalamic nucleus normally exerts an inhibitory or regulating influence on the globus pallidus and ventral thalamus. Removal of this influence by selective destruction of the subthalamic nucleus is expressed physiologically by bursts of irregular choreoid activity, presumably arising from the intact pallidum and conveyed by pallidofugal fibers to the ventrolateral thalamic nuclei, thence by thalamocortical fibers to the ipsilateral premotor cortex, and from there by short association fibers to the motor cortex. Ultimately the abnormal movement is expressed via the lateral corticospinal tract, which in this instance functions as the final executive pathway.

A general principle that emerged from these observations was the central role of the ventrolateral and ventroanterior nuclei of the thalamus. Together, they form a vital link in an ascending fiber system, not only from the basal ganglia but also from the cerebellum, to the motor and premotor cortex. Thus both basal ganglionic and cerebellar influences are brought to bear, via thalamocortical fibers, on the corticospinal system and on other descending pathways from the cortex. Direct descending pathways from the basal ganglia to the spinal cord are relatively insignificant.

The foregoing view of basal ganglionic organization has been broadened considerably, the result of new anatomic, physiologic, and pharmacologic data (see in particular the reviews of Alexander and Crutcher, of DeLong, and of Penney and Young). Whereas earlier concepts emphasized the serial connectivity of the basal ganglionic structures and the funneling of efferent projections to the ventrolateral thalamus and then to the motor cortex, current evidence indicates an organization into several parallel basal ganglionic–cortical circuits. Although these circuits run parallel to the premotor or prepyramidal pathway, they remain separate from it, anatomic and physiologically. At least five such circuits have been described, each focused on a different portion of the frontal lobe: the prototypical motor circuit, converging on the premotor cortex; the oculomotor circuit, on the frontal eye fields; two prefrontal circuits, on the dorsolateral prefrontal and lateral orbitofrontal cortex, respectively; and a limbic circuit, on the anterior cingulate and medial orbitofrontal cortex.

An additional and most important feature of basal ganglionic structure and function, also relatively recently appreciated, is the nonequivalence of all parts of the striatum. Particular cell types and zones of cells within this structure appear to mediate different aspects of motor control and utilize specific neurochemical transmitters (Albin et al, DeLong).

The most important basal ganglionic connections and circuitry are indicated in Fig. 4-1, Fig. 4-2, and Fig. 4-3. Conventionally it has been taught that the striatum, mainly the putamen, is the receptive part of the basal ganglia, receiving topographically organized fibers from all parts of the cerebral cortex and from the pars compacta (pigmented neurons) of the substantia nigra; and that the output nuclei of the basal ganglia consist of the medial (internal) pallidum and the nonpigmented portion of the substantia nigra (pars reticulata).

It has been proposed—on the basis of physiologic, lesion, and pharmacologic studies—that there are two main efferent projections from the putamen, but these models, being quite incomplete, should be viewed as provisional. Nonetheless, there are reasons to conceptualize a direct efferent system from the putamen onto the medial (internal) pallidum and then onto the substantia nigra, particularly the nonpigmented (pars reticulata) cells, and an indirect system that traverses the lateral (external) pallidum and continues on to the subthalamic nucleus, with which it has strong to-and-fro connections. In some ways the subthalamic nucleus and lateral pallidum operate as a single functional unit (at least in terms of the effects of lesions in those locations on parkinsonian symptoms and the neurotransmitters involved; see further on). The medial pallidum and reticular part of the nigra can be viewed in a similar unitary way, sharing the same input and output patterns. Within the indirect pathway, an internal loop is created by projections from the subthalamic nucleus to the medial segment of the pallidum and pars reticulata. A second offshoot of the indirect pathway, recently uncovered, consists of projections from the lateral pallidum to the medial pallidofugal output nuclei.

From the internal pallidum, two bundles of fibers reach the thalamus—the ansa and the fasciculus lenticularis (Fig. 4-3). The ansa sweeps around the internal capsule; the fasciculus traverses the internal capsule in a number of small fascicles and then continues medially and caudally to join the ansa in the prerubral field. Both these fiber bundles join the thalamic fasciculus, which then contains not only the pallidothalamic projections but also mesothalamic, rubrothalamic, and dentatothalamic ones. These projections are directed to separate targets in the ventrolateral nucleus of the thalamus and to a lesser extent in the ventral anterior and
intralaminar thalamic nuclei. The centromedian nucleus of the intralaminar group projects back to the putamen and, via the parafascicular nucleus, to the caudate. A major projection from the ventral thalamic nuclei to the ipsilateral premotor cortex completes the large cortical-striatal-pallidal-thalamic-cortical motor loop—(the prepyramidal circuit, mentioned above)—with conservation of the somatotopic arrangement of motor fibers.

There is pharmacologic and physiologic evidence that a balanced functional architecture, one excitatory and the other inhibitory, is operative within individual circuits. The direct striato-medial pallidal-nigral pathway is activated by glutamnergic projections from the sensorimotor cortex and by dopamineergic nigral (pars compacta)-striatal projections. Stimulation of this direct pathway inhibits the medial pallidum, which, in turn, disinhibits the ventrolateral and ventroanterior nuclei of the thalamus. As a consequence, thalamocortical drive is enhanced and cortically initiated movements are facilitated. The indirect circuit arises from putaminal neurons that contain gamma-aminobutyric acid (GABA) and smaller amounts of enkephalin. These striatal projections have an inhibitory effect on the lateral pallidum, which, in turn, disinhibits the subthalamic nucleus through GABA release, providing excessive subthalamic drive to the medial pallidum and substantia nigra pars reticulata. The net effect is thalamic inhibition and reduced thalamocortical input to the precentral motor fields. These complex anatomic and physiologic relationships have been summarized in numerous schematic figures, such as Fig. 4-4 (see also the review by Lang and Lozano).

It has been suggested that enhanced conduction through the indirect pathway leads to hypokinesia (by increasing pallidothalamic inhibition), whereas enhanced conduction through the direct pathway results in hyperkinesia (by reducing pallidothalamic inhibition). The direct pathway is perceived by Marsden and Obeso as facilitating cortically initiated movements, and the indirect pathway as suppressing potentially conflicting and unwanted motor patterns. This view is supported by studies of motor organization in acquired hemidystonia (Ceballos-Baumann and colleagues) and lesioning studies in Parkinson disease.

In more conventional physiologic terms, Denny-Brown and Yanagisawa, who studied the effects of ablation of individual extrapyramidal structures in monkeys, concluded that the basal ganglia function as a kind of clearinghouse where, during an intended or projected movement, one set of activities is facilitated and all other unnecessary ones are suppressed. Another theory, stated somewhat differently, suggests that the basal ganglia function as a brake or switch. The tonic inhibitory ("brake") action of the basal ganglia prevents their target structures from generating unwanted motor activity. The "switch" function refers to the capacity of the basal ganglia to select which of many available motor programs will be active at any given time. Still other theories focus on the role of the basal ganglia in the initiation, sequencing, and modulation of motor activity ("motor programming"). Also, it appears that the basal ganglia participate in the constant priming of the motor system, enabling the rapid execution of motor acts without premeditation—e.g., hitting a baseball. In most ways, these conceptualizations restate the same notions of balance and selectivity imparted to all motor actions by the basal ganglia. Despite the recent impressive expansion of knowledge, the precise mechanisms by which the basal ganglia control motor function remains elusive. The manner in which excessive or depleted activity of various components of the basal ganglia gives rise to hypokinetic and hyperkinetic movement disorders is discussed further on under "Symptoms of Basal Ganglia Disease."

**Pharmacologic Considerations**

During the past three decades, a series of pharmacologic observations—some abstracted above—has considerably enhanced our understanding of basal ganglionic function and led to the discovery of a rational treatment of Parkinson disease and other extrapyramidal syndromes. Whereas physiologists had for years failed to discover the functions of the basal ganglia by stimulation and crude ablation experiments, clinicians became aware that the use of certain drugs, such as reserpine and the phenothiazines, regularly produced extrapyramidal syndromes (parkinsonism, choreoathetosis, dystonia, etc.). These observations generally stimulated the study of central nervous system transmitter substances in general. The current view is that the integrated basal ganglionic control of movement can be best understood by considering, in the context of the anatomy described above, the physiologic effects of neurotransmitters that convey the signals between cortex, striatum, globus pallidus, subthalamic nucleus, substantia nigra, and thalamus.

The most important neurotransmitter substances from the point of view of basal ganglionic function are glutamate, GABA, dopamine, acetylcholine, and serotonin, as already alluded to. They are summarized in Fig. 4-4, and a more complete account of this subject than is possible here may be found in the recent reviews of Penney and Young and of Ciliax and colleagues at the end of this chapter.

Glutamate is the neurotransmitter of the corticostratal excitatory projections and of the excitatory neurons of the subthalamic nucleus. GABA is the inhibitory neurotransmitter of striatal, pallidal, and substantia nigra (pars reticulata) projection neurons. Acetylcholine (ACH), long established as the neurotransmitter at the neuromuscular junction as well as in the autonomic ganglia, is also physiologically active in the basal ganglia. The highest concentration of ACH as well as of choline acetylase and acetylcholinesterase (the enzymes necessary for the synthesis and degradation, respectively, of ACH) is in the striatum. Acheolin is synthesized and released by the large but sparse (Goog type 2) nonsynaptic neurons. It has a mixed but mainly excitatory effect upon the more numerous spiny neurons within the putamen that constitute the main origin of the direct and indirect pathways. Dopamine, by contrast, has an inhibitory effect on these neurons (see below). It is likely that the effectiveness of the belladonna alkaloids and other atropinic agents—which have been used empirically for many years in the treatment of Parkinson disease and dystonia—depends on their capacity to antagonize ACH at sites within the basal ganglia and in projections from the pedunculopontine nuclei. Acetylcholine appears also to act on the presynaptic membrane of striatal cells and to influence their release of neurotransmitters, as discussed below.

In addition, the basal ganglia contain other biologically active substances—substance P, enkephalin, cholecystokinin, somatostatin, and neuropeptide Y—which may enhance or diminish the effects of other neurotransmitters, i.e., they act as neuromodulators. The neurons utilizing these substances are just now being identified.

O f the catecholamines, dopamine has the most pervasive role in the functioning of the basal ganglia. The areas richest in dopamine are the substantia nigra, where it is synthesized in the nerve cell bodies of the pars compacta, and the termination of these fibers in the striatum. In the most simplified models, stimulation of the dopaminergic neurons of the substantia nigra induces a specific response in the striatum—namely, an inhibitory effect on the already low firing rate of neostriatal neurons. However, the effects of dopamine have proved more difficult to unravel, in large part because there are now four known types of postsynaptic receptors (D1 to D4), each with its particular anatomic distribution and pharmacologic action. This heterogeneity is reflected in the excitatory effect of dopamine on the small spiny neurons of the putamen and an inhibitory effect on others.

Certain drugs—namely reserpine, the phenothiazines, and the butyrophenones, notably haloperidol—may induce parkinsonian syndromes in humans. Reserpine acts by depleting the striatum and other parts of the brain of dopamine, haloperidol and the phenothiazines produce parkinsonism by a different mechanism, probably by...
causing a blockade of dopamine receptors within the striatum.

New insight into Parkinson disease has come from the discovery that it can be faithfully reproduced in humans and primates by the toxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). This toxin was discovered accidentally in drug addicts who self-administered an analogue of meperidine. The toxin interacts with high affinity to monoamine oxidase (MAO), an extraneuronal enzyme that transforms it to a toxic metabolite—pyridinium. The latter is bound by melatonin in the dopaminergic nigral neurons in sufficient quantities to destroy the cells. In monkeys made parkinsonian by the administration of MPTP, electrophysiologic studies have shown increased activity in the medial globus pallidus and decreased activity in the lateral globus pallidus, as predicted from the previously described models. This comes about because of the differential loss of activity of dopaminergic striatal neurons that project to each of these parts of the pallidum. The end result is increased inhibition of thalamocortical neurons. As pointed out by Bhatia and Marsden, it is difficult to explain why medial pallidal lesions do not regularly cause parkinsonism. Perhaps it is because the subtle imbalance between the medial and lateral pallidal circuits that exists in Parkinson disease is not reproduced. This may also explain why crude lesions such as infarcts, hemorrhages, and tumors rarely produce the complete parkinsonian syndrome of tremor, bradykinesia, and rigidity without paralysis or reflex changes. Indeed, striking improvements in parkinsonian symptoms are obtained by placing lesions in the medial pallidum (pallidotomy), as discussed on page 1136.

In order to correct the basic nigral dopamine deficiency, attempts were made to administer dopamine to Parkinson patients. However, dopamine as such cannot cross the blood-brain barrier and has no therapeutic effect. But the immediate dopamine precursor, L-dopa, does cross the barrier and is effective in decreasing the akinesia, rigidity, and tremor of Parkinson disease as well as of MPTP-induced parkinsonism. This effect is greatly enhanced by the inhibition of dopa-decarboxylase, an important enzyme in the catalysis of dopamine. The addition of this enzyme inhibitor (carbidopa or benserazide) to L-dopa results in a marked increase of dopamine concentration in the brain, while sparing other organs from exposure to high levels of the drug. Similarly, drugs that inhibit catechol O-methyltransferase (COMT), another enzyme that breaks down dopamine, can prolong the effects of administered L-dopa.

Because of the pharmacologic activities of ACh and dopamine, it was originally postulated by Hornykiewicz that a functional equilibrium exists in the striatum between the excitatory activity of ACh and the inhibitory activity of dopamine. In Parkinson disease, the decreased release of dopamine by the substantia nigra onto the striatum disinhibits neurons that synthesize ACh, resulting in a predominance of cholinergic activity—a notion supported by the observation that parkinsonian symptoms are aggravated by centrally acting cholinergic drugs and improved by anticholinergic drugs. According to this theory, administration of anticholinergic drugs restores the ratio between dopamine and acetylcholine, with the new equilibrium being set at a lower-than-normal level because the striatal levels of dopamine are low to begin with. The use of drugs that enhance dopamine synthesis or dopamine release or that directly stimulate dopaminergic receptors in the striatum (e.g., bromocriptine) represents a more physiologic method of treating Parkinson disease.

The Pathology of Basal Ganglionic Disease

The extrapyramidal motor syndrome as we know it today was first delineated on clinical grounds and so named by S. A. K. Wilson in 1912. In the disease that now bears his name and that he called hepaticentric degeneration, the most striking abnormality in the nervous system was a bilaterally symmetrical degeneration of the putamen, corresponding to the point of cavitary. To these lesions Wilson attributed the characteristic symptoms of rigidity and tremor. Shortly thereafter, van Woerkom described a similar clinical syndrome in a patient with acquired liver disease (Wilson’s cases were familial); in the acquired form also, the most prominent lesions consisted of foci of neuronal degeneration in the striatum. Clinicopathologic studies of Huntington chorea—beginning with those of Meynert (1871) and followed by those of Jeorjesma (1908) and Alzheimer (1911)—related the movement disorder as well as the rigidity to a loss of nerve cells in the striatum. In 1920, Osakada and Cecile Volk gave a detailed account of the neuropathologic changes in several patients who had been afflicted with choreoathetosis since early infancy; the changes, which they described as a status fibrosis or status dysmyelinauts, were said to be confined to the caudate and lenticular nuclei. Tretiakoff (1919) was the first to demonstrate the consistent pathology of the substantia nigra in cases of paralysis agitans. A series of observations, culminating with those of J. Purdon Martin and later of Mitchell and colleagues, related hemiballismus to lesions in the subthalamic nucleus of Luys and its immediate connections.

More recently, Bhatia and Marsden, relying on published imaging studies, reviewed some 240 cases in which there were lesions in the caudate, putamen, and globus pallidus associated with movement and behavioral abnormalities. Dystonia had occurred in 36 percent, chorea in 8 percent, parkinsonism in only 6 percent, and dystonia-parkinsonism in 3 percent. Bilateral lesions of the subthalamus nuclei resulted in parkinsonism in 19 percent and dystonia-parkinsonism in 6 percent. The commonest persisting behavioral abnormality was abulia (apathy and loss of initiative, spontaneous thought, and emotional responsivity), occurring in 28 percent of those with caudate lesions. The deficiencies of this type of case analysis, conceded by the authors, included the crudity of the anatomy (judged by early computed tomography studies) and the lack of precise information regarding the temporal aspects of the functional disorder—time of onset, duration, and changes during the course of the illness. We find it surprising that choreoathetosis was not more frequent. Needed, of course, are detailed anatomic (postmortem) studies of cases in which the disturbances of function were stable for many months or years. Such an example is the case of generalized dystonia with pallidoluysian atrophy reported by Wooten and coworkers.

Table 4-2 summarizes the clinicopathologic correlations accepted by most neurologists, but it must be emphasized that there is still much uncertainty as to the finer details.

Table 4-2 Clinicopathologic correlations of extrapyramidal motor disorders

<td>Hypokinesia and Bradykinesia</td>
</tr>
</tbody>
</table>

The terms hypokinesia and akinesia refer to a disinclination on the part of the patient to use an affected part and to engage it freely in all the natural actions of the body. There may, in addition, be slowness in the initiation and execution of movement. In contrast to what occurs in paralysis (the primary symptom of corticospinal tract lesions), strength is not significantly diminished. Also, hypokinesia is unlike apraxia, in which a lesion erases the memory of the pattern of movements necessary for an intended act, leaving other actions intact. Clinically, the phenomenon of hypokinesia or akinesia is expressed most clearly in the parkinsonian patient and takes the form of an extreme underactivity (poverty of movement). The frequent automatic, habitual movements observed in the normal individual—such as putting the hand...
to the face, folding the arms, or crossing the legs—are absent or greatly reduced. In looking to one side, the eyes move, not the head. In arising from a chair, there is a failure to make the usual small preliminary adjustments, such as pulling the feet back, pulling the hands on the arms of the chair, and so forth. Blinking is infrequent. Saliva is not swallowed as quickly as it is produced, and drooling results. The face lacks expressivity mobility (“masked facies,” hypomimia). Speech is rapid and monotonous and the voice is soft.

Bradykinnesia, which connotes slowness rather than lack of movement, is probably another aspect of the same physiologic difficulty. Not only is the parkinsonian patient slightly “slow off the mark” (displaying a longer-than-normal interval between a command and the first contraction of muscle—i.e., increased reaction time), but the velocity of movement, or the time from onset to completion of movement, is slower than normal. Hallett distinguishes between akinnesia and bradykinnesia, equating akinnesia with the abduction time and bradykinnesia with a prolonged time from the beginning to the completion of the movement. He concedes that akinnesia is severe when rigidity is slight or absent. There is no slowness in formulating the plan of movement; that is to say, there is no bradykinnesia. For a time, bradykinnesia was attributed to the frequently associated rigidity, which could reasonably hamper all movements, but the incorrectness of this explanation became apparent when it was discovered that an appropriately placed stimulus in a patient with parkinsonism may elicit rigidity while leaving the akinnesia unaltered. Thus it appears that apart from their contribution to the maintenance of posture, the basal ganglia provide an essential element for the performance of the large variety of voluntary and semiautomatic actions required for the full repertoire of human natural mobility.

In reality, they usually occur together and have many points of clinical similarity, and there are reasons to believe that they have a common anatomic and physiologic basis. The normal triphasic sequence of agonist-antagonist-agonist is intact but lacks the energy (number of activated motor units) to complete the movement. Several triphasic sequences are then needed, which slows the movement. That cells in the basal ganglia participate in the initiation of movement is also evident from the fact that the firing rates in these cells increase before movement is detected clinically.

In terms of pathologic anatomy and physiology, bradykinesthesia may be caused by any process or drug that interrupts some component of the cortico-striato-pallido-thalamic circuit. Rigidity (discussed further on) is frequently combined. Clinical examples include reduced dopaminergic input from the substantia nigra to the striatum, as in Parkinson disease; dopamine receptor blockade by neuroleptic drugs; extensive degeneration of striatal neurons, as in striatonginal degeneration and the rigid form of Huntington chorea; and destruction of the medial pallidum, as in Wilson and Hallervorden-Spatz disease.

A number of other disorders of voluntary movement may also be observed in patients with diseases of the basal ganglia. A persistent voluntary contraction of hand muscles, as in holding a pencil, may fail to be inhibited, so that there is interference with the next willed movement. This has been termed “tonic innervation” and may be brought out by asking the patient to repetitively open and close a fist. Attempts to perform an alternating sequence of movements may be blocked at one point with a tendency for the voluntary movement to adopt the frequency of the coexistent tremor. Muscles fatigue more readily on repeated activity. In still other cases, performance of a simple movement (e.g., touching finger to nose, forcefully striking an object with the fisted hand) is rendered impossible by the simultaneous contraction of agonist and antagonist muscles not only of the arm and hand but also of the neck, trunk, and even the legs (“intentional spasm”).

Disorders of Postural Fixation, Equilibrium, and Righting

These deficits are also demonstrated most clearly in the parkinsonian patient. The prevailing posture is one of involuntary flexion of the trunk and limbs and of the neck. The inability of the patient to make appropriate adjustments to tilting or falling and the inability to move from the reclining to the standing position are closely related phenomena. A gentle push on the patient's sternum or back may start a series of small corrective steps that the patient cannot control (festination). These postural abnormalities are not the result of weakness or of defects in proprioceptive, labyrinthine, or visual function, the principal forces that control the normal posture of the head and trunk. Anticipatory and compensatory righting reflexes are also manifestly impaired—early in progressive supranuclear palsy and later in Parkinson disease. These postural abnormalities have been compared to the flexed postures of the head and neck and disorders of equilibrium and righting that have been produced in monkeys by the ablation of the globus pallidus bilaterally (Richter).

A point of interest is whether akinesthesia and disorders of postural fixation are invariable negative manifestations of extrapyramidal diseases and whether, without them, there could be any secondary release effects such as dystonia, choreoathetosis, and rigidity. The question has no clear answer. Akinetia and abnormalities of posture are invariable features of both Parkinson and Wilson diseases; they seem to be present also in Huntington chorea and in the double athetosis of cerebral palsy, but one cannot be sure of their existence in hemiballismus.

Rigidity

In the form of altered muscle tone known as rigidity, the muscles are continuously or intermittently firm and tense. Although brief periods of electromyographic silence can be obtained in selected muscles by persistent attempts to relax the limb, there is obviously a low threshold for involuntary sustained muscle contraction, and this is present during most of the waking state, even when the patient appears quiet and relaxed. In contrast to spasticity, the increased resistance on passive movement that characterizes rigidity is not preceded by an initial “free interval” and has an even or uniform quality throughout the range of movement of the limb, like that experienced in bending a lead pipe or pulling a strand of toffee. When released, the limb does not resume its original position, as happens in spasticity.

Rigidity usually involves all muscle groups, both flexor and extensor, but it tends to be more prominent in muscles that maintain a flexed posture, i.e., in the flexor muscles of trunk and limbs. It appears to be somewhat greater in the large muscle groups, but this may be merely a matter of muscle mass. Certainly the small muscles of the face and tongue and even those of the larynx are often affected. The tendon reflexes are not enhanced. Nevertheless, like spasticity, rigidity represents a lower threshold for synaptic excitation of spinal and cranial motor neurons. It can be abolished by the extradural or subarachnoid injection of local anesthesia, and, as claimed by Foerster many years ago, by posterior root section, presumably by interrupting the afferent fibers of the gamma loop. Recording from muscle spindles has not confirmed this spindle overdrive, and although the phasic myotatic (tendon) reflexes are not increased, the tonic stretch reflexes are. In the electromyographic tracing, motor-unit activity is more continuous in rigidity than in spasticity, persisting even after apparent relaxation.

A special type of rigidity, first noted by Negro in 1901, is the cogwheel phenomenon. When the hypertonic muscle is passively stretched, e.g., when the hand is dorsiflexed, one encounters a rhythmically interrupted, ratchet-like resistance. Most likely this phenomenon represents an associated static or action tremor that is masked by rigidity but emerges freely during manipulation.

Rigidity is a prominent feature of many basal ganglionic diseases such as Parkinson disease (late stages), Wilson disease, striatongrial degeneration (multiple system atrophy), progressive supranuclear palsy, dystonia musculorum deformans (all discussed in Chap. 39), intoxication with neuroleptic drugs, and calcinosis of the basal ganglia. The rigidity is characteristically variable in degree, and in some patients with involuntary movements, particularly in those with chorea or dystonia, the limbs may be intermittently or persistently hypotonic.

A distinctive type of variable resistance to passive movement is that in which the patient seems unable to relax a group of muscles on request. When the limb muscles are passively stretched, the patient appears to actively resist the movement (gegenhalten, paratonia, or oppositional resistance). Natural relaxation requires concentration on the part of the patient. If there is inattentiveness—as happens with diseases of the frontal lobes, dementia, or other confusional states—this type of resistance is absent. When the patient is asked to repetitively open and close a fist, attempts to perform an alternating sequence of movements may be blocked at one point with a tendency for the voluntary movement to adopt the frequency of the coexistent tremor. Muscles fatigue more readily on repeated activity. In still other cases, performance of a simple movement (e.g., touching finger to nose, forcefully striking an object with the fisted hand) is rendered impossible by the simultaneous contraction of agonist and antagonist muscles not only of the arm and hand but also of the neck, trunk, and even the legs (“intentional spasm”).

Involuntary Movements (Chorea, Athetosis, Ballismus, Dystonia)

In deference to usual practice, these symptoms are described separately, as though each represented a discrete clinical phenomenon readily distinguishable from the others. In reality, they usually occur together and have many points of clinical similarity, and there are reasons to believe that they have a common anatomic and physiologic basis. One must be mindful that chorea, athetosis, and dystonia are symptoms and are not to be equated with disease entities that happen to incorporate one of these terms in their names (e.g., Huntington chorea, dystonia musculorum deformans). Here the discussion is limited to the symptoms. The diseases of which these symptoms are a part are considered elsewhere, mainly in Chap. 39.

Chorea

Derived from the Greek word meaning “dance,” chorea refers to involuntary arrhythmic movements of a forcible, rapid, jerky type. These movements may be
simple or quite elaborate and of variable distribution. Although the movements are purposeless, the patient may incorporate them into a deliberate act, as if to make them less noticeable. When superimposed on voluntary actions, they may assume an exaggerated and bizarre character. Grimacing and peculiar respiratory sounds may be other expressions of the movement disorder. Usually the movements are discrete, but if they are very numerous, they become confluent and then resemble athetosis, as described below. In moments when the involuntary movements are absent or briefly held in abeyance, volitional movements of normal strength are possible, since there is no paralysis, but these movements tend also to be excessively quick and poorly sustained. The limbs are often slack or hypotonic and, because of this, the knee jerks tend to be pendular; with the patient sitting on the edge of the examining table and the foot free of the floor, the leg swings back and forth four or five times in response to a tap on the patellar tendon, rather than once or twice, as it does normally. A choreic movement may be superimposed on the reflex movement, checking it in flight, so to speak, and giving rise to the “hung-up” reflex.

The hypotonia in chorea as well as the pendular reflexes may suggest a disturbance of cerebellar function. Lacking, however, are “intention” tremor and true incoordination or ataxia. In patients with hypernatemia and other metabolic disorders, it may be necessary to distinguish chorea from myoclonus. Chorea differs from myoclonus mainly with respect to the speed of the movements; the myoclonic jerk is much faster and may involve single muscles or part of a muscle as well as groups of muscles.

Diseases that are characterized by chorea are listed in Table 4-3. Chorea is a major feature of Huntington disease (hereditary or chronic chorea), in which the movements tend to be choreoathetotic. Also, there is an inherited form of chorea typically without dementia. Not infrequently, chorea has its onset in late life without other identifying features of Huntington disease. It is referred to as senile chorea, a term that is hardly helpful in understanding the process. Its relation to Huntington chorea is unsettled. It may be a delayed form of the disease, and a few such patients we have seen have had atypical depressions or mild psychosis; but others remain for a decade with only chorea. A number of far less common degenerative conditions are associated with chorea, among them dentatorubropallidoluysian atrophy. These are discussed in Chapter 39.

The use of neuroleptic drugs may provoke choreoathetosis, at least in part. For this reason, neuroleptic drugs have been used in the treatment of chorea in some cases, with varying degrees of success.

The term stems from a Greek word meaning “unfixed” or “changeable.” The condition is characterized by inability to sustain the fingers and toes, tongue, or any other part of the body in one position. The maintained posture is interrupted by relatively slow, sinuous, purposeless movements that have a tendency to flow into one another. As a rule, the abnormal movements are most pronounced in the digits and hands, face, tongue, and throat, but no group of muscles is spared. One can detect as basic patterns of movement an alternation between extension-pronation and flexion-supination of the arm and between flexion and extension of the fingers, the flexed and adducted thumb being trapped by the extended fingers as the hand closes. Other characteristic movements are vicious-inversion of the foot, retraction and pursing of the lips, twisting of the neck and torso, and alternate wrinkling and relaxation of the forehead or closing of the eyelids. The movements appear to be slower than those of chorea, but all gradations between the two are seen; in some cases, it is impossible to distinguish between them, hence the term choreoathetosis. Discrete voluntary movements of the hand are executed more slowly than normal, and attempts to perform them may result in a cocontraction of antagonistic muscles and a spread (overflow) of contraction to muscles not normally required in the movement (“intention spasm”). The overflow appears related to a failure of the striatum to suppress the activity of unwanted muscle groups. Like polymyoclonus, some forms of athetosis occur only during the performance of precise movements (intention action athetosis). In other forms, the spams appear to occur spontaneously, i.e., they are involuntary and, if persistent, give rise to more or less fixed dystonic postures. The dystonia may be so severe that it prevents the patient from opening the eyes (supranuclear ophthalmoplegia).

Athetosis may affect all four limbs or may be unilateral, especially in children who have suffered a hemiplegia at some previous date (posthemiplegic athetosis). Many athetotic children have degrees of rigidity and motor deficit due to associated corticospinal tract disease, and these may account for the slower quality of athetosis compared to chorea. In other patients with generalized choreoathetosis, as pointed out above, the limbs may be intermittently hypotonic.

The combination of athetosis and chorea of all four limbs is a cardinal feature of Huntington disease and of a state known as double athetosis, which begins in childhood. Athetosis appearing in the first years of life is usually the result of a congenital or postnatal condition such as hypoxia or rarely kernicterus. Postmortem examinations in some of the cases have disclosed a peculiar pathologic change of probable hypoxic etiology, a status marmoratus, in the striatum (Chapter 38); in other cases, of probable kernicteric etiology, there has been a loss of nerve cells and medullated fibers—a status dysmyelina—in the same regions. In adults, athetosis may occur as an episodic or persistent disorder in hepatic encephalopathy, as a manifestation of chronic intoxication with phenothiazines or haloperidol, and as a feature of certain degenerative diseases, most notably Huntington chorea but also Wilson disease, Hallervorden-Spatz disease, Leigh disease, and other mitochondrial disease variants; less frequently, athetosis may be seen with Niemann-Pick (type C) disease, Kufs disease, neuroacanthocytosis, and ataxia telangiectasia. It may also occur as an effect of excessive L-dopa in the treatment of Parkinson disease, in which case it appears to be due to a decrease in the activity of the subthalamic nucleus and the medial segment of the globus pallidus (Mitchell et al). Athetosis, usually in combination with chorea, may occur rarely in patients with AIDS and in those taking anticonvulsants. Localized forms of athetosis may occasionally follow vascular lesions of the lenticular nucleus or thalamus.

Typical choreic movements are the dominant feature of Sydenham chorea, and of the variety of that disease associated with pregnancy (chorea gravidarum), disorders that are related in some way to streptococcal infection. Strial abnormalities have been demonstrated by MRI in some cases, usually transient but rarely persistent (Emery and Vieco). Also, in recent years it has been suggested that the spectrum of poststreptococcal disorders be extended to tic and obsessive-compulsive behavior in children. In these cases the neurologic problems arise suddenly, subside, and return with future streptococcal infections, as discussed in Chapter 6.

Anoikis is a term used to describe the loss of adhesion of cells to other cells or to extracellular matrix. It is a fundamental process in cell biology and has been implicated in various diseases, including cancer, wound healing, and embryonic development.
(Dooling and Adams).

**Ballismus** The term ballismus designates an uncontrollable, poorly patterned flinging movement of an entire limb. As remarked earlier, it is closely related to chorea and athetosis, indicated by the frequent coexistence of these movement abnormalities and the tendency for ballismus to devolve into a less obtrusive choreoathetosis of the distal parts of the affected limb. Ballistic movements are usually unilateral (hemiballismus) and the result of an acute lesion of the contralateral subthalamic nucleus or immediately surrounding structures (infarction or hemorrhage, rarely a demyelinating or other lesion). Rarely, a transitory form is linked to a subdural hematoma or thalamic or parietal lesion. The flinging movements may be almost continuous or intermittent, occurring several times a minute, and of such dramatic appearance that it is not unusual for an uninitiated physician to regard them as hysterical in nature.

Bilateral ballismus is very infrequent and usually asymmetrical; here a metabolic disturbance, particularly nonketotic hyperosmolar coma, is the usual cause.

When ballismus persists for weeks on end, as it often did before effective treatment became available, the continuous forceful movements can result in exhaustion and even death. In most cases, medication with haloperidol or phenothiazine suppresses the violent movements. In extreme cases stereotactic lesions placed in the ventrolateral thalamus and zona incerta have proved effective (Krauss and Mundinger).

**Dystonia (Torsion Spasm)** (See also Chap. 6 on focal dystonias.) Dystonia is a persistent attitude or posture in one or the other of the extremes of athetoid movement, produced by cocontraction of agonist and antagonist muscles in one region of the body. It may take the form of an overextension or overflexion of the hand, inversion of the foot, lateral flexion or retroflexion of the head, torsion of the spine with arching and twisting of the back, forceful closure of the eyes, or a fixed grimace (Fig. 4-5). Defined in this way, dystonia is closely allied to athetosis, differing only in the persistence or fixity of the postural abnormality and the disproportionate involvement of the large axial muscles (those of the trunk and limb girdles). The term dystonia is now generally used in this way, but it has been given other meanings as well. Wilson referred to any variability in muscle tone as dystonia. This term has also been applied to fixed abnormalities of posture that may be the end result of certain diseases of the motor system; thus Denny-Brown speaks of "hemiplegic dystonia" and the "flexion dystonia of parkinsonism." If the term is to be used in the latter sense, it would be better to speak of the persistent but reversible athetotic movements of the limbs and trunk as "torsion spasms" or "phasic dystonia," in contrast to "fixed dystonia."

Dystonia, like athetosis, may vary considerably in severity and may show striking fluctuations in individual patients. In its early stages it may be interpreted as an annoying mannerism or hystoria, and only later—in the face of persisting postural abnormality, lack of the usual psychologic features of hysteria, and the emerging character of the illness—is the correct diagnosis made. Dystonia may be limited to the facial, cervical, or trunk muscles or to those of one limb and may cease when the body is in repose. Severe instances result in grotesque movements and distorted positions of the body; sometimes the whole musculature seems to be thrown into spasm by an effort to move an arm or an speak.

Generalized dystonia is seen in its most pronounced form as an uncommon heritable disease, dystonia musculorum deformans, in which case it is associated with a specific mutation on chromosome 9, termed DYT1 (page 1141). It was in relation to this disease that Oppenheim and Vogt, in 1911, introduced the term dystonia. Widespread torsion spasm may also be a prominent feature of certain other heredodegenerative disorders, such as familial striatal nerosis with affection of the optic nerves and other parts of the nervous system (Mansden et al, Novotny et al). Nygaard and colleagues have described yet another familial form in which one of several types of dystonia is coupled with elements of parkinsonism and is responsive to minute doses of L-dopa, as described below (Segawa disease).

Restricted or fragmentary forms of dystonia (dyskinesias) are the types most commonly encountered in clinical practice. Characteristically the spasms in-volve only the oriblocals or and face or mandibular muscles (blepharospasm-ornamental dystonia), tongue, cervical muscles (spasmotic torticolis), hand (writer's cramp), or foot. These are described more fully in Chap. 6 as well as in Chap. 39. Dystonia also occurs as a manifestation of many other diseases ("symptomatic dystonias"). The latter include double athetosis due to hypoxic damage to the brain, kernicterus, Hallervorden-Spatz disease, Huntington disease, Wilson hepatolenticular degeneration, Parkinson disease, lysosomal storage diseases, striato-pallidodentatal calcification (due sometimes to hypoparathyroidism), thyroid disease, and chronic or previous exposure to phenothiazines.

The most frequent cause of acute dystonic reactions is drug intoxication—with phenothiazines, butyrophenones, or metoclopramide and even with the newer neuroleptic agents such as olanzapine, which have the relative advantage of producing these side effects far less frequently than the other drugs mentioned above. These reactions respond to some extent to diphenhydramine or benztropine given two or three times in 24 to 48 h. Also, L-dopa, calcium channel blockers, and a number of anticonvulsants and anxiolytics are among a long list of other medications that may on occasion induce dystonia, the various causes of which are listed in Table 4-4.

All manner of drugs have been used in the treatment of chronic dystonia, with a notable lack of success. However, Fahn has reported beneficial effects (more so in children than in adults) with the anticholinergic agents trihexyphenidyl (Artane) and ethopropazine (Parsidil) given in massive doses—which are achieved by increasing the dosage very gradually. A distinct subset of dystonic patients (described by Nygaard et al) have responded to extremely small doses of L-dopa. The
**Chapter References**

The cerebellum, principally a motor organ, is responsible for the regulation of muscular tone; the coordination of movements, especially skilled voluntary ones; and the control of posture and gait. The mechanisms by which these functions are accomplished have been the subject of intense investigation by anatomists and physiologists. Their studies have yielded a mass of data, testimony to the complexity of the organization of the cerebellum and its afferent and efferent connections. A coherent picture of cerebellar function is now emerging, although it is not yet possible, with a few notable exceptions, to relate each of the symptoms of cerebellar disease to a derangement of a discrete anatomic or functional unit of the cerebellum.

Knowledge of cerebellar function has been derived mainly from the study of natural and experimental ablative lesions and to a lesser extent from stimulation of the cerebellum, which produces little in the way of movement or alterations of induced movement. Notably, none of the motor activities of the cerebellum reach conscious kinesthetic perception; its main role is to assist in the initiation and modulation of willed movements that are generated in the cerebral hemispheres. The following outline of cerebellar structure and function has of necessity been simplified; a full account can be found in the writings of Jansen and Brodal, Gilman, Ito, and Thach and colleagues, listed at the end of this chapter.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

The classic studies of the comparative anatomy and fiber connections of the cerebellum have led to its subdivision into three parts (Fig. 5-1): (1) The flocculonodular lobe, located inferiorly, which is phylogenetically the oldest portion of the cerebellum and is much the same in all animals (hence archicerebellum). It is separated from the main mass of the cerebellum by the posterolateral fissure (Fig. 5-2), and the nodulus is the portion of the corpus cerebelli rostral to the primary fissure. In lower animals, the anterior lobe constitutes most of the cerebellum, but in humans it is relatively small, consisting of the anterosuperior vermis and the contiguous paravermian cortex. (2) The posterior lobe, or neocerebellum, consisting of the middle divisions of the vermis and their large lateral extensions. The major portions of the human cerebellar hemispheres fall into this subdivision.

Figure 5-1 Diagram of the cerebellum, illustrating the major fissures, lobes, and lobules and the major phylogenetic divisions (left).

This anatomic subdivision corresponds roughly with the distribution of cerebellar function, based on the arrangement of its afferent fiber connections. The flocculonodular lobe receives special proprioceptive impulses from the vestibular nuclei and is therefore also referred to as the vestibulocerebellum; it is concerned essentially with equilibrium. The anterior vermis and part of the posterior vermis are referred to as the spinocerebellum, since projections to these parts derive to a large extent from the proprioceptors of muscles and tendons in the limbs and are conveyed to the cerebellum in the dorsal spinocerebellar tract (from the lower limbs) and the ventral spinocerebellar tract (upper limbs). The main influence of the spinocerebellum appears to be on posture and muscle tone. The neocerebellum derives its afferent fibers from the cerebral cortex via the pontine nuclei and brachium pontis, hence the designation pontocerebellum; this portion of the cerebellum is concerned primarily with the coordination of skilled movements that are initiated at a cerebral cortical level. These divisions are necessarily incomplete because it is now appreciated that certain portions of the cerebellar hemispheres are involved to some extent in tactual, visual, auditory, and even visceral functions.

On the basis of ablation experiments in animals, three characteristic clinical syndromes, corresponding to these major divisions of the cerebellum, have been delineated. Lesions of the nodulus and flocculus have been associated with a disturbance of equilibrium and frequently with a positional nystagmus; individual movements of the limbs are not affected. Anterior lobe ablation in primates results in increased shortening and lengthening reactions, somewhat increased tendon reflexes, and an exaggeration of the postural reflexes, particularly the "positive supporting reflex," which consists of an extension of the limb in response to light pressure on the foot pad. Ablation of a cerebellar hemisphere in cats and dogs yields inconsistent results, but in monkeys it causes hypotonia and clumsiness of the ipsilateral limbs; if the dentate nucleus is included in the hemispheric ablation, these abnormalities are more enduring and the limbs also show an ataxic or "intention" tremor.

As one might expect, cerebellar function and structure are hardly as simple or precise as the preceding outline might suggest. The seminal studies of Chambers and Sprague and of Jansen and Brodal indicate that in respect to both its afferent and efferent projections, the cerebellum is organized into longitudinal (sagittal) rather than transverse zones. There are three longitudinal zones—the vermian, paravermian or intermediate, and lateral—and there seems to be considerable overlapping from one to another. Chambers and Sprague, on the basis of their investigations in cats, concluded that the vermian zone coordinates movements of the eyes and balance, the paravermian zone mediates the gravity and movement of the head in space. Interruption of vestibulocerebellar connections disturbs the posture, tone, locomotion, and equilibrium of the entire body and results in instability of ocular fixation and nystagmus. The intermediate zone, which receives both peripheral and central projections (from motor cortex), influences postural tone and also individual movements of the ipsilateral limbs. The lateral zone is concerned mainly with coordination of movements of the ipsilateral limbs but is involved in other functions as well.

The effarent fibers of the cerebellar cortex, which consist essentially of the axons of Purkinje cells, project onto the deep cerebellar nuclei. The projections from Purkinje cells are inhibitory, and those from the nuclei are excitatory. According to the scheme of Jansen and Brodal, cells of the vermis project mainly to the fastigial nucleus; those of the intermediate zone, to the globose and emboliform nuclei (represented by the interpositus nucleus in animals); and those of the lateral zone, to the dentate nucleus. The deep cerebellar nuclei, in turn, project to the cerebral cortex and certain brainstem nuclei via two main pathways: fibers from the dentate, emboliform, and globose nuclei form the superior cerebellar peduncle, enter the upper pontine tegmentum as the brachium conjunctivum, decussate completely at the level of the inferior colliculus, and ascend to the ventrolateral nucleus of the thalamus and, to a lesser extent, to the intralaminar thalamic nuclei (Fig. 5-2). Some of the ascending fibers, soon after their decussation, synapse in the red nucleus, but most of them traverse this nucleus without synapsing. Ventral thalamic nuclear groups that receive these ascending effenter fibers project to the supplementary motor cortex of that side. Since the pathway from the cerebellar nuclei to the thalamus and then on to the motor cortex is crossed and the connection from the motor cortex through the corticospinal is again crossed, the effects of a lesion in one cerebellar hemisphere are manifest on the ipsilateral side of the body (see also page 69).
A small group of fibers of the superior cerebellar peduncle, following their decussation, descend in the ventromedial tegmentum of the brainstem and terminate in the reticulotegmental and paramedian reticular nuclei of thepons and inferior olivary nuclei of the medulla. These nuclei, in turn, project via the inferior cerebellar peduncle to the cerebellum, mainly the anterior lobe, thus completing a cerebellar-reticular-cerebellar feedback system (Mollaret triangle, page 106) (Fig. 5-3). The fastigial nucleus sends fibers to the vestibular nuclei of both sides and, to a lesser extent, to other nuclei of the reticular formation of thepons and medulla. There are also direct fiber connections with the alpha and gamma motor neurons of thespinal cord. The inferior olivary nuclei project via therestiform body (inferior cerebellar peduncle) to thecontralateral cerebellar cortex and corresponding parts of the deep cerebellar nuclei. Thus the cerebellum influences motor activity through its connections with the motor cortex and brainstem nuclei and their descending motor pathways. The integration at the thalamic level of basal ganglionic influences with those of the cerebellum is detailed in Chap. 4.

The disturbances of movement and posture that result from lesions of the human cerebellum were first cogently analyzed by two eminent neurologists, Joseph Babinski and Gordon Holmes. For Babinski, the essential function of the cerebellum was the orchestration of muscle synergies in the performance of voluntary movement. A loss or impairment of this function—i.e., asynergia or dyssynergia—resulted in irregularity or fragmentation of the normal motor sequences involved in any given act. This deficit, most apparent in the execution of rapid movements, was referred to by Babinski as dys- or adiadochokinesis. He also pointed out that this was accompanied by certain maladjustments of stance and by catatlypsy (perseveration of a posture), features that are not as widely appreciated nowadays.

The abnormalities observed by Holmes were in the acceleration and deceleration of movement and, in general, in the rate, range, and force of movement, resulting in an undershooting or overshooting of the target. He used the term decomposition of movements to describe the fragmentation of a smooth movement into a series of irregular, jerky components. In Holmes’s view, these abnormalities were largely attributable to an underlying hypotonia. The terminal ("intention") tremor, for example, and the inability to check the displacement of an outstretched limb were attributed to this defect (see further on).

The hypotheses of both Babinski and Holmes have been sustained by modern physiologic studies. In their analysis of rapid (ballistic) projected movements, Hallett and colleagues have demonstrated that the cerebellum is essential for the proper timing of agonist and antagonist muscle action in the course of a coordinated act. With cerebellar lesions, there is a prolongation of the interval between the commanded act and the onset of movement. Also, there is a derangement of the triphasic agonist-antagonist-agonist motor sequence, referred to in Chap. 3 and Chap. 4: the agonist burst may be too long or too short, or it may continue into the antagonist burst, resulting in excessive agonist-antagonist cocontraction at the onset of movement. These findings could explain what has variously been described as asynergia, decomposition of movement, and dysmetria, as alluded to above. Diener and Dichgans confirmed these fundamental abnormalities in the timing and amplitude of reciprocal inhibition and of cocontraction of agonist-antagonist muscles and remarked that these were particularly evident in multijoint movements. The observations of Upgava and coworkers are pertinent in this regard; they found that contraction of hand muscles evoked by stimulation of the motor cortex was reduced when preceded (by 5 to 7 ms) by magnetic stimulation over the cerebellum.

Role of the Deep Cerebellar Nuclei The physiologic studies of Allen and Tsukahara and those of Thach and his colleagues have greatly increased our knowledge of the role of the deep cerebellar nuclei. These investigators studied the effects of cooling the deep nuclei during a projected movement in the awake macaque monkey. Their observations, coupled with established anatomic data, permit the following conclusions. The dentate nucleus receives information from the premotor and supplementary motor cortices via the pontocerebellar system and helps to initiate volitional movements. The latter are accomplished via efferent projections from the dentate nucleus to the ventrolateral thalamus and motor cortex. The dentatal neurons were shown to fire just before the onset of volitional movements, and inactivation of the dentatal neurons delayed the initiation of such movements. The interpositus nucleus also receives cerebrocortical projections via the pontocerebellar system; in addition, it receives spinocerebellar projections via the intermediate zone of the cerebellar cortex. The latter projections convey information from Golgi tendon organs, muscle spindles, cutaneous afferents, and spinal cord interneurons involved in movement. The interpositus nucleus fires in relation to a movement once it has started. Also, the prepositus nucleus appears to be responsible for making volitional oscillations (alternating movements). Its cells fire in tandem with these actions and their regularity and amplitude are impaired when these cells are inactivated. In addition, Thach has pointed out that the nucleus interposedromally dampens physiologic tremor and has suggested that this may play a part in the genesis of so-called intention tremor. The fastigial nucleus controls antigravity and other muscle synergies in standing and walking; ablation of this nucleus greatly impairs these motor activities.

Neuronal Organization of the Cerebellum Coordinated and fluid movements result from a neuronal organization in the cerebellum, which permits a computational comparison between desired and actual movements while the latter are being carried out. An enormous number of neurons are committed to these tasks as attested by the fact that the cerebellum contributes only 10 percent to the total weight and volume of the brain, but contains half of the brain’s neurons. Also, it has been estimated that there are forty times moreafferent axons than efferent axons in the various cerebellar pathways, a reflection of the enormous amount of information that is required for the control of motor function.

The cerebellar cortex is a stereotyped three-layered structure containing five types of neurons (Fig. 5-4 and Fig. 5-5). In its relatively regular geometry it is similar to thecolumnar architecture of the cerebral cortex (page 467), but it differs in the greater degree of intracortical feedback between neurons and the convergent nature of input fibers. The outermost “molecular” layer of the cerebellum contains two types of inhibitory neurons, thestellate and the basket cells. They are interspersed among the dendrites of the Purkinje cells, the somates of which lie in the underlying layer. The Purkinje cell axons constitute the main output of the cerebellum, which is directed at the deep cerebellar and the vestibular nuclei. Purkinje cells are likewise entirely inhibitory and utilize the neurotransmitter GABA. The innermost “granular” layer contains an enormous number of densely packed granule cells and a few larger Golgi interneurons. Axons of granule cells travel long distances as “parallel fibers,” which are oriented along the long axis of the folia and form excitatory synapses with Purkinje cells. Each Purkinje cell is influenced by as many as a million
granule cells to produce a single "simple spike."

**Figure 5-4** Anatomic organization of the cerebellar cortex in a longitudinal and transverse section of a folium. Show are the relationships between (a) climbing fibers and Purkinje cells, (b) mossy fibers and both granule cells and Golgi cells, and (c) the parallel fibers that course longitudinally and connect these three main cell types. (From Kandel, Schwartz, and Jessel, with permission.)

The predominant afferent input to the cerebellum is via the mossy fibers, which excite Golgi and granule neurons through special synapses termed cerebellar glomeruli. The other main afferent input is via the climbing fibers, which originate in the inferior olives and communicate somatosensory, visual, and cerebral cortical signals (Fig. 5-4 and Fig. 5-5). The climbing fibers, so named because of their vine-like configuration around Purkinje cells and their axons, preserve a topographic arrangement from olivary neuronal groups; a similar topographic arrangement is maintained in the Purkinje cell projections. The climbing fibers have specific excitatory effects on Purkinje cells that result in prolonged "complex spike" depolarizations. The firing of stellate and basket cells is facilitated by the same parallel fibers that excite Purkinje cells, and these smaller cells in turn inhibit the Purkinje cells. These reciprocal relationships form the feedback loops that permit the exquisitely delicate inhibitory smoothing of limb movements that are lost when the organ is damaged.

**Pharmacologic Considerations**

A number of pharmacologic and biochemical considerations are of interest in this context. Four of the five cell types of the cerebellar cortex (Purkinje, stellate, basket, Golgi) are inhibitory; the granule cells are an exception and are excitatory. Afferent fibers to the cerebellum are of three types, two of which have been mentioned above: (1) Mossy fibers, which are the axons of the spino- and pontocerebellar tracts and of the pontine, vestibular, and reticular nuclei; they enter through all three cerebellar peduncles and project to the granule cell layer. (2) Climbing fibers, which are the axons of cells in the inferior olivary nucleus and project to the Purkinje cells of the opposite cerebellar hemisphere. The mossy fibers utilize aspartate, but the neuropeptide of the climbing fibers is unknown. Noradrenaline is the transmitter of the afferent fibers from the locus ceruleus. (3) Aminergic fibers, which project through the superior cerebellar peduncle and terminate on the Purkinje and granule cells in all parts of the cerebellar cortex. They are of two types: dopaminergic fibers, which arise in the ventral mesencephalic tegmentum and project to the interpositus and dentate nuclei; and to the granule and Purkinje cells throughout the cortex, and serotonergic neurons, which are located in the raphe nuclei of the brainstem and project diffusely to the granule cell and molecular layer. The granule cell axons elaborate the excitatory transmitter glutamate. All the inhibitory cerebellar cortical neurons appear to utilize gamma-aminobutyric acid (GABA). The neurotransmitters of the deep nuclei have not been fully elucidated.

**Clinical Features of Cerebellar Disease**

The symptoms produced in animals by ablation of discrete anatomic or functional zones of the cerebellum bear only an imperfect relationship to the symptoms of cerebellar disease in humans. This is understandable for several reasons. Most of the lesions that occur in humans do not respect the boundaries established by experimental anatomists. Even with lesions that are more or less confined to discrete functional zones (e.g., floculonodular lobe, anterior lobe), it is difficult to identify the resultant clinical syndromes with those produced by ablation of analogous zones in cats, dogs, and even monkeys, indicating that the functional organization of these parts varies from species to species.

Our own observations affirm what was stated above—that lesions of the cerebellum in humans give rise to the following abnormalities: (1) incoordination (ataxia) of volitional movement; (2) a characteristic tremor ("intention" or ataxic tremor), described in detail in Chap. 6; (3) disorders of equilibrium and gait; and (4) diminished muscle tone, particularly with acute lesions.

In general, extensive lesions of one cerebellar hemisphere, especially of the anterior lobe, cause hypotonia, postural abnormalities, ataxia, and perhaps mild weakness of the ipsilateral arm and leg. Lesions of the deep nuclei and cerebellar peduncles have the same effects as extensive hemispheric lesions. If the lesion involves a limited portion of the cerebellar cortex and subcortical white matter, there may be surprisingly little disturbance of function, or the abnormality may be greatly attenuated with the passage of time. For example, a congenital developmental defect or an early life sclerotic cortical atrophy of half of the cerebellum may produce no clinical abnormalities. Lesions involving the superior cerebellar peduncle or the dentate nucleus cause the most severe and enduring cerebellar symptoms, manifest mostly in the ipsilateral limbs. Disorders of stance and gait depend more upon vermicular than upon hemispheric or peduncular involvement.

**Incoordination**

The most prominent manifestations of cerebellar disease, namely, the abnormalities of in-tended (volitional) movement, are classified under the general heading of cerebellar incoordination or ataxia. Following Babinski, the terms dysynergia, dysmetria, and dystadiokinesis came into common usage to describe cerebellar abnormalities of movement. Holmes's characterization of these disturbances as abnormalities in the rate, range, and force of movement is at once less confusing and more accurate, as becomes apparent from an analysis of even simple movements—e.g., those elicited by finger-to-nose or by toe-to-finger testing, running the heel down the opposite shin, or tracing a square in the air with a hand or foot. In performing these tests, the patient should be asked to move the limb to the target or trace a figure accurately and rapidly.

The speed of initiating movement is slowed somewhat in cerebellar disease. In a detailed electrophysiologic analysis of this defect, Hallett and colleagues noted, in both slow and fast movements, that the initial agonist burst was prolonged and the peak force of the agonist contraction was reduced. Also, there is irregularity and slowing of the movement itself, in both acceleration and deceleration. These abnormalities are particularly prominent as the finger or toe approaches its target. Normally, deceleration of movement is smooth and accurate, even if sharp changes in direction are demanded by a moving target. With cerebellar disease, the velocity and force of the movement are not checked in the normal manner. The excursion of the limb may be arrested prematurely, and the target is then reached by a series of jerky movements. Or the limb overshoots the mark (hypermetria), due to delayed activation and diminished contraction of antagonist muscles; then the error...
Holmes believed that hypotonia was a fundamental defect in cerebellar disease, accounting not only for the defects in postural fixation (see below) but also for certain extension of a limb. It appears to be related to a depression of gamma and alpha motor neuron activity, as discussed in Hypotonia observations is illustrated in of the motor effects produced by stimulation of specific parts of the cerebellar cortex. The topographic representation of body parts based on these experimental relationships pertain in patients with familial cerebellar cortical degeneration of the “Holmes type” (page 1148). In both the alcoholic and familial degenerative cases, and its connections with the brainstem are probably involved. Holmes called it rubral tremor, and although the lower part of the red nucleus may be the site of the lesion, the nucleus itself is probably not involved in this type of tremor. Probably the tremor is due to interruption of the fibers of the superior cerebellar peduncle, which traverse the pons. Also, with certain sustained postures (e.g., with arms extended and hands on knees) the patient with corticobulbar disease may develop a rhythmic oscillation of the fingers, having much the same tempo as a parkinsonian tremor. A rhythmic tremor of the head or upper trunk (3 to 4 per second), mainly in the anteroposterior plane, often accompanies midline cerebellar disease. This is called titubation.

All of the foregoing defects in volitional movement are more noticeable in acts that require alternation or rapid change in direction of movement, such as pronation-supination of the forearm or successive touching of each fingertip to the thumb. The normal rhythm of these movements is interrupted by irregularities of force and speed. This is the abnormality that Babinski called adiadochokinesia. Even a simple movement may be fragmented (“decomposition” of movement), each component being affected with greater or lesser force than is required. These movements abnormalities together impart a highly characteristic clumsiness to the cerebellar syndromes, an appearance that is not simulated by the weak upper or lower motor neuron disorders or by diseases of the basal ganglia. As pointed out by Babinski, extension of the neck in the upright posture is not compensated for by flexion of the knees—another mark of asynergia.

Cerebellar lesions commonly give rise to a disorder of speech, which may take one of two forms, either a slow, slurred dysarthria, like that following interruption of the corticobulbar tracts, or a scanning dysarthria with variable intonation, so called because words are broken up into syllables, as when a line of poetry is scanned for meter. The latter disorder is uniquely cerebellar; in addition to its scanning quality, speech is slow, and each syllable, after an involuntary interruption, may be uttered with less force or more force (“explosive speech”) than is natural.

Myoclonic movements—i.e., brief (50- to 100-ms), random contractions of muscles or groups of muscles—are frequently combined with cerebellar ataxia. When multiple jerks mar a volitional movement, it may be mistaken for an ataxic tremor. (The same error may be caused by asterixis.) Ramsey Hunt described this symptom in connection with a rare heredodegenerative disease (see page 1150), but it has also been observed in neuronal storage diseases of various kinds. Action myoclonus may be the principal residual sign of hypoxic encephalopathy, as described on page 110, and it has been proposed that these conditions have a cerebellar origin. Myoclonus is described more fully in Chap. 6.

Ocular movement may be altered as a result of cerebellar disease, specifically if vestibular connections are involved. Patients with cerebellar lesions are unable to hold eccentric positions of gaze, resulting in the need to make rapid repetitive saccades to look eccentrically—i.e., gaze-paretic nystagmus. Conjugate voluntary gaze is then accomplished by a series of jerky movements (saccadic dysmetria). Smooth pursuit movements are slower than normal and require that the patient make catch-up saccades in an attempt to keep the moving target near the fovea. On attempted relaxation, the eyes may overshoot the target and then oscillate through several corrective saccades until precise fixation is attained. It will be recognized that these abnormalities, as well as those of speech, resemble the abnormalities of volitional movements of the limbs. Currently it is believed that nystagmus due to cerebellar disease depends upon lesions of the vestibulocerebellum (Thach and Montgomery). Skew deviation (vertical displacement of one eye), ocular flutter, and ocular myoclonus (opsoclonus) may also be related to cerebellar disease; these abnormalities and other effects of cerebellar ocular movement are discussed in Chap. 14.

Disorders of Equilibrium and Gait The patient with cerebellar disease has variable degrees of difficulty in standing and walking, as described more fully in Chap. 7. Standing with feet together may be impossible or maintained only briefly before pitching to one side or backward. Closing the eyes worsens this difficulty slightly, though the Romberg sign is absent. In walking, the steps are uneven and placement of the foot is misaligned, resulting in unexpected lurching.

The evidence that focculonodular lesions in humans cause a disturbance of equilibrium is not conclusive. It rests on the observation that with certain tumors of childhood, namely, medulloblastomas, there may be an unsteadiness of stance and gait but no tremor or incoordination of the limbs. Insofar as these tumors are thought to originate from cell rests in the posterior medullary velum, at the base of the nodulus, it has been inferred that the disturbance of equilibrium results from involvement of this portion of the cerebellum. However, the validity of this deduction remains to be proved. By the time such tumors are inspected at operation or autopsy, they have spread beyond the confines of the nodulus, and strict clinicopathologic correlations are not possible.

Data from patients in whom accurate clinic anatomic correlations can be made indicate that the disequilibrium syndrome, with normality of movements of the limbs, corresponds more closely with lesions of the anterior vermis than with lesions of the flocculus and nodulus. This conclusion is based on the study of a highly stereotyped form of cerebellar degeneration in alcoholics (Chap. 42). In such patients the cerebellar disturbance is often limited to one of stance and gait, in which case the pathologic changes are restricted to the anterior parts of the superior vermis. In more severely affected patients, in whom there is also incoordination of individual movements of the limbs, the changes are found to extend laterally from the vermis, involving the anterior portions of the anterior lobes (in patients with ataxia of the legs) and the more posterior portions of the anterior lobes (in patients whose arms are affected). In other diseases, involvement of the posterior vermis and its connections with the pontine and mesencephalic reticular formations have caused abnormalities of ocular movement (see Chap. 14). Similar clinicopathologic relationships pertain in patients with familial cerebellar cortical degeneration of the “Holmes type” (page 1148). In both the alcoholic and familial degenerative cases, despite a serious disturbance of stance and gait, the focculonodular lobe may be spared completely.

These clinicopathologic observations indicate that the cerebellar cortex, and the anterior lobe in particular, is organized somatotopically, as described earlier. This view has been amply confirmed experimentally by the mapping of evoked potentials from the cerebellar cortex, elicited by a variety of sensory stimuli, and an analysis of the motor effects produced by stimulation of specific parts of the cerebellar cortex. The topographic representation of body parts based on these experimental observations is illustrated in Fig. 5–6. The similarities between this scheme and the one derived from the study of human disease are at once apparent.

Figure 5–6 Somatotopic localization of motor and sensory function in the cerebellum. See text for explanation. (From Victor M et al: Arch Neurol 1:579, 1959.)

Hypotonia The term hypotonia refers to a decrease in the normal resistance that is offered by muscles to palpation or to passive manipulation (e.g., flexion and extension of a limb). It appears to be related to a depression of gamma and alpha motor neuron activity, as discussed in Chap. 3. Experimentally, in cats and monkeys, acute cerebellar lesions and hypotonia are associated with a depression of fusimotor efferent and spindle afferent activity; both static and dynamic afferents are depressed, but not the secondary afferents. With the passage of time, fusimotor activity is restored as hypotonia disappears (Gilman et al). As indicated earlier, Holmes believed that hypotonia was a fundamental defect in cerebellar disease, accounting not only for the defects in postural fixation (see below) but also for certain elements of ataxia and so-called intention tremor.
Hypotonia is much more apparent with acute than with chronic lesions and may be demonstrated in a number of ways. There may be mild flabbiness of the muscles on the affected side. Segments of the limbs may be displaced by the examiner through a wider range than normal. With recent, severe cerebellar lesions, there may be gross asymmetries of posture, so that the shoulder slumps or the body tilts to the ipsilateral side. A conventional test for hypotonia is to tap the wrists of the outstretched arms, in which case the affected limb (or both limbs in diffuse cerebellar disease) will be displaced through a wider range than normal and may oscillate; this is due to a failure of the hypertonic muscles to fixate the arm at the shoulder. When an affected limb is shaken, the flapping movements of the hand are of wider excursion than normal. If the patient places his elbows on the table with the arms flexed and the hands are allowed to hang limply, the hand of the hypertonic limb will sag more than that of the normal one. Forced flexion of a hypertonic arm at the elbow may obliterate the space between the volar aspect of the wrist and the deltoid. Babinski also was impressed with gross alterations of posture, apparently related to hypotonia. These alterations take the form of a passive extension of the neck and an involuntary bending of the knees, apparent when the patient is lifted from a bed or chair or upon first standing.

Failure to check a movement is a closely related phenomenon. Thus, after strongly flexing one arm against a resistance that is suddenly released, the patient may be unable to check the flexion movement, to the point where the arm may strike the face. This is due to a delay in contraction of the triceps muscle, which ordinarily would arrest overflexion of the arm. This abnormality, incorrectly referred to as Holmes’s rebound phenomenon, is more appropriately designated as an impairment of the check reflex. Stewart and Holmes, who first described this test, made the point that when resistance to flexion is suddenly removed, the normal limb moves only a short distance in flexion and then recoils or rebounds in the opposite direction. In this sense, rebound of the limb is actually deficient in cerebellar disease but is exaggerated in spastic states.

Patients with these various abnormalities of tone may show little or no impairment of motor power, indicating that the maintenance of posture involves more than the voluntary contraction of muscles. Also, it is noteworthy that most of the signs of cerebellar hypotonia are absent in the flaccid muscles of peripheral nerve disease—indicating that the cerebellum exerts a unique modulating effect at spinal segmental levels.

Other Symptoms of Cerebellar Disease
A slight loss of muscular power and excessive fatigability of muscle may occur with acute cerebellar lesions. Also, in unilateral cerebellar disease, the ipsilateral arm may not swing normally in walking. Insofar as these symptoms cannot be explained by other disturbances of motor function, they must be regarded as primary manifestations of cerebellar disease, but they are never severe or persistent and are of little clinical importance; anything approaching a hemiparesis in distribution or severity should not be attributed to cerebellar disease.

More abstruse than the role of the cerebellum in motor control is the alleged participation of this structure in all manner of cognitive function and behavior (see reviews of Leiner et al. and of Schmahmann and Sherman). These authors and others have described a wide range of deficits of memory and cognition, language function, and behavior in patients with disease apparently limited to the cerebellum (as determined by computed tomography and magnetic resonance imaging). It is true that cerebellar lesions interfere with the establishment of conditioned reflexes. To date, however, a uniform clinical pathologic syndrome in which a distinctive cognitive-behavioral deficit or group of deficits is related to a particular cerebellar lesion has not emerged, and the proposed mechanisms by which discrete cerebellar lesions might influence cognitive function remain somewhat speculative.

Differential Diagnosis of Ataxia
The ataxia of severe sensory neuropathy may simulate cerebellar ataxia; presumably this is due to involvement of the large peripheral spinocerebellar afferent fibers. However, seldom should there be difficulty in separating the two if one takes note of the loss of distal joint position sense, absence of associated cerebellar signs such as dysarthria or nystagmus, loss of tendon reflexes, and the corrective effects of vision on sensory ataxia. In the Miller Fisher syndrome, which is considered to be a variant of Guiillain-Barré neuropathy, sensation is intact or affected only slightly and the ataxia is presumably due to a selective peripheral disorder of spinocerebellar nerve fibers. Affection of these fibers in the cervical cord may produce the same effects. Vertiginous ataxia is primarily an ataxia of gait and is distinguished by the obvious complaint of vertigo and listing to one side, past-pointing, and rotary nystagmus. The nonvertiginous ataxia of gait due to vestibular paresis (e.g., streptomycin toxicity) has special qualities that are described in Chap. 7. Vertigo and cerebellar ataxia may be concurrent, as in some patients with a paraneoplastic disease and in those with infarction of the lateral medulla and inferior cerebellum, but the two conditions are usually separable. An unusual and transient ataxia of the contralateral limbs occurs acutely after infarction or hemorrhage in the anterior thalamus (thalamic ataxia); in addition to neighborhood signs, there is often an accompanying unilateral asterixis. Also, a lesion of the superior parietal lobule (areas 5 and 7 of Brodmann) may result in a similar ataxia of the contralateral limbs.

In the diagnosis of disorders characterized by generalized cerebellar ataxia, the mode of onset (rate of development) and degree of permanence of the ataxia are of particular importance, as summarized in Table 5-1. Unilateral ataxia is most often caused by infarction or tumor in the cerebellar hemisphere or by demyelinating disease affecting cerebellar connections, while the causes of generalized ataxia and of pure gait ataxia are many.

LEINER HC, LEINER AL, DOW RS: Does the cerebellum contribute to mental skills? Behav Neurosci 100:443, 1986.

The subject of tremor may suitably be considered at this point because of its association with diseases of the basal ganglia and cerebellum. In addition, a group of miscellaneous movement disorders—myoclonus, facial and cervical dyskinesias, occupational spasms (dystonias), and tics—are described in this chapter. These disorders are largely involuntary in nature and can be quite disabling, but they have an uncertain pathologic basis and an indefinite relationship to the extrapyramidal motor disorders or to other standard categories of neurologic disease. They are brought together here mainly for convenience of exposition.

TREMOR

Tremor may be defined as a more or less involuntary and rhythmic oscillatory movement produced by alternating or irregularly synchronous contractions of reciprocally innervated muscles. The rhythmic quality distinguishes tremor from other involuntary movements, and the involvement of agonist and antagonist muscles distinguishes it from clonus. Two general categories are recognized: normal (or physiologic) and abnormal (or pathologic). The former, as the name indicates, is a normal phenomenon; it is present in all contracting muscle groups and persists throughout the waking state and even in certain phases of sleep. The movement is so fine that it can barely be seen by the naked eye, and then only if the fingers are firmly outstretched; in most instances special instruments are required for its detection. It ranges in frequency between 8 and 13 Hz, the dominant rate being 10 Hz in adulthood and somewhat less in childhood and old age. Several hypotheses have been proposed to explain physiologic tremor, a traditional one being that it reflects the passive vibration of body tissues produced by mechanical activity of cardiac origin (ballistocardiogram). Assuredly this is not the whole explanation of physiologic tremor. As Marsden has pointed out, several additional factors—such as spindle input, the unused grouped firing rates of motor neurons, and the natural resonating frequencies and inertia of the muscles and other structures—are probably of greater significance. Certain abnormal tremors, namely, the metabolic varieties of postural or action tremor and at least one type of familial tremor, are believed by some workers to be variants or exaggerations of physiologic tremor—i.e., “enhanced physiologic tremor” (see further on).

Abnormal or pathologic tremor, which is what one means when the term tremor is used clinically, preferentially affects certain muscle groups—the distal parts of the limbs (especially the fingers and hands); less often, the proximal parts; the head, tongue, jaw, or vocal cords; and rarely the trunk—and is present only in the waking state. The rate in most forms is from 4 to 7 Hz, or about half that of physiologic tremor. In any one individual, the rate is fairly constant in all affected parts. With the advent of electromyography (EMG) and mechanical recording devices, abnormal tremors were subdivided according to their rate, their relationship to posture of the limbs and volitional movement, their pattern of EMG activity (synchronous or alternating) in opposing muscle groups, and their response to certain drugs. The following types of tremor, the features of which are summarized in Table 6-1, are the ones encountered most frequently in clinical practice.

Table 6-1 Main types of tremor

Postural and Action Tremors

These terms, which are used interchangeably, refer to a tremor that is present when the limbs and trunk are actively maintained in certain positions (such as holding the arms outstretched) and that may persist throughout active movement. More particularly, the tremor is absent when the limbs are relaxed but becomes evident when the muscles are activated. It is accentuated as greater precision of movement is demanded, but it does not approach the degree of augmentation seen with so-called intention tremor, which is associated with cerebellar disease. In contrast to rest or static (parkinsonian) tremor, which is characterized electrophysiologically by alternating activity in agonist and antagonist muscles, most cases of action tremor are characterized by relatively rhythmic bursts of grouped alpha motor neuron discharges that occur not quite synchronously and simultaneously in opposing muscle groups. Slight inequalities in the strength and timing of contraction of opposing muscle groups account for the tremor.

Action tremors are of several different types, a feature that makes them more difficult to interpret than other tremors.

Enhanced Physiologic Tremor One type of action tremor seems merely to be an exaggeration of normal or physiologic tremor; it has the same frequency as physiologic tremor but a greater amplitude. Such a tremor, best elicited by holding the arms outstretched with fingers spread apart, is characteristic of intense fright and anxiety, certain metabolic disturbances (hyperthyroidism, hypercorticolism, hypoglycemia), pheochromocytoma, intense physical exertion, withdrawal from alcohol and other sedative drugs, and the toxic effects of several drugs—lithium, nicotinic acid, xanthines (coffee, tea, amphetamine, colas), and corticosteroids. It is noteworthy that a transient action tremor of this type can be reproduced by the intravenous injection of epinephrine or beta-adrenergic drugs such as isoproterenol.
Young and colleagues have adduced evidence that the enhancement of physiologic tremor that occurs in these various metabolic and toxic states is due to stimulation of muscular tremorogenic beta-adrenergic receptors by increased levels of circulating catecholamines. Thus it appears that synchronization of motor units in physiologic tremor, though not primarily of neural origin, is nevertheless influenced by central and peripheral nervous activity.

**Alcohol Withdrawal Tremor** This, the most prominent feature of the alcohol withdrawal syndrome, is a special type of action tremor, closely related to enhanced physiologic tremor. Withdrawal of other sedative drugs (benzodiazepines, barbiturates) following a sustained period of use may produce much the same effect. Using surface electrodes on agonist and antagonist muscles of the outstretched limb, Lefebvre-D’Amour and colleagues have described two somewhat different types of tremor in the alcohol withdrawal period: In the first, with frequency greater than 8 Hz, EMG recordings show continuous activity in antagonistic muscles. Thus it reserves its existence and tremor but is of greater amplitude (enhanced physiologic tremor) and is responsive to propranolol (Koller et al.). The second, of less than 8 Hz, is characterized by discrete bursts of EMG activity occurring synchronously in antagonist muscles, like that observed in one type of familial tremor (see below). Either of these types may occur after a relatively short period of inoxication (“morning shakes”). A number of alcohols, upon recovery from the withdrawal state, exhibit a persistent tremor of essential-familial type, described below. In such patients, the additive effects of an enhanced physiologic tremor probably account for the severity of tremor during alcohol withdrawal. The mechanisms involved in alcohol withdrawal symptoms are discussed in Chap. 42.

**Essential Tremor** This is the commonest type of action tremor, of lower frequency (4 to 8 Hz) than physiologic tremor. Tremor of this relatively slow type may occur as the only neurologic abnormality in several members of a family, in which case it is called familial or hereditary tremor. Such a tremor is inherited as an autosomal dominant trait with virtually complete penetrance. If the inherited nature of the tremor is not evident, it is referred to as essential tremor—and, if it becomes evident only in late adult life, as senile tremor. Sometimes referred to as “benign,” it is hardly so in many patients, in whom it worsens with age and interferes with normal activities. These tremors cannot be distinguished on the basis of their physiologic and pharmacologic properties and probably should not, therefore, be considered as separate entities.

Clinically, it may be difficult to distinguish essential and hereditary forms of tremor from enhanced physiologic tremor. One type of essential tremor is of the same frequency (6 to 8 Hz) as enhanced physiologic tremor, which has led several clinicians to declare their identity. However, there are certain clinical and physiologic differences, as indicated below.

**Familial or essential tremor** most often makes its appearance in the second decade, but it may begin in childhood and then persist. A second peak of increased incidence occurs in adults over 35 years of age. Both sexes are affected. It is a relatively common disorder, with an estimated prevalence of 415 per 100,000 persons over the age of 40 years (Haerer et al.). The tremor frequency is 4 to 8 Hz, usually at the lower end of this range, and it is of variable amplitude. The identifying feature is its appearance or marked enhancement with attempts to maintain a static limb posture. Like most tremors, essential tremor is worsened by emotion, exercise, and fatigue. The tremor practically always begins in the arms and is usually symmetrical, but in approximately 15 percent of patients it may appear first in the dominant hand. A severe isolated arm or leg tremor should suggest another disease (Parkinson disease or focal dystonia, as described further on). The tremor may be limited to the upper limbs or a side-to-side or nodding movement of the head may be added or occur independently. Infrequently, the tremor of the head precedes that of the hands. The head tremor is also postural in nature and disappears when the head is supported. In advanced cases, there is involvement of the jaw, lips, tongue, and larynx, the latter imparting a quaver to the voice. In the large series of familial case studies by Bain and colleagues, solitary jaw or head tremor was not found. Nor was there an association with Parkinson disease, cerebellar ataxia, or dystonia. Many patients with essential tremor will have identified the amplifying effects of anxiety and the ameliorating effects of alcohol on their tremor.

The lower limbs are usually spared or only minimally affected. Rare cases, in which the legs are affected disproportionately, have been described under the title of orthostatic tremor (Heilman, Thompson et al, Wee et al.). This tremor is most prominent or may occur only during quiet standing; it diminishes with walking and disappears when the patient is seated or reclining. In the latter positions, the tremor can be evoked by strong contraction of the leg muscles against resistance. In such patients, the arms are affected little or not at all. Some of these cases have reportedly responded to the administration of clonazepam and sodium valproate.

Electromyographic studies of familial essential tremors reveal that the tremor is generated by more or less rhythmic and almost simultaneous bursts of activity in pairs of agonist and antagonist muscles (Fig. 6-18). Less often, especially in the lower-frequency tremors, the activity in agonist and antagonist muscles alternates, a feature more characteristic of parkinsonism (see below). Tremor of either pattern may be disabling, but the slower, alternating-beat tremor is more of a handicap. Both types occur not only during voluntary movement (kinetic tremor) but also during the maintenance of certain postures (postural tremor).

Electroencephalographic studies of familial essential tremors reveal that the tremor is generated by more or less rhythmic and almost simultaneous bursts of activity in pairs of agonist and antagonist muscles. This, the commonest type of tremor, is of lower frequency (4 to 8 Hz) than physiologic tremor. Tremor of this relatively slow type may occur as the only neurologic abnormality in several members of a family, in which case it is called familial or hereditary tremor. Such a tremor is inherited as an autosomal dominant trait with virtually complete penetrance. If the inherited nature of the tremor is not evident, it is referred to as essential tremor—and, if it becomes evident only in late adult life, as senile tremor. Sometimes referred to as “benign,” it is hardly so in many patients, in whom it worsens with age and interferes with normal activities. These tremors cannot be distinguished on the basis of their physiologic and pharmacologic properties and probably should not, therefore, be considered as separate entities.

This type of tremor may increase in severity to a point where handwriting becomes illegible and the patient cannot bring a spoon or glass to his lips without spilling its contents. Eventually all tasks that require manual dexterity become difficult or impossible. Treatment of these tremors is discussed further on.

**Other Forms of Action Tremor** Action tremors are seen in a number of clinical settings in addition to those already mentioned. A coarse action tremor, sometimes combined with myoclonus, accompanies various types of myoclonus (e.g., primary and secondary tremor; the movements are very regular and EMG bursts occur simultaneously in antagonistic muscle groups. Like most tremors, essential tremor is worsened by emotion, exercise, and fatigue. The tremor practically always begins in the arms and is usually symmetrical, but in approximately 15 percent of patients it may appear first in the dominant hand. A severe isolated arm or leg tremor should suggest another disease (Parkinson disease or focal dystonia, as described further on). The tremor may be limited to the upper limbs or a side-to-side or nodding movement of the head may be added or occur independently. Infrequently, the tremor of the head precedes that of the hands. The head tremor is also postural in nature and disappears when the head is supported. In advanced cases, there is involvement of the jaw, lips, tongue, and larynx, the latter imparting a quaver to the voice. In the large series of familial case studies by Bain and colleagues, solitary jaw or head tremor was not found. Nor was there an association with Parkinson disease, cerebellar ataxia, or dystonia. Many patients with essential tremor will have identified the amplifying effects of anxiety and the ameliorating effects of alcohol on their tremor.

**Manteral of Essential Tremor** A curious fact about the familial and essential tremors of the non-alternate-beat type is that they can be suppressed by a few drinks of alcohol in more than 75 percent of patients; but once the effects of the alcohol have worn off, the tremor returns and may even be worse. Also, this type of tremor can often be inhibited by the beta-adrenergic antagonist propranolol (between 120 and 300 mg per day in divided doses or as a sustained-release preparation) taken orally over a long period of time. However, the benefit is variable and often incomplete; most studies indicate that 50 to 70 percent of patients have some symptomatic relief. Several but not all of the other beta-blocking drugs are similarly effective; metoprolol and nadolol, which may be better tolerated than propranolol (bronchospasm, sleepiness, impotence, etc.), are the ones most extensively studied. Young and associates have shown that neither propranolol nor ethanol, when injected intra-arterially into a limb, decreases the amplitude of essential tremor. These findings suggest that the therapeutic effects of these agents are due less to blockade of the peripheral beta-adrenergic tremorogenic receptors than to the action of these agents on structures within the central nervous system.

The anticonvulsant primidone (Mysoline, in low doses of 25 to 50 mg initially, and raised slowly) has also been found to be effective in controlling essential tremor and...
should be tried in patients who do not respond to or cannot tolerate beta-blocking medications. Amantadine has a modest effect on tremor and may be used as an adjunct.

The alternate-beat, kinetic-predominant type of essential tremor is said to respond well to clonazepam (Biary and Koller). Alcohol and primidone have been less effective in our experience. Injections of botulinum toxin, as for focal dystonia, can reduce the severity of essential tremor, but the accompanying weakness of arm and hand muscles often proves unacceptable to the patient. The apparent benefit of valproate and clonazepam for the lower limb (orthostatic) form of essential tremor has already been mentioned.

Parkinsonian (Rest) Tremor

This is a coarse, rhythmic tremor with a frequency of 3 to 5 Hz. Electromyographically, it is characterized by bursts of activity that alternate between opposing muscle groups. The tremor is most often localized in one or both hands and forearms and less frequently in the feet, jaw, lips, or tongue (Fitz, 5:12). It occurs when the limb is in an at rest or rest position and is suppressed or diminished by willed movement, at least momentarily, only to return if the limb assumes a rest position. For this reason the parkinsonian tremor is often referred to as a resting tremor or tremor at rest, but these terms need to be qualified. Maintaining the arm in an attitude of support or rest is often required to acquire a degree of muscular contraction, albeit slight. If the tremulous hand is completely relaxed, as it is when the arm is placed flatly supported on a table and elbow, the tremor usually disappears; however, the patient rarely achieves this state. Usually he maintains a state of slight tonic contraction of the trunk and proximal muscles of the limbs. Under conditions of complete rest, i.e., in all except the lightest phases of sleep, the tremor disappears, as do most abnormal tremors except palatal and ocular myoclonus.

Parkinsonian tremor takes the form of flexion-extension or abduction-adduction of the fingers or the hand; pronation-supination of the hand and forearm is also a common presentation. Flexion-extension of the fingers in combination with adduction-abduction of the thumb yields the classic "pill-rolling" tremor. It continues while the patient walks, unlike essential tremor; indeed, it may first become apparent or be exaggerated during walking. When the legs are affected, the tremor takes the form of a flexion-extension movement of the foot, sometimes the knee; in the jaw and lips, it is seen as an up-and-down and a pursing movement, respectively. The eyelids, if they are closed lightly, tend to flutter rhythmically (blepharoclonus), and the tongue, when protruded, may move in and out of the mouth at about the same tempo as the tremor elsewhere. The so-called cogwheel effect, which is perceived by the examiner on passive movement of the extremities (Negro's sign), is probably no more than a palpable tremor superimposed on rigidity and as such is not specific for Parkinson disease. The tremor frequency is surprisingly constant over long periods of time and amplitude is variable. Emotional stress augments the amplitude and may add the effects of an enhanced physiologic tremor; increasing rigidity of the limbs, with advance of the disease, reduces it. The tremor interferes surprisingly little with voluntary movement; for example, it is possible for a tremulous patient to raise a full glass of water to his lips and drain its contents without spilling a drop.

Resting tremor is most often a manifestation of the Parkinson syndrome, whether the idiopathic variety described by James Parkinson (paralysis agitans) or the drug-induced type. In the former, the tremor is relatively gentle and more or less limited to the distal muscles; often it is asymmetrical and, at the outset, it may be unilateral. The tremor of postencephalitic parkinsonism (which is not yet) often had a greater amplitude and involved proximal muscles. In neither disease is there a close correspondence between the degree of tremor and the degree of rigidity or akinesia. A parkinsonian type of tremor may also be seen in elderly persons without akinesia, rigidity, or mask-like facies. In some of these patients, the tremor is followed years later by the other manifestations of parkinsonism, but in the majority it is not, the tremor remaining stationary for many years or progressing very slowly, unaffected by anti-Parkinson drugs. Patients with the familial (Wilsonian) or the acquired form of hepatic cerebellar degeneration may also show a tremor of parkinsonian type, usually mixed with ataxic tremor and other extrapyramidal motor abnormalities.

Parkinsonian tremor is suppressed to some extent by the phenothiazine derivative ethopropazine (Parsidol), by trihexyphenidyl (Artane) and other anticholinergic drugs, which are consistently but not completely effective. Beta-adrenergic blocking agents and primidone are often more effective than to anti-Parkinson medications. Treatment is discussed in greater detail in Chap. 39.

Intention (Ataxic) Tremor

The word intention is ambiguous in this context because the tremor itself is not intentional and occurs not when the patient intends to make a movement but only during the most demanding phases of active performance. In this sense it is a kinetic, or action, tremor, but the latter term has other connotations to neurologists, as described above. The term ataxic is a suitable substitute for intention because this tremor is always combined with and adds to cerebellar ataxia. Its salient feature is that it requires for its full expression the performance of an exacting, precise, projected movement. The tremor is absent when the limbs are inactive and during the first part of a voluntary movement, but as the action continues and fine adjustments of the movement are demanded (e.g., in touching the tip of the nose or the examiner's finger), more or less rhythmic (2- to 4-Hz) interruption of forward progression with side-to-side oscillation appears and may continue for several beats after the target has been reached. Unlike familiar tremor, the oscillations occur in more than one plane (Young). The tremor and ataxia may seriously interfere with the patient's performance of skilled acts. In some patients there is a rhythmic oscillation of the head on the trunk (titubation), or of the trunk itself, at approximately the same rate. As indicated above, this type of tremor invariably indicates disease of the cerebellum or its connections, particularly via the superior cerebellar peduncle.

As remarked on page 94, there is another, more violent type of tremor associated with cerebellar ataxia, in which every movement, even lifting the arm slightly or the eyelids, if they are closed lightly, tend to flutter rhythmically (blepharoclonus), and the tongue, when protruded, may move in and out of the mouth at about the same tempo as the tremor elsewhere. The so-called cogwheel effect, which is perceived by the examiner on passive movement of the extremities (Negro's sign), is probably no more than a palpable tremor superimposed on rigidity and as such is not specific for Parkinson disease. The tremor frequency is surprisingly constant over long periods of time and amplitude is variable. Emotional stress augments the amplitude and may add the effects of an enhanced physiologic tremor; increasing rigidity of the limbs, with advance of the disease, reduces it. The tremor interferes surprisingly little with voluntary movement; for example, it is possible for a tremulous patient to raise a full glass of water to his lips and drain its contents without spilling a drop.

Hysterical Tremor

Tremor is a relatively rare manifestation of hysteria, but it may simulate some types of organic tremor, thereby causing difficulty in diagnosis. Hysterical tremors are usually consistent but may be interrupted by gestures that are apparently unrelated to the tremor. In some patients the tremor is accentuated rather than diminished by willed movement. In others, the tremor may be very mild or absent “at rest” and become obvious only with movement of the limbs. As mentioned above, a patient with classic hysterical tremor may, in addition, show a fine tremor of the outstretched hands, i.e., a postural or action tremor, and occasionally an element of ataxic tremor as well. In a similar vein, essential or familial tremor may, in its advanced stages, assume the aspects of a cerebellar, or intention, tremor. Gordon Holmes was careful to note that patients with acute cerebellar lesions sometimes show a parkinsonian tremor in addition to the usual signs of ataxia and ataxic tremor.

Tremors of Mixed Type

Not all tremors correspond exactly with the ones described above. There is frequently a variation in one or more particulars from the classic pattern, or one type of tremor may coexist with another. In some parkinsonian patients, for example, the tremor is accentuated rather than dampened by active movement; in others, the tremor may be very mild or absent “at rest” and become obvious only with movement of the limbs. As mentioned above, a patient with classic hysterical tremor may, in addition, show a fine tremor of the outstretched hands, i.e., a postural or action tremor, and occasionally an element of ataxic tremor as well. In a similar vein, essential or familial tremor may, in its advanced stages, assume the aspects of a cerebellar, or intention, tremor. Gordon Holmes was careful to note that patients with acute cerebellar lesions sometimes show a parkinsonian tremor in addition to the usual signs of ataxia and ataxic tremor.

The features of one type of tremor may be so mixed with those of another that satisfactory classification is not possible. For example, in certain patients with essential or familial tremor or with cerebellar de-generation, one may observe a rhythmic tremor, characteristically parkinsonian in tempo, which is not apparent in repose but appears with certain sustained postures. It may take the form of an abduction-adduction or flexion-extension of the fingers when the patient’s weight is partially
The Pathophysiology of Tremor

The exact anatomic basis of parkinsonian tremor is not known. In Parkinson disease, the visible lesions predominate in the substantia nigra and this was true also of the postencephalitic form of the disease. In animals, however, experimental lesions confined to the substantia nigra do not result in tremor; neither do lesions in the striatal-pallidal area of the basal ganglia. Moreover, not all patients with lesions of the substantia nigra have tremor. In some there are only bradykinesia and rigidity. In a group of eight patients poisoned with the meperidine analogue MPTP, which destroys the neurons of the pars compacta of the substantia nigra (page 1133), four developed a tremor, and it had more the characteristics of a proximal action or postural tremor than of a rest tremor (Burns et al).

Ward and others have produced a Parkinson-like tremor in monkeys by placing a lesion in the ventromedial tegmentum of the midbrain, just caudal to the red nucleus and dorsal to the substantia nigra. Ward postulated that interruption of the descending fibers at this site liberates an oscillating mechanism in the lower brainstem; the latter presumably involves the limb innervation via the reticulospinal pathway. Alternative possibilities are that the lesion in the ventromedial tegmentum interrupts the brachium conjunctivum, or a tremorogenic action of the dentatothalamic system (Fig. 5-3).

Ataxic tremor has been consistently produced in monkeys by inactivating the deep cerebellar nuclei or sectioning the superior cerebellar peduncle or the brachium conjunctivum. A lesion of the nucleus interpositus or dentate nucleus causes an ipsilateral tremor of ataxic type, as one might expect, associated with other manifestations of cerebellar ataxia. In addition, such a lesion gives rise to a “resting,” which is the term that Carpenter applied to a “resting,” or parkinsonian, tremor. He found that the latter tremor was most prominent during the early postoperative period and was less enduring than ataxic tremor. Nevertheless, the concurrence of the two types of tremor and the fact that both can be abolished by ablation of the contralateral ventrolateral thalamic nucleus suggest that they have closely related neural mechanisms. The conflicting observations regarding the role of the inferior olives and ovolocerebellar system in the genesis of essential tremor have been mentioned earlier.

To date, only a few cases of essential tremor have been examined postmortem, and these have disclosed no consistent lesion to which the tremor could indisputably be attributed (Harkavy and Blackwood; Koller and Bunse). Essential tremors of sporadic and familial type, like parkinsonian and ataxic (intention) tremors, can be abolished or diminished by small stereotactic lesions of the basal ganglia or thalamus; in these respects also they differ from essential tremors. Colebatch and colleagues, who studied cerebral and cerebellar blood flow in patients with essential tremor, found that the cerebellum was selectively activated; they postulated a release of an oscillatory mechanism of the cerebro-cerebellar pathway. Dubinsky and Hallett have demonstrated that the inferior olives become hypermetabolic in patients with essential tremor when their tremor is activated. However, the inferior olivary localization has been questioned by Wills and colleagues, who recorded an increased blood flow in the cerebellum and red nuclei but not in the olives. The fact that the tremor can be abolished by lesions in the cerebellum as well as in the ventrolateral thalamus suggests that the oscillatory activity is conducted to the motor cortex via the dentatothalamic system. These mechanisms have been reviewed by Elble.

In patients with tremor of either the parkinsonian, postural, or intention type, Narabayashi has recorded rhythmical burst discharges of unitary cellular activity in the nucleus intermedialis ventralis of the thalamus (as well as in the medial pallidum and subthalamic nucleus), synchronous with the beat of the tremor. Neurons that exhibit the synchronous bursts are arranged somatotopically and respond to kinesthetic impulses from the muscles and joints involved in the tremor. A stereotaxic lesion in any of these sites abolishes the tremor. The effectiveness of the thalamic lesion may be due to interruption of pallidothalamic and dentato-thalamic projections or, more likely, to interruption of projections from the ventrolateral thalamus to the premotor cortex, since the impulses responsible for cerebellar tremor, like those of the postural tremor, are ultimately mediated by the lateral corticospinal tract. This concept would explain why a lesion of the subthalamic nucleus causes a contralateral dyskinesia, whereas a lesion of the dentate nucleus or of the brachium conjunctivum, before its decussation, gives rise to a (ipsilateral) ataxia and tremor.

In the clinical analysis of tremor in humans, the aforementioned types are usually distinguishable on the basis of rhythmicity, amplitude, frequency, relation to movement, postural set, and relaxation. Such analysis also differentiates tremors from a large array of nontremorous states, such as fasciculations, sensory ataxia, myoclonus, asterixis, epilepsia partialis continua, clonus, and shivering.

Palatal Tremor

This is a rare and unique disorder consisting of rapid, involuntary movements of the soft palate. For many years it was considered to be a form of uniphasic myoclonus (hence the terms palatal myoclonus or palatal nystagmus). Because of the ongoing rhythmic movement, it is now classified as a tremor. There are two forms of this movement, according to Deuschl and colleagues. One is called essential palatal tremor and reflects the rhythmic activation of the tensor veli palatini muscles; it has no known pathologic basis. The other form moves impetuously a repetitive audible click, which ceases during sleep. The second, more common form is a symptomatic palatal tremor; it involves thelevator veli palatini muscles and is due to a diverse group of brainstem lesions that interrupt the central tegmental tract(s), which contain descending fibers from midbrain nuclei to the inferior olivary complex. In patients with this tremor, the frequency of the tremor is 25 to 420 cycles per minute in the essential form and 107 to 164 cycles per minute in the symptomatic form.

Symptomatic palatal tremor, in contrast to the essential type and all other tremors, persists during sleep and is often associated with oculopulsion and unilateral or bilateral cerebellar signs. In some cases of the symptomatic type, the pharynx as well as the facial and extraocular muscles (pendular or convergence nystagmus), diaphragm, and vocal cords, even the muscles of the neck and shoulders partake of the persistent rhythmic movements. A similar phenomenon, in which contraction of the masseters occurs concurrently with pendular ocular convergence, has been observed in Whipple disease (ocularomasticatory myorhythmia).

Magnetic resonance imaging reveals no lesions to account for essential palatal tremor, but in the symptomatic form one can see the tegmental brainstem lesions and conspicuous enlargement of the inferior olivary nucleus, unilaterally or bilaterally. With unilateral palatal tremor, it is the contralateral olive that becomes enlarged. It has been proposed that the lesions in the symptomatic form interrupt the circuit (dentate nucleus–brachium conjunctivum–central tegmental tract–olivary nucleus–dentate nucleus) that Laresele and Ben Hamida call the “triangle of Guillain and Mollaret, after the persons who first carefully studied the condition (page 89). Our own postmortem material confirms the central tegmental-diencephalic loops but contains no examples of the production of palatal myoclonus by lesions of the cerebellum or of the dentate and red nuclei. The tremor is seen in young, neoplastic, demyelinating (multiple sclerosis), or traumatic and have been found in the midbrain or pontine tegmentum. There are no reports on the pathologic anatomy of essential palatal tremor. The pathologic basis of palatal tremor remains conjectural. Matsuo and Ajaki postulate a generation hypersensitivity of the inferior olivary nucleus and its dentate connections; Kane and Thach have added evidence that the critical event in the genesis of palatal tremor is denervation not of the olives but of the nucleus ambiguus and the dorsolateral reilcellar formation adjacent to it. More recently, Hallett and Dubinsky have suggested that palatal tremor may be based on the same mechanism as postural tremor—i.e., presumably a disinhibition of the olive and a rhythmic coupling of neurons in the olives induced by a lesion of the dentato-olivary pathway. We are uncertain whether to designate these rhythmic disorders as uniphasic myoclonus or as tremors.

The use of drugs in treating this movement disorder has met with variable success. Clonazepam (0.25 to 0.5 mg/day, increasing gradually to 3.0 to 6.0 mg/day) and tetrabenazine and haloperidol have been helpful on occasion. Selective injection of the palatal muscles with botulinum toxin affords modest relief.

Asterixis

The movement disorder known as asterixis was described by Adams and Foley in 1953. It consists essentially of arrhythmic lapses of sustained posture. These sudden interruptions in sustained muscular contraction allow gravity or the inherent elasticity of muscles to produce a movement, which the patient then corrects, sometimes with overspells. Later Adams and Schwab demonstrated that the initial movement or lapse in posture is associated with EMG silence for a period of 35 to 65 milliseconds. Dubinsky and Hallett have demonstrated that the inferior olives become hypermetabolic in patients with essential tremor when their tremor is activated. However, the inferior olivary localization has been questioned by Wills and colleagues, who recorded an increased blood flow in the cerebellum and red nuclei but not in the olives. ThePositioning of the hands, as in the writing position, or it may appear as a tremor of the outstretched fingers or of the thigh when the patient is seated. Also difficult to classify are tremors that are intermixed with dystonia. These are discussed further on, in the section on cervical dystonia.
resting the forearms on the bed or the arms of a chair. Flexion movements of the hands may then occur once or several times a minute. The lapses in sustained muscle contraction and the corresponding lapses in EMG activity are usually generalized and can be provoked by the persistent contraction of any muscle group—including, for example, the protruded tongue, the closed eyelids, or the trunk muscles. If small finger muscles are affected, an EMG may be required to separate asterisks from tremor and myoclonus.

This sign was first observed in patients with hepatic encephalopathy but was later noted in those with hypercapnia, uremia, and other metabolic and toxic encephalopathies. However, lapses of this type may sometimes appear in the neck and arms of a normal person during a period of drowsiness. They may be evoked by phenytoin and other anticonvulsants, suggesting that these drugs are present in excessive concentrations.

Unilateral asterixis has been noted in an arm and leg on the side opposite an infarction in the territory of the anterior cerebral artery, contralateral to a stereotaxic thalamotomy, thalamic infarction or hemorrhage, and with an upper midbrain lesion, usually as a transient phenomenon after stroke. Montalban and colleagues observed unilateral asterixis in 45 patients without metabolic or toxic abnormalities and in more than half the patients, there were lesions in the contralateral thalamus; in the remainder, there was an abnormality in the pons or a cerebral hemisphere.

**CLONUS, MYOCLOONUS, AND POLYMYOCLOONUS**

The terms clonus (or clonic), myoclonus (or myonic), and polymyoclonus have been used indiscriminately to designate any rhythmic or arrhythmic series of brief, shock-like muscular contractions attendant upon disease of the central nervous system. In this text, the terms are used as follows: Clonus refers to a series of rhythmic, uniphasic or monophasic (i.e., unidirectional) contractions and relaxations of a group of muscles, differing in this way from tremors, which are always diphasic or bidirectional. Clonus specifies the short-like contraction(s) of a group of muscles, irregular in rhythm and amplitude, and, with few exceptions, asynchronous and asymmetrical in distribution; if such contractions affect two or more groups of muscles, the phenomenon is referred to as clonus multiplex or myoclonus multiplex. Widespread, lighting-like, arrhythmic contractions are referred to as myoclonus multiplex or polymyoclonus. In the discussion that follows, it will become evident that this is not a matter of mere pedantry but that each of the three phenomena has a distinctive pathophysiology and particular clinical implications.

**Clonus**

Reference has already been made to the type of clonus that appears in relation to spasticity and heightened tendon reflexes in diseases affecting the corticospinal tract (page 55). **Epilepsia partialis continua** is a special type of rhythmic clonus in which one group of muscles, usually of the face, arm, or leg, is continuously (day and night) involved in a series of rhythmic monophasic contractions. These may continue for weeks, months, or years. In most cases there is a corresponding EEG abnormality. The disorder appears to be cerebral in origin, but its precise anatomic and physiologic basis cannot be determined in most cases (see Chap. 16 for further discussion).

**Myoclonus**

Patients with idiopathic epilepsy may complain of a sustained myoclonic jerk or a short burst of myoclonic jerks, occurring particularly on awakening and on the day or two preceding a major generalized seizure, after which these movements cease. Very few patients with this type of myoclonus show progressive mental and physical deterioration. One-sided myoclonic jerks are the dominant feature of a particular form of childhood epilepsy—so-called benign epilepsy with rolandic spikes (page 342). Diffuse myoclonic jerks are the main or only manifestation of a fairly common neurologic disorder with distinctive EEG features called juvenile myoclonic epilepsy; this diagnosis is suggested by an onset during adolescence and symptoms that become prominent with sleep deprivation and alcohol consumption (page 335). Myoclonus may be associated with atypical petit mal and akinetic seizures in the Lennox-Gastaut syndrome (page 335); the patient often falls during the brief lapse of potential mechanisms that follows a single myoclonic contraction. Similarly, in the West syndrome of infantile spasms, the arms and trunk are suddenly flexed or extended in a single massive myoclonic jerk ("jackknife" or "salam" seizures); mental regression occurs in fully 80 to 90 percent of cases, when even the seizures are successfully treated with adrenocorticotropic hormone (ACTH).

**Diffuse Myoclonus (Myoclonus Multiplex, or Polymyoclonus)**

Under the title **paramyoclonus multiplex**, Friedrich in 1881 described a sporadic instance of widespread muscle jerking in an adult. It was probably in the course of this description that the term myoclonus was used for the first time. Muscle involvements were diffuse, particularly those of the lower limb and proximal segments of the limbs, and the myoclonus persisted for many years, being absent only during sleep. No other neurologic abnormalities accompanied the movement abnormality. The nature and pathologic basis of this disorder were never determined, and its status as a clinical entity has never been secure. Over the years, the term **paramyoclonus multiplex** has been applied to all varieties of myoclonic disorder (and other motor phenomena as well), to the point where it has nearly lost its specific clinical connotation. Myoclonus multiplex of the type described by Friedrich may occur in pure or "essential" form as a benign, often familial, nonprogressive disease or as part of an otherwise progressive syndrome; such disorders have been defined under the diagnosis of the originally described syndrome and the latter as secondary forms, but these designations have little fundamental value, serving only to indicate differences in severity and clinical course.

**Essential Myoclonus**

So-called essential myoclonus may begin at any period of life but usually appears first in childhood and is of unknown etiology. An autosomal dominant mode of inheritance is evident in some families. The myoclonus takes the form of irregular twitches of one or another part of the body, involving groups of muscles, singles muscles, or even a portion of a muscle. As a result, an arm may suddenly flex, the head may jerk backward or forward, or the trunk may curve or straighten. The face, neck, jaw, tongue, and ocular muscles may twitch; also the diaphragm. Some muscle contractions cause no visible displacement of a limb. Even fascicles of the platysma may twitch, according to Wilson. In this and other forms of myclonus, the muscle contraction is brief (20 to 50 ms), i.e., faster than that of a twitch or clonus. The essential myoclonus may be so mild that only a family history is available. For example, in one family studied by R. D. Adams, the patient registered little complaint, accepting the constant intrusions of motor activity with stoicism, and lead relatively normal, active lives.

**Myoclonic Epilepsy (see also page 335)** Myoclonic epilepsy, or myoclonus epilepsy, constitutes another important syndrome of multiple etiologies. A relatively benign idiopathic form, juvenile myoclonic epilepsy, has been mentioned and is discussed further on page 335. A more serious type of myoclonus epilepsy, which in the beginning may be an isolated phenomenon, is eventually associated with dementia and other signs of progressive neurologic disease (familial variety of Unverricht and Lundborg, page 349). An outstanding feature of the latter is a remarkable sensitivity of the myoclonus to stimuli of all sorts. If a limb is passively or biologically, the muscle contraction is brief (20 to 50 ms), i.e., faster than that of the contralateral thalamus; in the remaining, there was an abnormality in the pons or a cerebral hemisphere.
Diffuse Myoclonus with Neurologic Disease of Diverse Type (Table 6-2) The clinical settings in which one observes widespread random myoclonic jerks as a transient or persistent phenomenon are viral encephalitis, Creutzfeldt-Jakob disease, general paresis, advanced Alzheimer and Lewy-body disease, occasionally in Wilson disease, and most often with acquired metabolic disorders (prototypically uremic and anoxic encephalopathy) and certain drug intoxications, notably with haloperidol and amphetamines. An acute onset of polymyoclonus with confusion may occur with lithium intoxication; once ingestion is discontinued, there is improvement (slowly over days to weeks) and the myoclonus is replaced by diffuse action tremors, which later subside. Diffuse, severe myoclonus may be a prominent feature of early tetanus and strychnine poisoning. A polymyoclonus that occurs in acute anoxic encephalopathy should be distinguished from postanoxic action, or intention, myoclonus that emerges with recovery (see below). Encephalopathy with diffuse myoclonus may occur in Hashimoto thyroiditis and in Whipple disease with central nervous system involvement (both are discussed in Ch. 44). The factor common to all these disorders is the presence of diffuse neuronal disease and, as a group, they account for most of the instances of polymyoclonus observed by the neurologist.

### Spinal, or Segmental, Myoclonus

This type of myoclonus was described by Lance and Adams in 1963 in a group of patients who were recovering from hypoxic encephalopathy. When the patient is relaxed, the limb and other skeletal muscles are quiet (except in the most severe cases), and only seldom does the myoclonus appear during slow, smooth (ramp) movements. Fast (ballistic) movements, however, especially when directed to a target, as in touching the examiner’s finger, elicit a series of irregular myoclonic jerks that differ in speed and rhythmically from intention tremor. For this reason it was called intentional, or action, myoclonus. Only the limb that is moving is involved; hence it is a localized, stimulus-evoked myoclonus. Speech may be affected; it is fragmented by the myoclonic jerks, and a syllable or word may be almost compulsively repeated, as in palilalia.

### Intention, or Action, Myoclonus (Postanoxic) This type of myoclonus was described by Lance and Adams in 1963 in a group of patients who were recovering from hypoxic encephalopathy. When the patient is relaxed, the limb and other skeletal muscles are quiet (except in the most severe cases), and only seldom does the myoclonus appear during slow, smooth (ramp) movements. Fast (ballistic) movements, however, especially when directed to a target, as in touching the examiner’s finger, elicit a series of irregular myoclonic jerks that differ in speed and rhythmically from intention tremor. For this reason it was called intentional, or action, myoclonus. Only the limb that is moving is involved; hence it is a localized, stimulus-evoked myoclonus. Speech may be affected; it is fragmented by the myoclonic jerks, and a syllable or word may be almost compulsively repeated, as in palilalia.

Action myoclonus is always associated with cerebellar ataxia. The pathologic anatomy has not been ascertained. Lance and Adams found the irregular discharges to be transmitted via the corticospinal tracts, preceded in some cases by a discharge from the motor cortex. Chadwick and coworkers postulated a reticular loop reflex mechanism. Hallett and colleagues found that a cortical reflex mechanism was operative in some cases and a reticular reflex mechanism in others. Whether these are two aspects of one mechanism could not be decided. Barbiturates and valproic acid have been helpful in some cases. Clonazepam is our preference in combination with valproate. Several clinical trials have suggested that the experimental drug picomycin may be useful.

### Spinal, or Segmental, Myoclonus

The notion that monophasic restricted myoclonus emanates from the cerebellum or brainstem cannot be sustained, for there are forms that are traceable to a purely spinal lesion. A form that has been termed “propriospinal” involves repetitive flexion or extension myoclonus of the torso that is aggravated by stretching or action; it has been attributed, on the grounds of its electrophysiologic features, to a spinal origin.

A sharply demarcated segmental myoclonus has been induced in spinal animals by the Newcastle disease virus, and examples of myelitis with irregular segmental myoclonic jerks (either rhythmic or arrhythmic) have been reported in humans. In our experience, the phenomenon has usually occurred with zoster myelitis and rarely with multiple sclerosis or after spinal traumatic injury. A subacute spinal myoclonus of obscure origin was described many years ago by Campbell and Garland and similar cases continue to be cited in the literature. When highly ionic contrast media were used for myelography, painful spasms and myoclonus sometimes occurred in segments where the dye was concentrated by a block.

### Pathophysiology of Myoclonus Multiplex

It seems logical to assume that myoclonus is caused by abnormal discharges of aggregates of motor neurons or interneurons because of the directly enhanced excitability of these cells or the removal of some inhibitory mechanism.

Sensory relationships are a prominent feature of myoclonus multiplex, particularly those related to metabolic disturbances, and will eventually shed some light on the mechanism. Flickering light, a loud sound, or an unexpected tactile stimulus to some part of the body initiates a jerk so quickly and consistently that it must utilize a direct sensorimotor pathway or the mechanism involved in the startle reaction. Repeated stimuli may recruit a series of incremental myoclonic jerks that culminate in a generalized convulsion, as often happens in the familial myoclonic syndrome of Unverricht-Lundborg. Another type of sensory myoclonus is the audiogenic form, characteristic of Tay-Sachs disease. Each auditory stimulus results in blinking, abrupt elevation of the arms, and other movements. This generalized myoclonic jerk does not fatigue with successive stimuli and is modality-specific.

Evidence implicating cortical hyperexcitability in myoclonus is indirect, being based mainly on the finding that the cortical components of the somatosensory evoked potential are exceedingly large. In some such instances, the myoclonic jerks also have a strict time relationship ("time-locked") to preceding spikes in the contralateral
Pathologic examinations have been of little help in determining the essential sites of this unstable neuronal discharge because, in most cases, the neuronal disease is so diffuse. The most restricted lesions associated with myoclonus are seemingly located in the cerebellar cortex, dentate nuclei, and pretectal region. A lack of modulating influence of the cerebellum on the thalamocortical system of neurons has been postulated as a likely mechanism, but it is uncertain whether the disinhibitory activity is then expressed through corticospinal or reticulospinal pathways. Pentylenetetrazol injections evoke myoclonus in the limbs and the myoclonus persists after transection of corticospinal and other descending tracts until the lower brainstem (medullary reticular) structures are destroyed.

**PATHOLOGIC STARTLE SYNDROMES**

To some degree, everyone startles or jumps in reaction to a totally unanticipated, potentially frightening stimulus. This is the normal startle reflex. It is a protective reaction, being seen also in animals, and its purpose seemingly is to prepare the organism for escape. By pathologic startle we refer to a greatly exaggerated startle reflex and to a group of other stimulus-induced disorders of which startle is a predominant part. In most ways, startle cannot be separated from myoclonus (simplex) except for its generalized nature and a striking evocation by various stimuli.

Aside from exaggerated forms of the normal startle reflex, the most common startle syndrome is so-called startle disease, also referred to as hyperexplexia or hyperkinetik (Kastul and Villeneuve). There is a familial proclivity to this disease (e.g., the "jumping Frenchmen of Maine," and others as described further on). The subject has been reviewed by Wilkins and colleagues and by Ryan et al; the latter authors, by linkage analysis, have localized the gene to chromosome 5q.

With the description of an increasing number of cases of startle disease, the special attributes of the condition have become more familiar. Any stimulus—most often an auditory one—but also a flash of light, a tap on the neck, back, or nose, or even the presence of someone behind the patient—normally evokes a sudden contraction of the orbicularis, neck, and muscle mass with occasional flinging of the legs on occasion. In the abnormal startle response, the contraction is more severe and widespread, with less tendency to habituate. There may be a jump and occasionally an involuntarily shout and fall to the ground. As pointed out by Suhren and associates and by Kurczynski, the condition is transmitted in some families as an autosomal dominant trait. In the proband described by the latter author, affected infants were persistently hypertonic and hyperreflexic (up to 2 to 4 years of age) and had nocturnal and sometimes diurnal generalized myoclonic jerks, all of which subsided with maturation of the nervous system. Later in life, excessive startle must be distinguished from epileptic seizures, which may begin with a startle or myoclonic dystonic jerk (startle epilepsy) and from Gilles de la Tourette syndrome, of which startle may be a prominent manifestation. With startle disease, even with a fall, there is no loss of consciousness, and the manifestations of tic and other neuropsychologic abnormalities are absent.

The auditory startle response may be a manifestation of other neurologic diseases. It is a prominent feature of Tay-Sachs disease (page 996) and of some cases of the ataxias (see page 1590). Auditory, visual, and somatic startle reactions are conspicuous features of some of the lipid storage diseases and of Creutzfeldt-Jakob disease. During the startle, the EEG may show a vertex or frontal spike–slow wave complex, followed by a general desynchronization of the cortical rhythms; between startles the EEG is normal.

The mechanism of the startle disorder has been of a matter of speculation. In animals, the anatomic substrate has been localized in the pontine reticular nuclei, with transmission to the lower brainstem and spinal motor neurons via the reticulospinal tracts. Some authors have postulated a disinhibition of certain brainstem centers. Others, on the basis of testing by somatosensory evoked potentials, have suggested that hyperactive long-loop reflexes constitute the physiologic basis of startle disorders. Wilkins and coworkers consider hyperexplexia to be an independent phenomenon (different from the normal startle reflex) and to fall within the spectrum of stimulus-sensitive myoclonic syndromes. Clonazepam controls the startle disorder to a varying degree. Sedative drugs relieve the rigidity in infants and the startle reaction to a lesser extent.

The relationship of hyperexplexia to the phenomenon displayed by the “jumping Frenchmen of Maine” is not altogether clear. The latter was described originally by James Beard, in 1868, among small pockets of socially backward, French-speaking lumberjacks in northern Maine. The subjects displayed a greatly excessive response to minimal stimuli, to which no adaptation was possible. The reaction consisted of jumping, raising the arms, screaming, and flailing of limbs, sometimes with echolalia, echopraxia, and a forced obedience to commands, even if this entailed a risk of serious injury. A similar syndrome in Malayasia and Indonesia is known as ratah and in Siberia as myornych. This syndrome has been explained in psychologic terms as operant-conditioned behavior (Sant-Hilaire et al) or as a culturally determined behavior (Simons). Possibly the complex secondary phenomena can be explained in this way, but the stereotyped onset with an uncontrollable startle and the familial occurrence described earlier attest to a biologic basis akin to that of hyperexplexia.

**SPASMODIC TORTICOLLIS AND OTHER FOCAL DYSTONIAS**

These focal or segmental dystonias, in contrast to the generalized dystonic disorders described in Chap. 4, are intermittent, arrhythmic, brief or prolonged spasms or contractions of a muscle or adjacent group of muscles that places the body part in a forced and unnatural position. When limited to the neck muscles, the spasms may be more or less rhythmic, with rotation or partial extension of the head or craniocervical dystonia (torticollis), or the posterior or anterior neck muscles may be involved predominantly and the head hyperextended (retrocollic spasm, retrocollic spasm, or inclined forward (anterior- or procollic spasm, anticrollic spasm). Other dystonias restricted to cranio cervical muscle groups are spasms of the orbicularis oculi, causing forced closure of the eyelids (blepharospasm); contraction of the masseter muscle, which may produce a sharp opening or closing of the jaw and retraction or pursing of the lips (oromandibular dystonia). With the latter condition, the tongue may undergo involuntary forceful protrusion; the throat and neck muscles may be thrown into violent spasm when the patient attempts to speak or the facial muscles may contract in a grimace; and the laryngeal muscles may be involved, imparting a high-pitched, strained quality to the voice (spasmogenic dystonia). More often, spasmogenic dystonia occurs as an isolated phenomenon. Of the large number of focal dystonias seen in the movement disorder clinic of Columbia Presbyterian Hospital, 44 percent were classified as torticollis, 26 percent as spasmogenic dystonia, 14 percent as blepharospasm, 10 percent as focal dystonia of the right hand and arm (writer's cramp), and 3 percent as oromandibular dystonia.

These movement disorders are involuntary and cannot be inhibited, thereby differing from habit spasms or tics. For many years torticollis was thought to be a type of neurosis, but all neurologists now agree that it is a localized form of dystonia. As discussed in Chap. 4, it is characteristic of these spasms and similar focal dystonias that occur in the hands or feet to display a simultaneous activation of agonist and antagonist muscles (cocontraction), a tendency for the spasm to spread to adjacent muscle groups that are not normally activated in the movement (overflow), and an arrhythmic intermixed tremor; but these features tend not to be as prominent in focal dystonias as in the generalized varieties (described in Chap. 4).

Any of the typical forms of restricted dystonia may represent a tardive dyskinesia; i.e., they complicate treatment with neuroleptic drugs (see pages 1264 and 1637). The most common of these is combined with a more or less constant movement of the tongue and lips, which may include lip smacking, tongue protrusion, and similar movements in the orbicularis of the mouth and jaw muscles, which may cause forceful opening or closure of the mouth (oromandibular dystonia) and retrusion or pursing of the lips (oromandibular dystonia). With the latter condition, the tongue may undergo involuntary forceful protrusion; the throat and neck muscles may be thrown into violent spasm when the patient attempts to speak or the facial muscles may contract in a grimace; and the laryngeal muscles may be involved, imparting a high-pitched, strained quality to the voice (spasmogenic dystonia). More often, spasmogenic dystonia occurs as an isolated phenomenon. Of the large number of focal dystonias seen in the movement disorder clinic of Columbia Presbyterian Hospital, 44 percent were classified as torticollis, 26 percent as spasmogenic dystonia, 14 percent as blepharospasm, 10 percent as focal dystonia of the right hand and arm (writer's cramp), and 3 percent as oromandibular dystonia.

The pathogenesis of the idiopathic (primary) focal dystonias is uncertain, although there is evidence that a large proportion are genetically determined. Authoritative commentators including Marsden have classed the adult-onset focal dystonias with the broader category of idiopathic torsion dystonia. This view is based on the recognition of each of the focal dystonias as an early component of the idiopathic syndrome in children, the occurrence of focal and segmental dystonias in family members, as well as a tendency of the dystonia in some adult patients to spread to other body parts. There are families in which the only manifestation of the DYT1 mutation (the gene abnormality associated with dystonia musculorum deformans) is a late-onset writer's cramp, described further on. The genetics of torsion dystonia has been reviewed by Korf.

It is noteworthy that no consistent pathologic changes have been demonstrated in any of the idiopathic and genetically determined dystonias. Most physiologists cast the disorder in terms of reduced cortical inhibition of unwanted muscle contractions, as summarized in the review by Berardelli and colleagues. Specific changes in
Spasmodic Torticollis (Idiopathic Cervical Dystonia)

This is the most frequent form of restricted dystonia, localized to the neck muscles (see also page 1144). It usually begins in early to middle adult life (peak incidence in the fifth decade) and tends to worsen slowly. A condition of unknown cause, almost always sporadic, it is somewhat more common in women. The quality of the neck and head movements varies; they may be deliberate and smooth or jerky or cause a persistent deviation of the head to one side. Sometimes brief bursts of myoclonic twitching or a slightly irregular, high-frequency kinetic tremor accompanies deviation of the head, possibly representing an effort to overcome the contraction of the neck muscles. The tremor tends to be in the direction of the dystonic movement, which has been termed a directional “vector.” The spasms are worse when the patient stands or walks and are characteristically reduced or abolished by a contactual stimulus, such as placing a hand on the chin or neck or exerting mild but steady counterpressure on the side of the deviation or sometimes on the opposite side, or bringing the occiput in contact with the back of a high chair. These maneuvers become less effective as the disease progresses. In the majority of cases, the spasms cease when the patient lies down. In chronic cases, the agonizing gnawing hypochondryal Pain in the contracting muscles is a common complaint, especially if there is associated cervical arthropathy.

Although the most prominently affected muscles are the sternomastoid and trapezius, EMG studies also show sustained or intermittent activity in the posterior cervical muscles on both sides of the neck. In most patients the spasms remain confined to the neck muscles and persist in unmodified form, but in some the muscle spasms spread beyond the neck, involving muscles of the shoulder girdle and back or the face and limbs. The distinction between these two forms is not fundamental. About 15 percent of patients with torticollis also have oral, mandibular, or hand dystonia, 10 percent have blepharospasm, and a similarly small number have a family history of dystonia or tremor (Chan et al). No neuropathologic changes were found in the single case studies reported by Tarlov and by Zweig and colleagues.

Spasmodic torticollis is resistant to treatment with L-dopa and other antiparkinsonian agents, although occasionally they give slight relief. In a few of our patients (four or five of several hundred), the condition disappeared without therapy, an occurrence observed in 10 to 20 percent in the series of Dauer et al. In their experience, remissions usually occurred during the first few years after onset in patients whose disease began relatively early in life; however, nearly all these patients relapsed within 5 years.

The periodic (every 3 to 4 months) injection of minute amounts of botulinum toxin type A directly into several sites in the affected muscles is by far the most effective form of treatment. The injections are best guided by clinical and EMG analysis to determine which tonically contracted muscles are most responsible for the aberrant postures. All but 10 percent of patients with torticollis have had some degree of relief from symptoms with this treatment. Adverse effects (excessive weakness of injected muscles, local pain and dysphagia—the latter from a systemic effect of the toxin) are usually mild and transitory. Five to 10 percent of patients become resistant to repeated injections because of the development of neutralizing antibodies to the toxin (see Brin, Dauer et al).

In the most severe cases and those refractory to treatment with botulinum toxin, a combined version of the spinal accessory nerve (of the more affected sternomastoid) and of the first three cervical motor roots bilaterally has been successful in reducing spasm of the muscles without totally paralyzing them.

Considerable relief has been achieved for as long as 6 years in one-third to one-half of cases treated in this way (Krauss et al, Ford et al). Bilateral thalamotomy has also been tried, but it is less effective and carries a considerable risk, particularly to speech and swallowing, so it should be reserved for the most severely affected patients with more widespread dystonia. These surgical procedures are rarely necessary now that botulinum toxin treatment has been refined.

Blepharospasm

From time to time, patients in late adult life, predominantly women, present with the complaint of inability to keep their eyes open. Any attempt to look at a person or object is associated with a persistent tonic spasm of the eyelids. During conversation, the patient struggles to overcome the spams and is distracted by them. All customary activities are hampered to a varying extent. Reading and watching television are impossible at some times but surprisingly easy at other. Jankovic and Orman, in a survey of 250 such patients, found that the condition of 75 percent progressed in severity over the years to the point, in about 15 percent of cases, where the patients were, in effect, legally blind.

One’s first inclination is to think of this disorder as photophobia, and indeed the patient may state that bright light is annoying (ocular inflammation, especially of the iris, may produce severe blepharospasm): However, the spasms persist in dim light and even after anesthetia of the corneas. Extraocular movements are quite normal. Blepharospasm may occur as an isolated phenomenon, but just as often it is combined with oromandibular spasms (see below) and sometimes with spastomodisc dysphonia, torticollis, and other dystonic fragments. Again, it has been postulated that these various focal dystonias have a psychiatric basis, but with the exception of a depressive reaction in some patients, psychiatric symptoms are lacking and the use of psychotherapy, acupuncture, behavioral modification therapy, hypnosis, etc., has generally failed to cure the spasms. Again, no neuropathologic lesion or uniform pharmacologic profile has been established in any of these disorders (Marsden et al; see also Hallett).

In the treatment of blepharospasm, a variety of antiparkinsonian, anticholinergic, and tranquilizing medications may be tried, but one should not be sanguine about the chances of any patients. A very few of these patients have had temporary and partial relief from L-dopa. Sometimes the blepharospasm disappears spontaneously (in 13 percent of the cases in the series of Jancovic and Orman). The most effective treatment consists of the injection of botulinum toxin into several sites in the orbicularis oculi and the levator palpebral muscles. The benefit lasts for 3 to 5 months and several cycles of treatment are usually required. There appear to be no adverse systemic effects. Thermolytic destruction of the fibers in the branches of the facial nerves that innervate the orbicularis oculi is reserved for the most resistant and disabling cases.

Other Causes of Blepharospasm

There are several clinical settings other than the one described above in which blepharospasm may be observed. In the days following cerebral infarction or hemorrhage, the stimulus of lifting the patient’s eyelids may lead to strong involuntary closure of the lids. Reflex blepharospasm, as Fisher has called this phenomenon, is more commonly associated with a right hemiplegia and is more prominent on the nonparalyzed side. A homolateral blepharospasm has also been observed with a small thalamomesencephalic infarct. In patients with Parkinson disease, progressive supranuclear palsy, or Wilson disease, and with other lesions in the rostral brainstem, light closure of the eyelids may induce blepharospasm and an inability to open the eyelids voluntarily.

We have seen an instance of blepharospasm as part of a paraneoplastic midbrain encephalitis, and there have been several reports of it with autoimmune disease such as systemic lupus and myasthenia gravis, but the mechanism in these cases is as obscure as for the ideopathic variety.

Lingual, Facial, and Oromandibular Spasms

These special varieties of involuntary movements also appear in later adult life, with a peak age of onset in the sixth decade. Women are affected more frequently than men. The most common type is characterized by forceful opening of the jaw, retraction of the lips, spasms of the platysma, and protrusion of the tongue; or the jaw may be clamped shut and the lips may purse. Other patterns include lateral jaw deviation and bruxism. Common terms for this condition are the Meige syndrome, after the French neurologist who gave an early description of it, and the Brueghel syndrome, because of the similarity of the grotesque grimace to that of a subject in a Brueghel painting called De Gapper. Difficultly in speaking and swallowing is common or spasmodic dysphonia and blepharospasm are frequently combined, and occasionally patients with these disorders develop torticollis or dystonia of the trunk and limbs. A number have tremor of affected muscles or of the hands as well. All these prolonged, forceful spasms of facial, tongue, and neck muscles have resulted from the administration of phenothiazine and butyrophenone drugs. More often, however, the disorder induced by neuroleptics is different, consisting of choreathetotic chewing, lip smacking, and licking movements (tardive orofacial dyskinesia; see pages 1254 and 1637).

Very few cases of the Meige syndrome have been studied neuropathologically. In some of them no lesions were found. In one case there were foci of neuronal loss in the cortical areas that are pertinent to the dystonias associated with overuse of certain body parts (craft and occupational dystonias) are described below.
deviation of the jaw may last for days and adventitious lingual movements may be added. A form that occurs with hemifacial atrophy has been described by Kaufman. 

High doses of benztropine may be helpful, but local botulinum toxin injection is probably the best alternative. A spasm that is confined to one side of the face (hemifacial spasm) is not, strictly speaking, a dystonia and is considered with disorders of the facial nerve on page 1455.

**Writer's Cramp, Musician's Spasm, and Other Craft (Occupational) Dystonias**

The so-called craft or occupational cramps or spasms should be mentioned here, since the prevailing opinion is that they are restricted or focal “task-specific” dystonias. Men and women are equally affected, most often between the ages of 20 and 50 years. In the commonest form, writer's cramp, the patient observes, upon attempting to write, that all the muscles of thumb and fingers either go into spasm or are inhibited by a feeling of stiffness and pain or hampered in some other inexplicable way. The spasm may be painful and spread into the forearm or even the upper arm and shoulder. Sometimes the spasm fragments into a tremor that interferes with the execution of fluid, cursive movements. Immediately upon cessation of writing, the spasm disappears. Although the disturbance in writer's cramp is usually limited to the specific act of writing, it may involve other equally demanding manual tasks. At all other times and in the execution of grosser movements, the hand is normal, and there are no other neurologic abnormalities. Many patients learn to write in new ways or to use the other hand, though that, too, may become involved. A few of our younger patients have developed spasmodic torticollis at a later date.

The performance of other highly skilled motor acts, such as playing the piano or fingering the violin, may be similarly affected. The "loss of lip" in trombonists and other instrumentalists may represent an analogous phenomenon, seen only in experienced musicians. In each case a delicate motor skill, perfected by years of practice and performed almost automatically, suddenly comes to require a conscious and labored effort for its execution. Discrete movements are impaired by a spreading innervation of unneeded muscles (intention spasm), a feature common to athetic states.

The nature of these disorders is quite obscure. They have been classed traditionally as "occupational neuroses," and a psychiatric causation has been suggested repeatedly, but careful clinical analysis has not borne this out. Once developed, the disability persists in varying degrees of severity, even after long periods of inactivity of the affected part.

In monkeys, Byl and colleagues found that sustained, rapid, and repetitive highly stereotypical movements greatly expanded and degraded the cortical representation of sensory information from the hand. These authors hypothesized that degradation of sensory feedback to the motor cortex was responsible for excessive and persistent motor activity, including dystonia. Such a change in cortical responses to magnetic stimulation has also been found by a number of investigators in patients with writer's cramp. Other theories pertaining to the pathology of the focal dystonias have been reviewed by Berardelli et al.

A high degree of therapeutic success has reportedly been obtained by injections of botulinum toxin into specifically involved muscles of the hand and forearm (Cohen et al, Rivest et al) and this is now the most widely used form of therapy. It has been claimed that the patient can be helped by a deconditioning procedure that delivers an electric shock whenever the spasm occurs or by biofeedback, but these forms of treatment have not been rigorously tested.

**TICS AND HABIT SPASMS**

Many persons throughout their lives are given to habitual movements. They range from simple, highly personalized, idiosyncratic mannerisms (e.g., of the lips and tongue) to repetitive actions such as sniffing, clearing the throat, protruding the chin, or blinking whenever these individuals become tense. Stereotypy and irresistibility are the main identifying features of these phenomena. The patient admits to making the movements and feels compelled to do so in order to relieve perceived tension. Such movements can be suppressed for a short time by an effort of will, but they reappear as soon as the subject's attention is diverted. In certain cases the tics become so ingrained that the person is unaware of them and seems unable to control them. An interesting feature of many tics is that they correspond to purposive, coordinated acts that normally serve the organism. It is only their incessant repetition when uncalled for that marks them as habit spasms or tics. The condition varies widely in its expression from a single isolated movement (e.g., blinking, sniffing, throat clearing, or stretching the neck) to a complex of movements.

Children between 5 and 10 years of age are especially likely to develop habit spasms. These consist of blinking, hitching up one shoulder, sniffing, throat clearing, jerking the head or eyes to one side, grimacing, etc. If ignored, such spasms seldom persist for longer than a few weeks; providing more rest and a calmer environment may be helpful. In adults, relief of nervous tension by sedative or tranquilizing drugs and psychotherapy may be helpful, but the disposition to tics persists. A putative relationship to streptococcal infection is mentioned below.

When idle, adults often display a wide variety of fidgeting types of movement, gestures, and mannerisms that vary in degree from one person to another. Lay persons refer to them as "bad habits." Special types of rocking, head bobbing, and other movements, particularly self-stimulating movements, are disorders of motility unique to the mentally retarded. These "rhythmmas" have no known pathologic anatomy in the basal ganglia or elsewhere in the brain. Apparently they represent a persistence of some of the rhythmic, repetitive movements (head banging, etc.) of normal infants. In some cases of impaired vision and photic epilepsy, eye rubbing or moving the fingers rhythmically across the field of vision is observed, especially in mentally retarded children.

Gilles de la Tourette Syndrome

Multiple tics—associated with sniffing, snorting, involuntary vocalization, and troublesome compulsive and aggressive impulses—constitute the rarest and most severe tic syndrome. The Tourette syndrome begins in childhood, usually as a simple tic; as the condition progresses, new tics are added to the repertoire. It is the multiplicity of tics and the combination of motor and vocal tics that distinguish the Tourette syndrome from the more benign, restricted tic disorders.

Vocal tics, usually loud and irritating in pitch, are characteristic. Some patients display repetitive and annoying motor behavior, such as jumping, squatting, or turning in a circle. Other common types of repetitive behavior include the touching of other persons and repeating one's own words (palilalia) and the words or movements of others. Explosive and involuntary cursing and the compulsive utterance of obscenities (coprolalia) are the most dramatic manifestations. Interestingly, the latter phenomena are uncommon in Japanese patients, whose decorous culture and language contain few obscenities. The full repertoire of tics and compulsions comprised by the Tourette syndrome has been described by Tolosa and Jankovic.

Stone and Jankovic have noted the occurrence of persistent blepharospasm, torticollis, and other dystonic fragments in a small number of patients with Tourette syndrome. Feinberg and associates have described four patients with amyathric myoclonus and vocalization, but it is not clear whether these symptoms represent an unusual variant of Tourette's disease or a new clinical entity. So-called soft neurologic signs are noted in half of the patients, and hyperactivity and disorders of attention and perception are frequent. Evidence of "organic" impairment by psychological tests was found in 40 to 60 percent of Shapiro's series; however, intelligence does not deteriorate. Nonspecific abnormalities of the EEG occur in more than half of the patients.

In one-third of the cases reported by Shapiro and colleagues, tics were observed in other members of the family. Several other studies have reported a familial clustering of cases in which the pattern of transmission appears to be autosomal dominant with incomplete penetrance (Pauls and Leckman). Support for the primary genetic nature of Tourette syndrome derives also from twin studies, which have revealed higher concordance rates in monozygotic twin pairs than in dizygotic pairs. An ethnic bias (Ashkenazi Jews) has been reported, ranging from 19 to 62 percent in several series, but this has not been borne out in equally large series outside of New York (Lees et al).

As to causation, little is known. The disease, if it is such, is unrelated to social data or to psychiatric illness; there is no consistent association with infection, trauma, or other disease. Hyperactive children who have been treated with stimulants appear to be at increased risk of developing or exacerbating tics (Price et al), but a causal relationship has not been established beyond doubt. Reports of a relationship to obsessive-compulsive neuroses have also been inconsistent. MRI and CT and positron emission tomography (PET) have shown no uniform abnormalities, and histopathologic changes have not been discerned in the few brains examined by the usual histologic means. Dysfunctional dopamine markers in postmortem striatal tissue, found almost consistently in patients with Tourette syndrome, suggest a significant alteration of dopamine uptake mechanisms; more recently, Wolf et al have found that differences in D2 dopamine receptor binding in the head of the caudate nucleus predicted differences in the phenotypic severity of Tourette syndrome. These observations, coupled with the facts that l-dopa exacerbates the symptoms of Tourette syndrome and that the highly effective therapeutic agent haloperidol blocks dopamine (particularly D2) receptors, support the notion of a dopaminergic abnormality in the basal ganglia, more specifically in the caudate nucleus. In this latter respect, reported instances of compulsive behavior in lesions of the head in the caudate nucleus and its projections from orbitalfrontial and cingulate cortices may be pertinent.

Using the model of Sydenham chorea, a recent line of investigation has implicated streptococcal infection in the genesis of abruptly appearing Tourette syndrome and of less generalized tics in children. This association has also been adopted by some authors to explain obsessive-compulsive behavior of sudden and unexplained nature.

Pauls and Leckman
onset. These putative disorders have been summarized by Swedo and colleagues under the acronym PANDAS (pediatric autoimmune neuropsychiatric disorders with streptococcal infection). In a few cases there has been a relapsing course that is similar to some Sydenham cases. This information is intriguing but not confirmed.

The course of the illness is unpredictable. In some adolescents it subsides spontaneously and permanently or undergoes long remissions, but in other patients it persists throughout life. This variability emphasizes the difficulty in separating transient habit spasms from the Tourette chronic multiple tic syndrome. Haloperidol has proved to be an effective therapeutic agent, but it should be used only in severely affected patients and in small doses (0.25 mg initially, increasing the dosage gradually to 2 to 10 mg daily). The addition of benzotropine mesylate (0.5 mg daily) at the outset of treatment may help to prevent the adverse effects of haloperidol. Patients who do not respond to haloperidol may respond to the neuroleptic pimozide, which has a more specific antidopaminergic action than haloperidol. Pimozide should be given in small amounts (0.25 mg daily) to begin with and increased gradually to 8 to 9 mg daily. The antispasticity agent tetrabenzine may also be useful if high doses can be tolerated. Kurlan and associates have noted a lessening of tics after treatment with naltrexone, 50 mg daily.

Akathisia

The term akathisia was coined by Haskovec in 1904 to describe an inner feeling of restlessness, an inability to sit still, and a compulsion to move about. When sitting, the patient constantly shifts his body and legs, crosses and uncrosses his legs, and swings the free leg. Running in place and persistent pacing are also characteristic. This abnormality of movement is most prominent in the lower extremities and may not be accompanied, at least in mild forms of akathisia, by perceptible rigidity or other neurologic abnormalities. In its advanced form, patients complain of difficulty in concentration, distracted or dazed by the constant movement.

First noted in patients with Parkinson disease and senile dementia, akathisia is now observed most often in patients receiving neuroleptic drugs (page 1132). However, this disorder may be observed in psychiatric patients who are receiving no medication and in some patients with Parkinson disease; it can also be induced in normal individuals by the administration of neuroleptic drugs or l-dopa.

The main diagnostic considerations are an agitated depression, particularly in patients already on neuroleptic medications, and the “restless legs” syndrome of Eckborn (page 412). Patients with the latter affliction describe a sensation in the legs rather than an inner restlessness, although both disorders create an irresistible desire for movement. At times these distinctions are blurred and treatment must be empiric. Many of the medications utilized for the restless legs syndrome, such as propoxyphene or clonazepam, may be tried, or treatment can be directed to the akathisia by selecting a less potent neuroleptic (if it is the suspected cause), or by using an anticholinergic medication, amantadine, or—perhaps the most effective and best tolerated—beta-adrenergic blocking drugs.

CHAPTER REFERENCES

Certain disorders of motor function manifest themselves most clearly as impairments of upright stance and locomotion, and their evaluation depends on a knowledge of the neural mechanisms underlying these peculiarly human functions. Analysis of stance, carriage, and gait is a particularly rewarding medical exercise; with some experience, the examiner can sometimes reach a neurologic diagnosis merely by noting the manner in which the patient enters the office. Considering the frequency of falls that result from gait disorders and their consequences, such as hip fractures, and the resultant need for hospital and nursing home care, this is an important subject for all physicians (Tinetti and Williams).

NORMAL GAIT

The normal gait seldom attracts attention, but it should be observed with care if slight deviations from normal are to be appreciated. The body is erect, the head is straight, and the arms hang loosely and gracefully at the sides, each moving rhythmically forward with the opposite leg. The feet are slightly everted, the steps are approximately equal, and the internal malleoli almost touch as each foot passes the other. The medial edges of the heels, as they strike the ground with each step, form a straight line. As each leg moves forward, there is coordinated flexion of the hip and knee, dorsiflexion of the foot, and a barely perceptible elevation of the hip so that the foot clears the ground. Also, with each step, the thorax advances slightly on the side opposite the swinging lower limb. The heel strikes the ground first, and inspection of the shoes will show that this part is most subject to wear. The muscles of greatest importance in maintaining the erect posture are the erector spinae and the extensors of the hips and knees.

The normal gait cycle, defined as the period between successive points at which the heel of the same foot strikes the ground, is illustrated in Fig. 7-1; it is based on the studies of Murray and coworkers and of Olsson. In this figure, the cycle is initiated by the heel strike of the right foot. The stance phase, during which the foot is in contact with the ground, occupies 60 to 65 percent of the cycle. The swing phase begins when the right toes leave the ground. Noteworthy is the fact that for 20 to 25 percent of the walking cycle, both feet are in contact with the ground (double limb support). In later life, when the steps shorten and cadence (the rhythm and number of steps per minute) decreases, the proportion of double limb support increases (see further on). Surface electromyograms show an alternating pattern of activity in the legs, predominating in the flexors during the swing phase and in the extensors during the stance phase.

![Figure 7-1](image-url) The normal gait cycle, based on the studies of Olsson and of Murray et al. See text for details.

When analyzed in greater detail, the requirements for locomotion in an upright, bipedal position may be reduced to the following elements: (1) antigravity support of the body, (2) stepping, (3) the maintenance of equilibrium, and (4) a means of propulsion. Locomotion is impaired in the course of neurologic disease when one or more of these mechanical principles are prevented from operating normally.

The upright support of the body is provided by righting and antigravity reflexes, which allow a person to arise from a lying or sitting position to an upright bipedal stance and to maintain firm extension of the knees, hips, and back, modifiable by the position of the head and neck. These postural reflexes depend on the afferent vestibular, somatosensory (proprioceptive and tactile), and visual impulses, which are integrated in the spinal cord, brainstem, and basal ganglia. (Transsection of the neuraxis between the red and vestibular nuclei leads to exaggeration of these antigravity reflexes—de cerebrate rigidity.)

Stepping, the second element, is a basic movement pattern present at birth and integrated at the spinal-midbrain-diencephalic level. Its appropriate stimuli are contact of the sole with a flat surface and a shifting of the center of gravity—first laterally onto one foot, allowing the other to be raised, and then forward, allowing the body to move onto the advancing foot. Rhythmic stepping movements can be initiated and sustained in decerebrate or “spinal” cats and dogs. This is accomplished through the activity of interneurons that are organized as rhythmic “locomotor generators,” akin to the pattern generators that permit the rhythmic movement of wings or fins. There is no evidence for a similar system of locomotor control in monkeys or humans, in whom the spinal mechanisms for walking cannot function independently but depend upon higher command centers. The latter are located in the posterior subthalamic region, caudal midbrain tegumentum, and pontine reticular formation; they control the spinal gait mechanisms through the reticulospinal, vestibulospinal, and tectospinal pathways in the ventral cord (Edelberg et al., Lawrence and Kupfers). Probably, in the human, the brainstem locomotor regions are activated by cerebral cortical centers.

Equilibrium involves the maintenance of balance at right angles to the direction of movement. The center of gravity during the continuously unstable equilibrium that prevails in walking must shift within narrow limits from side to side and forward as the weight is borne first on one foot, then on the other. This is accomplished through the activity of highly sensitive postural and righting reflexes, both peripheral (stretch reflexes) and central (vestibulocerebellar reflexes). These reflexes are activated within 100 ms of each shift in the support surface and require reliable afferent information from the visual, vestibular, and proprioceptive systems.

Propulsion is provided by leaning forward and slightly to one side and permitting the body to fall a certain distance before being checked by the support of the leg.
Here, both forward and alternating lateral movements must occur. But in running, where at one moment both feet are off the ground, a forward drive or thrust by the hind leg is also needed.

Obviously gait varies considerably from one person to another, and it is a commonplace observation that a person may be identified by the sound of his footsteps, notably the pace and the lightness or heaviness of tread. The manner of walking and the carriage of the body may even provide clues to an individual's personality and occupation; Sherlock Holmes was proud of his talent for reading such clues. Furthermore, the gait of men and women differ, a woman's steps being quicker and shorter and movement of the trunk and hips more graceful and deliberate. Certain female characteristics of gait, if observed in the male, immediately impart an impression of femininity; or male characteristics, observed in the female, suggest masculinity. The changes in stance and gait that accompany aging—the slightly stooped posture and slow, stiff tread—are so familiar that they are not perceived as abnormalities.

**ABNORMAL GAITS**

Since normal body posture and locomotion require intact vestibular function, proprioception, and vision (we see where we are going and pick our steps), the effects on normal function of deficits in these senses are worth noting.

A blind person—or a normal one who is blindfolded or walks in the dark—moves cautiously, with arms slightly forward to avoid collisions, and shortens his step slightly on a smooth surface; with shortening of the step, there is less rocking of the body and the gait is unusually stiff.

Disorders of vestibular function are most often the result of prolonged administration of aminoglycoside antibiotics or other toxic medications, which destroy the hair cells of the vestibular labyrinth. This also occurs in some patients in the late stages of Menière disease and, infrequently, for no definable reason. Patients with vestibulopathy show unsteadiness in standing and walking, often without widening their base, and an inability to descend stairs without holding onto the banister. They complain of a sense of imbalance, usually with movement but at times when standing still—a sensation that may be likened to being on the deck of a rolling ship. Running and turning quickly are even more impaired, with lurching in all directions. The patient has great difficulty in focusing his vision on a fixed target when he is moving or on a moving target when he is either stationary or moving. When the body is in motion or the head is moved suddenly, objects in the environment appear blurred or actually jiggle up and down or from side to side (oscillopsia). Driving a car or reading on a train is difficult or impossible; even when walking, the patient may need to stop in order to read a sign. These abnormalities indicate a loss of stabilization of ocular fixation by the vestibular system during body movements. An elderly person, unlike a child or young adult, has difficulty compensating for these abnormalities. Proof that the gait of such persons is dependent on visual clues comes from their performance blindfolded or in the dark, when their unsteadiness and staggering increase to the point of falling. The diagnosis is confirmed by testing labyrinthine function (caloric and rotational testing, electronystagmography, and posture platform testing).

A loss of proprioception—as occurs in patients with severe large-fiber polyneuropathy, posterior root lesions (e.g., tabes dorsalis, lumbosacral compression), or complete interruption of the posterior columns in the cervical spinal cord (multiple sclerosis, vitamin B deficiency, spondyloitic or neoplastic compression)—abolishes or seriously impairs the capacity for independent locomotion. After years of training, such patients still have difficulty in initiating gait and in forward propulsion. As Purdon Martin has illustrated, they hold their hands in front of the body, bend the body and head forward, walk with a wide base and irregular, uneven steps, but still rock the body. If they are tilted to one side, they fail to compensate for their abnormal posture. If they fall, they cannot arise without help; they are unable to crawl or to get into an "all fours" posture. They have difficulty in getting up from a chair. When standing, if instructed to close their eyes, they sway markedly and may fall (Romberg sign). This informs us that static postural reactions are primarily dependent on proprioceptive rather than on visual or labyrinthine information.

With lesions of the basal ganglia, both in monkeys and in humans, the posture of the body and the postural responses to disturbed equilibrium are faulty. There is difficulty in taking the first step; once it is taken, the body pitches forward and a fall can be prevented only by catch-up stepping (propulsion). Similarly, a step backwards may induce a series of quickening steps in that direction (retropulsion). Corrective righting reflexes are clearly in abeyance when the patient is pushed off balance (Denny-Brown). These abnormalities are elaborated further on, under "Festinating Gait."

**Examination of the Patient with Abnormal Gait**

When confronted with a disorder of gait, the examiner must observe the patient's stance and the attitude and dominant positions of the legs, trunk, and arms. It is good practice to watch patients as they walk into the examining room, when they are apt to walk more naturally than during the performance of special tests. They should be asked to stand with feet together and head erect, with eyes open and then closed. A normal person can stand with feet together and eyes closed while moving the head from side to side, a test that eliminates both visual and vestibular cues and induces certain compensatory trunk and leg movements that depend on proprioceptive afferent mechanisms (Ropper). A Romberg sign—marked swaying or falling with the eyes closed but not with the eyes open—usually indicates a loss of postural sense, not of cerebellar function, although with vestibular or cerebellar dysfunction there may be a less pronounced exaggeration of swaying with eyes closed and feet together. Swaying due to nervousness may be overcome by asking the patient to touch the tip of his nose alternately with the forefinger of one hand and then the other.

The patient should be asked to walk, noting in particular any hesitation in starting and negotiating turns, width of base, length of stride, foot clearance, arm swing, and cadence. A tendency to veer to one side, as with unilateral cerebellar disease, can be brought out by having the patient walk around a chair. When the affected side is toward the chair, the patient tends to walk into it; when it is away from the chair, there is a veering outward in ever-widening circles. More delicate tests of gait are walking a straight line heel to toe and having the patient arise quickly from a chair, walk briskly, stop and turn suddenly, and then sit down again.

It is instructive to observe the patient's postural reaction to a sudden push backward and forward or to the side. With postural instability there is a delay or inadequacy of reactive postural activity. Finally, the patient should be asked to hop on one leg and to jog. If all these tests are successfully executed, it may be assumed that any difficulty in locomotion is not due to impairment of a proprioceptive, labyrinthine-vestibular, basal ganglionic, or cerebellar mechanism. Detailed musculoskeletal and neurologic examination is then necessary to determine which of several other disturbances of function is responsible for the patient's disorder of gait.

The following types of abnormal gait are so distinctive that, with a little practice, they can be recognized at a glance.

**Cerebellar Gait**

The main features of this gait are a wide base (separation of legs), unsteadiness, irregularity of steps, and lateral veering. Steps are uncertain, some are shorter and others longer than intended, and the patient may compensate for these abnormalities by shortening his steps and shuffling, i.e., keeping both feet on the ground simultaneously. Cerebellar gait is often referred to as "reeeling" or "drunken," but these adjectives are not entirely apt, as explained further on.

With cerebellar ataxia, the unsteadiness and irregular swaying of the trunk are more prominent when the patient arises from a chair or turns suddenly while walking and may be most evident when he has to stop walking abruptly and sit down; it may be necessary for him to grasp the chair for support. It is noteworthy that patients with purely cerebellar gait abnormalities may not complain of imbalance or vertigo. Cerebellar ataxia may be so severe that the patient cannot stand without assistance. If it is less severe, standing with feet together and head erect is difficult. In its mildest form, the ataxia is best demonstrated by having the patient walk a line heel to toe; after a step or two, he loses his balance and finds it necessary to place one foot to the side to avoid falling.

The patient with cerebellar ataxia who sways perceptibly when standing with feet together and eyes open even more so with eyes closed. By contrast, reactions of visual clues from a patient with proprioceptive loss causes a marked increase in swaying or falling (Romberg test). Thus, the deficit in cerebellar gait is not primarily in antagonistic support, stepping, or propulsion but in the coordination of proprioceptive, labyrinthine, and visual information in reflex movements, particularly those that are required to make rapid adjustments to changes in posture and position.

Cerebellar abnormalities of stance and gait are usually accompanied by signs of cerebellar incoordination of the arms and legs, but they need not be so. The presence of the latter signs depends on involvement of the cerebellar hemispheres as distinct from the ancerosuperior (vermian) midline structures. With thalamic and midbrain lesions (beyond the decussation of the brachium conjunctivum), the ataxic signs are on the opposite side. If the lesions are bilateral, there is often titubation (tremor) of the head and trunk.

Cerebellar gait is seen most commonly in patients with multiple sclerosis, cerebellar tumors (particularly those affecting the vermis disproportionately—e.g., medulloblastoma), stroke, and the cerebellar degenerations. In certain forms of cerebellar degeneration in which the disease process remains stable for many years, e.g., the type associated with chronic alcoholism, the gait disorder becomes altered as compensations are acquired. The base is wide and the steps are still short but...
more regular, the trunk is inclined slightly forward, the arms are held somewhat away from the body, and the gait assumes a more mechanical, rhythmic quality. In this way the patient can walk for long distances, but he still lacks the capacity to make the necessary postural adjustments in response to sudden changes in position, such as occur in walking on uneven ground.

Many patients with cerebellar disease, particularly of acute type, also show pendulosity of the patellar reflexes and other signs of hypotonia of the limbs when they are examined in the sitting or recumbent position, as discussed in Chap. 5. Paradoxically, walking without the support of a cane or the arm of a companion brings out a certain stiffness of the legs and firmness of the muscles. The latter abnormality may be analogous to positive supporting reactions observed in cats and dogs following ablation of the anterior vermis; such animals react to pressure on the foot pad with an extensor thrust of the leg.

**Drunken, or Reeling, Gait**

This is characteristic of intoxication with alcohol and other sedative drugs. The drunken patient totters, reels, tips forward and then backward, appearing each moment to be on the verge of losing his balance and falling. Control over the trunk and legs is greatly impaired. The steps are irregular and uncertain. Such patients appear stupefied and indifferent to the quality of their performance, but under certain circumstances they can momentarily correct the defect. As indicated above, the adjectives drunken and reeling are used frequently to describe the gait of cerebellar disease, but the similarities between them are only superficial. The severely intoxicated patient totters in many different directions and seemingly makes little or no effort to correct his staggering by watching his legs or the ground, as in cerebellar or sensory ataxia. Also, the variability of the drunken gait is noteworthy. Despite wide excursions of the body and deviation from the line of march, the drunken patient may, for short distances, be able to walk on a narrow base and maintain his balance. In contrast, the patient with cerebellar gait has great difficulty in correcting his balance if he sways or lurches too far to one side. Milder degrees of the drunken gait more closely resemble the gait disorder that follows loss of labyrinthine function (see earlier discussion).

**Gait of Sensory Ataxia**

This disorder of gait is due to an impairment of joint-position or muscular kinesthetic sense resulting from interruption of afferent nerve fibers in the peripheral nerves, posterior roots, posterior columns of the spinal cords, or medial lemnisci and occasionally from a lesion of both parietal lobes. Whatever the location of the lesion, its effect is to deprive the patient of knowledge of the position of his limbs and, more relevant to gait, to interfere with afferent kinesthetic information that does not attain conscious perception. A sense of imbalance is usually present. These patients are aware that the trouble is in the legs and not in the head, that foot placement is awkward, and that the ability to recover quickly from a misstep is impaired. The resulting disorder is characterized by varying degrees of difficulty in standing and walking; in advanced cases, there is a complete failure of locomotion, although muscular power is retained.

The principal features of the gait disorder are the brusqueness of movement of the legs and stamp of the feet. The feet are placed far apart to correct the instability, and patients carefully watch the ground and their legs. As they step out, the legs are flung abruptly forward and outward, in irregular steps of variable length and height. Many steps are attended by an audible stamp as the foot is forcibly brought down onto the floor (possibly to enhance joint-position sense). The body is held in a sharply flexed position, and some of the weight is supported on the cane that the severely ataxic patient usually carries. To use Ramsay Hunt's characterization, the patient with this gait disorder is described by his "stamp and stick." The ataxia is markedly exaggerated when the patient is deprived of his visual cues, as in walking in the dark. Such patients, when asked to stand with feet together and eyes closed, show greatly increased swaying or falling (the latter being the actual sign described by Romberg). It is said that in cases of sensory ataxia, the shoes do not show wear in any one place because the entire sole strikes the ground at once. Examination invariably discloses a loss of position sense in the feet and legs and usually of vibratory sense as well.

Formerly, a disordered gait of this type was observed most frequently with tabes dorsalis, hence the term tabetic gait; but it is also seen in Friedreich ataxia and related forms of spinocerebellar degeneration, subacute combined degeneration of the cord (vitamin B12 deficiency), syphilitic meningomyelitis, chronic sensory neuropathy, and those cases of multiple sclerosis or compression of the spinal cord (spondylosis and meningioma are the common causes) in which the posterior columns are predominantly involved.

**Steppage, or Equine, Gait**

This is caused by paralysis of the peroneal muscles, with resultant inability to dorsiflex and evert the foot (foot drop). The steps are regular and even, but the advancing foot hangs with the toes pointing toward the ground. Walking is accomplished by excessive flexion at the heel, the leg being lifted abnormally high in order for the foot to clear the ground. There is a slipping noise as the foot strikes the floor. Thus there is a superficial similarity to the tabetic gait, especially in severe polyneuropathy, where the features of steppage and sensory ataxia may be combined. However, patients with steppage gait alone are not troubled by a perception of imbalance; they fall mostly from tripping on carpet edges and curbstones.

Foot drop may be unilateral or bilateral and occurs in diseases that affect the peripheral nerves of the legs or motor neurons in the spinal cord, such as chronic acquired axonal neuropathies, Charcot-Marie-Tooth disease (peroneal muscular atrophy), progressive spinal muscular atrophy, and poliomyelitis. It may also be observed in certain types of muscular dystrophy in which the distal musculature of the limbs is involved.

A particular disorder of gait, also of peripheral origin and resembling steppage gait, may be observed in patients with painful dysesthesias of the soles of the feet. Because of the exquisite pain evoked by tactile stimulation of the feet, the patient treads gingerly, as though walking barefoot on hot sand or pavement, with the feet rotated in such a way as to limit contact with their most painful portions. Peripheral neuropathy (most often of the alcoholic-nutritional type), causalgia, and erythromelalgia are the usual causes.

**Hemiplegic and Paraplegic (Spastic) Gaits**

The patient with hemiplegia or hemiparesis holds the affected leg stiffly and does not flex it freely at the hip, knee, and ankle. The leg tends to rotate outward to describe a semicircle, first away from and then toward the trunk (circumduction). The foot scrubs the floor, and the toe and outer sole of the shoe are worn. One can recognize a spastic gait by the sound of slow, rhythmic scuffing of the foot and wearing of the medial toe of the shoe. The arm on the affected side is weak and stiff to a degree variable; it is carried in a flexed position and does not swing naturally. In the hemiparetic child, the arm tends to abduct as he steps forward. This type of gait disorder is most often a sequela of stroke or trauma but may result from a number of other cerebral conditions that damage the corticospinal pathway on one side.

The spastic paraplegic or paraparetic gait is, in effect, a bilateral hemiplegic gait affecting only the lower limbs. Each leg is advanced slowly and stiffly, with restricted motion at the hips and knees. The legs are extended or slightly bent at the knees and the thighs may be strongly adducted, causing the legs almost to cross as the patient walks (scissors gait). The steps are regular and short, and the patient advances only with great effort, as though wading waist-deep in water. An easy way to remember the main features of the hemiplegic and paraplegic gaits is through the letter S, for slow, stiff, and scraping. The defect is in the stepping mechanism and in propulsion, not in support or equilibrium.

A spastic paraparetic gait is the major manifestation of cerebral diplegia (cerebral palsy), the result of anoxia or other damage to the brain in the perinatal period. Also, this disorder of gait is seen in a variety of chronic spinal cord diseases involving the dorsolateral and ventral funiculi, including multiple sclerosis, syringomyelia, any type of chronic meningomyelitis, combined system disease of both the pernicious anemia (PA) and non-PA types, chronic spinal cord compression, and familial forms of spastic paraplegia. Frequently, the effects of posterior column disease are added, giving rise to a mixed gait disturbance—a spinal ataxia.

**Festinating and Parkinsonian Gait**

The term "festation" derives from the Latin festinare, "to hasten," and appropriately describes the involuntary acceleration or hastening that characterizes the gait of Parkinson disease (page 1130). Diminished or absent arm swing, turning en bloc, hesitation in starting to walk, shuffling, or "freezing" briefly when encountering doorways or other obstacles are the other stigmata of the parkinsonian gait. When they are joined to the typical tremor, unblinking and mask-like facial expression, general atitude of flexion, immobility, and poverty of movement, there can be little doubt as to the diagnosis. The arms are carried slightly flexed and ahead of the body, the body is incompletely turned to the side, and the patient is impelled to take increasingly short and rapid steps as though trying to catch up to his center of gravity. The steps become more and more rapid, and the patient could easily break into a trot and collide with an obstacle or fall if not assisted. Festination may be apparent when the patient is walking forward or backward. The defects are in the body from side to side, so that the feet may clear the floor, and in moving the legs quickly enough to overtake the center of gravity. The problem is compounded by the inadequacy of postural support reflexes,
demonstrable, in the standing patient, by a push against the sternum or a tug backward on the shoulder. A normal person readily retains his stability or adjusts to modest displacement of the trunk with a single step backward, but the parkinsonian patient may stagger or fall unless someone stands by to prevent it.

Other unusual gait disturbances are sometimes observed in Parkinson disease and were particularly prominent in the postencephalitic form, now practically extinct. For example, such a patient may be unable to take a step forward or does so only after he takes a few hops or one or two steps backward. Or walking may be initiated by a series of short steps or a series of steps of increasing size. Occasionally such a patient may run better than he walks or walk backward better than forward. Often, walking so preoccupies the patient that talking simultaneously is impossible and he must stop to answer a question.

Choreoathetotic and Dystonic Gaits

Diseases characterized by involuntary movements and dystonic postures severely affect gait. In fact, a disturbance of gait may be the initial and dominant manifestation of such diseases, and the testing of gait often brings out abnormalities of movement of the limbs and posture that are otherwise not conspicuous.

As the patient with congenital athetosis or Huntington chorea stands or walks, there is a continuous play of irregular movements affecting the face, neck, hands, and, in the advanced stages, the large proximal joints and trunk. The position of the arms and upper parts of the body varies with each step, at times giving the impression of a puppet. There are jerks of the head, grimacing, squirming and twisting movements of the trunk and limbs, and peculiar respiratory noises. One arm may be thrust ahead and the other held behind the body, with wrist and fingers undergoing alternate flexion and extension, supination and pronation. The head may incline in one direction or the other, the lips alternately retract and purse, and the tongue intermittently protrudes from the mouth. The legs advance slowly and awkwardly, the result of superimposed involuntary movements and postures. Sometimes the foot is planter-flexed at the ankle, and the weight is carried on the toes; or it may be dorsiflexed or inverted. An involuntary movement may cause the leg to be suspended in the air momentarily, imparting a liltting or waltzing character to the gait, or it may twist the trunk so violently that the patient may fall.

In dystonia musculorum deformans and in focal axial dystonias, the first symptom may be a limp due to inversion or planter flexion of the foot or a distortion of the pelvis. One leg may be rigidly extended or one shoulder elevated, and the trunk may assume a position of exaggerated flexion, lordosis, or scoliosis. Because of the muscle spasms that deform the body in this manner, the patient may have to walk with knees flexed. The gait may seem normal as the first steps are taken, the abnormal postures asserting themselves as the patient continues to walk. Prolonged standing, with a limb lordosis, combined with flexion of one leg or both legs at the hip, give rise to the so-called dromedary gait of Oppenheimer. In the more advanced stages, walking becomes impossible owing to torsion of the trunk or the continuous flexion of the legs.

The general features of choreoathetosis and dystonia are described more fully in Chap. 4.

Waddling (Glueteal or Trendelenburg) Gait

This gait is characteristic of progressive muscular dystrophy, but it occurs as well in chronic forms of spinal muscular atrophy, in certain inflammatory myopathies, and with congenital dislocation of the hips.

In normal walking, as weight is placed alternately on each leg, the hip is flexed by the gluteal muscles, particularly the gluteus medius, allowing for a slight rise of the opposite hip and of the trunk to the weight-bearing side. With weakness of the gluteus, there is a failure to stabilize the weight-bearing hip, causing it to bulge outward and the opposite side of the pelvis to drop, with inclination of the trunk to that side. The alternation in lateral trunk movements results in the roll or waddle.

In progressive muscular dystrophy, an accentuation of the lumbar lordosis is often associated. Also, childhood cases may be complicated by muscular contractures leading to an equinovarus position of the foot, so that the waddle is combined with circumduction of the legs and “walking on the toes.”

With unilateral gluteal weakness, often the result of damage to the first sacral nerve root, tilting and drooping of the pelvis is apparent on only one side as the patient overlifts the leg when walking.

Toppling Gait

Toppling, meaning tottering and falling, may occur with brainstem and cerebellar lesions, especially in the older person following a stroke. It is a frequent feature of the lateral medullary syndrome, in which falling occurs to the side of the infarction. In patients with vestibular neuritis, falling also occurs to the same side as the lesion. With the Tullio phenomenon (vertigo induced by loud high-pitched sounds, or yawning following a fenestration operation on the vestibule), the toppling is contraversive; with midbrain strokes, the falls tend to be backward. In patients with progressive supranuclear palsy (see page 1139), where dystonia of the neck is combined with paralysis of vertical gaze and pseudobulbar features, unexplained falling is often an early and prominent feature. In addition, the gait is uncertain and hesitant—features that are enhanced, no doubt, by the hazard of falling unpredictably. The cause of the toppling phenomenon is unclear; it does not have its basis in weakness, ataxia, or loss of deep sensation. It appears to be a disorder of balance that is occasioned by precipitant action or the wrong placement of a foot and by a failure of the righting reflexes. Slowness of motor response is another factor. When the deficit is due to a central vestibular disorder, the patient may describe a sense of being pushed (pulsion) rather than of imbalance. In midbrain disease, including progressive supranuclear palsy, a remarkable feature is the lack of appreciation of a sense of imbalance. In the advanced stages of Parkinson disease, falling of a similar type may be a serious problem.

Gait Disorder in Normal-Pressure Hydrocephalus

Progressive difficulty in walking is usually the initial and most prominent symptom of normal-pressure hydrocephalus (NPH), a disorder of cerebrospinal fluid (CSF) circulation described on page 663. The gait disturbance in NPH has few specific features. Certainly it cannot be categorized as an ataxic or spastic gait or what has been described as an “apraxic” gait; nor does it have more than a superficial resemblance to the parkinsonian gait. Its main features—diminished cadence, widened base, short steps, and shuffling—are the natural compensations observed in patients with all manner of gait disorders. Patients with the gait disorder of NPH often complain of a sense of imbalance or even of dizziness, but most of them have difficulty in articulating the exact problem. Like patients with other disorders of frontal lobe function, they can carry out the motions of stepping while supine or sitting but have difficulty in taking steps when upright or attempting to walk. There appears to be a dyscontrol of the entire axial musculature as the patient awkwardly assumes the erect posture—with hips and knees only slightly flexed and stiff and a delay in swinging the legs over the side of the bed.

Sudarsky and Simon have quantified these defects by means of high-speed cameras and computer analysis. They have also demonstrated a reduction in height of the stance base, short steps, and shuffling—are the natural compensations observed in patients with all manner of gait disorders. Patients with the gait disorder of NPH often complain of a sense of imbalance or even of dizziness, but most of them have difficulty in articulating the exact problem. Like patients with other disorders of frontal lobe function, they can carry out the motions of stepping while supine or sitting but have difficulty in taking steps when upright or attempting to walk. There appears to be a dyscontrol of the entire axial musculature as the patient awkwardly assumes the erect posture—with hips and knees only slightly flexed and stiff and a delay in swinging the legs over the side of the bed.

Frontal Lobe Disorder of Gait

Standing and walking may be severely affected by diseases that affect the frontal lobes, particularly their medial parts and their connections with the basal ganglia. This disorder is sometimes spoken of as a frontal lobe ataxia or as an apraxia of gait, since the difficulty in walking cannot be accounted for by weakness, loss of sensation, cerebellar incoordination, or basal ganglionic abnormalities. Whether the gait disorder should be designated as an apraxia, in the sense of Liepmann’s concept of arm and hand apraxia, is questionable, since walking is instinctual and not learned. Patients with so-called apraxia of gait do not have apraxia of individual limbs, particularly of the lower limbs; conversely, patients with apraxia of the limbs usually walk normally. More likely, the disorder represents a loss of integration, at the cortico- and basal ganglionic levels, of the essential instinctual elements of stance and locomotion that are acquired in infancy and often lost in old age.

Patients assume a posture of slight flexion, with the feet placed farther apart than normal. They advance slowly, with small, shuffling, hesitant steps. At times they halt, unable to advance without great effort, although they do much better with a little assistance or with exhortation to walk in step with the examiner or to a marching cadence. Turning is accomplished by a series of tiny, uncertain steps that are made with one foot, the other foot being planted on the floor as a pivot. There is a need...
to seek support from a companion's arm or nearby furniture. The initiation of walking becomes progressively more difficult; in advanced cases, the patient makes only feeble, abortive stepping movements in place, unable to move his feet and legs forward; in even more advanced cases, the patient can make no stepping movements whatsoever, as though his feet were glued to the floor. These late phenomena have been referred to colloquially as "magnetic feet" or the "slipping clutch" syndrome (Denny-Brown) and as "gait ignition failure" (Atchison et al.). In some patients, difficulty in the initiation of gait may be an early and apparently isolated phenomenon, but invariably, with the passage of time, sometimes of years, the other features of the frontal lobe gait disorder become evident. Finally, as in untreated NPH, these patients become unable to stand or even to sit; without support, they fall helplessly backward or to one side. Most patients, while seated or supine, are able to make complex movements with their legs, such as drawing imaginary figures or pedaling a bicycle, at a time when their gait is seriously impaired. Eventually, however, all movements of the legs become slow and awkward, and the limbs, when passively moved, offer variable resistance (gegenhalten). Difficulty in turning over in bed is highly characteristic and may eventually become complete. These advanced motor disabilities are usually associated with dementia, but the two disorders need not evolve in parallel. Thus, some patients with Alzheimer disease may show a serious degree of dementia for several years before a gait disorder becomes apparent, in other conditions, such as NPH and Binswanger disease, the opposite pertains. Or both the dementia and gait disorder may evolve more or less together. Grasping, groping, hyperactive tendon reflexes, and Babinski signs may or may not be present. The end result in some cases is a "cerebral paraplegia in flexion" (Yakovlev), in which the patient lies curled up in bed, immobile and mute, with the limbs fixed by contractures in an attitude of flexion (Fig. 7-2).

Figure 7-2 The evolution of erect stance and gait and paraplegia in flexion of cerebral origin according to Yakovlev. The ripening forebrain of the fetus drives the head and body up and moves the individual onward. When the "driving brain" (frontal lobe, striatum, and pallidum) degenerates, the individual "curls up" again. (Adapted by permission from Yakovlev.) Lesser degrees of this sequence, indicated by the upper line, may account for the changes in gait and posture that accompany normal aging (see Fig. 7-3).

Figure 7-3 Diagram illustrating the changes in posture and gait that accompany aging ("senile gait"). With aging (figure on left), there occurs a decrease in the length of stride, excursion of the hip, elevation of the toes of the forward foot and the heel of the rear foot, shoulder flexion on forward arm swing, and elbow extension on backward swing. (Redrawn permission from Murray et al.)

In addition to NPH and Alzheimer disease, the causes of frontal lobe gait disorder include widespread neoplasm (meningioma, infiltrating glioma), subcortical arteriosclerotic encephalopathy (Binswanger disease; see Thompson and Marsden) Pick disease, and frontal lobe damage from trauma, stroke, or a ruptured anterior communicating aneurysm.

Gait of the Aged

An alteration of gait unrelated to overt cerebral disease is an almost universal accompaniment of aging (Fig. 7-3). Lost with aging are the speed, balance, and many of the quick and graceful adaptive movements that characterize the gait of younger individuals. A slightly stooped posture, varying degrees of slowness and stiffness of walking, shortening of the stride, slight widening of the base, and a tendency to turn en bloc are the main objective characteristics. The shortening of stride and widening of the base provide the support that enables the elderly individual to more confidently maintain his balance but result in a somewhat guarded gait, like that of a person walking on a slippery surface or in the dark.

Lacking to a varying degree in the elderly is the ability to make the rapid compensatory postural changes ("rescue responses") that are necessary to cushion or prevent a fall. A slight misstep, a failure to elevate the foot sufficiently, or tipping of the center of gravity to one side often cannot be corrected—features, no doubt, that account for the frequency of falls and fear of falling. Most persons with this type of gait disturbance are aware of impaired balance and their need for caution to avoid falls (the "cautious gait"); see Nutt et al.). As such, this gait disorder lacks specificity, being a general adaptive or defensive reaction to all forms of defective locomotion.

The nature of this gait disorder is not fully understood. It may simply represent a mild degree of neuronal loss, attributable to aging itself, which in a severe (pathologic) form is referred to as a "frontal lobe disorder of gait" (as discussed above). Inadequate proprioception, slowness in making corrective postural responses, diminished vestibular function of varying degree, and weakness of pelvic and thigh muscles are probably contributing factors, as are degenerative joint changes of the spine, hips, and knees. Fisher has remarked upon the similarity of the senile gait to that of NPH and suggests that this form of hydrocephalus underlies the gait disorder of many elderly but mentally competent persons. The changes in gait due to aging are discussed further in Chap. 29.

Gaits of the Mentally Retarded

There are, in addition to the disorders described above, peculiarities of gait that defy analysis. One has only to observe the assortment of gait abnormalities among the institutionalized mentally handicapped to appreciate this fact. An ungraceful stance with the head too far forward or the neck extended and arms held in odd positions, a wide-based gait with awkward lurches or feet stomping the floor—each patient with his own ungraceful style—these are but a few of the peculiarities that meet the eye. One tries in vain to relate them to a disorder of proprioception, cerebellar deficit, or pyramidal or extra-pyramidal disease.

The only plausible explanation that comes to mind is that these pathologic variants of gait are based on a retardation of the natural developmental sequence of the cerebral and spinal mechanisms involved in bipedal locomotion, posture, and righting. The acquisition of the refinements of locomotion—such as running, hopping, jumping, dancing, balancing on one foot, kicking a ball, etc.—are age-linked; i.e., each has its average age of acquisition. There are wide individual variations, but the most striking extremes are found in the mentally handicapped, who may be retarded in these ways as well as in cognitive development. The rhythmic rocking movements and hand clapping, odd mannerisms, waving of the arms, tremors, and other stereotyped patterns mentioned in Chap. 29 make their performances even

§
Hysterical Gait

This may take one of several forms. There may be a hysterical monoplegia, hemiplegia, or paraplegia. In walking, the patient may hesitate and advance the leg in a grossly ataxic or tremulous manner. Typically, patients with a hysterical paralysis of the leg do not lift the foot from the floor while walking; instead, they tend to drag the leg as a useless member or push it ahead of them as though it were on a skate. In hysterical hemiparesis, the characteristic circumscription of the leg is absent, as are the usual hemiparetic postures, hyperactive tendon reflexes, and Babinski sign. The hysterical paraplegic cannot very well drag both legs and usually depends on canes or crutches or remains helpless in bed or in a wheelchair; the muscles may be flaccid or rigid, with development of contractures. The hysterical gait may take other dramatic forms. Some patients look as though they were walking on stilts, others assume extreme dystonic postures, and still others lurch wildly in all directions without falling, actually demonstrating by their gyrations a normal ability to make rapid and appropriate postural adjustments. The gait disorder may be accompanied by similarly exaggerated movements of the arms, as though to impress the observer with the great effort required to walk and maintain balance. The many forms of hysterical gait have been well described by Keane. Leg movements in bed may be unpaired or the patient may display a Hoover sign (page 65). Many of the patients exhibit abnormalities of the voice and visual fields, tremors, and weakness of muscle contraction.

Astartia-abasia—in which patients, though unable to either stand or walk, display more or less normal use of their legs while in bed and have an otherwise normal neurologic examination and body carriage—is nearly always a hysterical condition. When such patients are placed on their feet, they may take a few steps and then become unable to advance their legs; they lurch in all directions and crumple to the floor if not assisted. On the other hand, one should not assume that a patient who manifests a disorder of gait but no other neurologic abnormality is necessarily suffering from hysteria. Lesions that are restricted to the anterolateral cerebellar vermis may cause an ataxia that becomes manifest only when the patient attempts to stand and walk; this is true of normal-pressure hydrocephalus and frontal lobe disease as well (see above).

Rehabilitative Measures

Once the gait abnormality is stable, i.e., neither progressive nor regressive, one should explore the possibility of rehabilitation by a combination of medical therapy and other corrective measures. The antispasticity agents baclofen and tizanidine are somewhat helpful when stiffness of the limbs exceeds weakness. They may reduce spasticity of the legs, but sometimes at the expense of exposing, to a greater degree than before, a loss of muscle power—the net effect being to the patient's disadvantage. Hypofunction of the labyrinths, as in drug-induced or idiopathic vestibulopathy, has greatly challenged physiatrists. Balance training and the more effective use of postural correction and vision have helped some of these patients to move more steadily and better able to function in the activities of daily living and at work (Baloh and Honrubia). Exercises to strengthen leg muscles can be beneficial, as can weight loss. Likewise, gait ataxia from proprioceptive defects can probably be corrected to some extent by careful attention to visual control and proper placement of the feet. Some success has been reported by Heitmann and colleagues in training elderly who fall frequently. Ventricular shunting in idiopathic hydrocephalus has restored locomotion in patients with this syndrome. Once dementia becomes conjoined with any of the gait disorders that occur in older age, rehabilitation stands little chance of success, since the ability to attend to small changes in terrain and posture are lost. Progression from the use of a cane, to a pronged cane, and finally to a four-posted walker allows patients with all types of gait disorders to maintain some mobility. The optimal use of these orthoses is best directed by an experienced physical therapist.

Pain, it has been said, is one of “nature’s earliest signs of morbidity,” and it stands pre-eminent among all the sensory experiences by which humans judge the existence of disease within themselves. Indeed, pain is the most common symptom of disease. Relatively few diseases do not have a painful phase, and in many pain is a characteristic without which diagnosis must be in doubt.

The painful experiences of the sick pose manifold problems in virtually every field of medicine, and physicians must learn something of these problems and their management if they are to practice their profession effectively. They must be prepared to recognize disease in patients who have felt only the first rumblings of discomfort, before other symptoms and signs have appeared. Even more problematic are patients who seek treatment for pain that appears to have little or no structural basis; further inquiry may disclose that fear of serious disease, worry, or depression has aggravated some relatively minor ache or that the complaint of pain has become the means of seeking drugs or monetary compensation. They must also cope with the “difficult” pain cases in which no amount of investigation brings to light either medical or psychiatric illness. Finally, the physician must be prepared to manage patients who demand relief from intractable pain caused by established and incurable disease. To deal intelligently with such pain problems requires familiarity with the anatomy of sensory pathways and the sensory supply of body segments as well as insight into the psychologic factors that influence the perception of and reaction to pain.

The dual nature of pain is responsible for some of our difficulty in understanding it. One aspect, the easier to comprehend, is its evocation by particular stimuli and the transmission of pain impulses along certain pathways, i.e., the sensation of pain. Far more abstruse is its quality as a mental state intimately linked to emotion, i.e., the quality of anguish or suffering—“a passion of the soul,” in the words of Aristotle—which defies definition and quantification. This duality is of practical importance, for certain drugs or surgical procedures, such as cingulotomy, may reduce the patient’s reaction to painful stimuli, leaving his awareness of the sensation largely intact. Alternatively, interruption of certain neural pathways may abolish all sensation in an affected part, but the symptom of pain may persist (i.e., denervation dysesthesia or anesthesia dolorosa), even in an amputated limb (“phantom pain”). Unlike most sensory modalities—which are aroused by a specific stimulus such as touch-pressure, heat, or cold—pain can be evoked by any one of these stimuli if it is intense enough.

It is apparent to the authors that in highly specialized medical centers, and often even in “pain centers,” few physicians are capable of handling difficult and unusual pain problems in any comprehensive way. In fact, it is to the neurologist that other physicians regularly turn for help with these matters. Although much has been learned about the anatomy of pain pathways, their physiologic mechanisms, and which structures to ablate in order to produce analgesia, relatively little is known about which patients should be subjected to these destructive operations or how to manage their pain by medical means. Here is a subspecialty that should challenge every thoughtful physician, for it demands the highest skill in medicine, neurology, and psychiatry.

ANATOMY AND PHYSIOLOGY OF PAIN

Historical Perspective

For more than a century, views on the nature of pain sensation have been dominated by two major theories. One, known as the specificity theory, was from the beginning associated with the name of von Frey. He asserted that the skin consisted of a mosaic of discrete sensory spots and that each spot, when stimulated, gave rise to one sensation—either pain, pressure, warmth, or cold; in his view, each of these sensations had a distinctive end organ in the skin and each stimulus-specific end organ was connected by its own private pathway to the brain. A second theory was that of Goldscheider, who abandoned his own earlier discovery of pain spots to argue that they simply represented pressure spots, a sufficiently intense stimulation of which could produce pain. According to the latter theory, there were no distinctive pain receptors, and the sensation of pain was the result of the summation of impulses excited by pressure or thermal stimuli applied to the skin. Originally called the intensity theory, it later became known as the pattern or summation theory.

In an effort to conciliate the pattern and specificity theories, Head and his colleagues, in 1905, formulated a novel concept of pain sensation, based on observations that followed division of the cutaneous branch of the radial nerve in Head’s own forearm. The zone of impaired sensation contained an innervated area in which superficial sensation was completely abolished. This was surrounded by a narrower ("intermediate") zone, in which pain sensation was preserved but poorly localized; extreme degrees of temperature were recognized in the intermediate zone, but perception of touch, lesser differences of temperature, and two-point discrimination were abolished. To explain these findings, Head postulated the existence of two systems of cutaneous receptors and conducting fibers: (1) an ancient protopathic system, subserving pain and extreme differences in temperature and yielding ungraded, diffuse impressions of an all-or-none type, and (2) a more recently evolved epicritic system, which mediated touch, two-point discrimination, and lesser differences in temperature as well as localized pain. The pain and hyperesthesia that follow damage to a peripheral nerve were attributed to a loss of inhibition that was normally exerted by the epicritic upon the protopathic system. This theory was used for many years to explain the sensory alterations that occur with both peripheral and central (thalamic) lesions. It lost credibility for several reasons, but mainly because Head’s original observations (and deductions upon which they were based) could not be corroborated (see Trotter and Davies; also Walsh). Nevertheless, both a fast and a slow form of pain conduction were later corroborated (see below).

A much later refinement of the pattern and specificity concepts of pain was made in 1965, when Melzack and Wall postulated their “gate-control” theory. They observed, in decerebrate and spinal cats, that peripheral stimulation of large myelinated fibers produced a negative dorsal root potential and that stimulation of small C (pain) fibers caused a positive dorsal root potential. They postulated that these potentials, which were a reflection of presynaptic inhibition or excitation, modulated the activity of secondary transmitting neurons (T cells) in the dorsal horn, and that this modulation was mediated through inhibitory (I) cells. The essence of this theory is that the large-diameter fibers excite the I cells, which, in turn, cause a presynaptic inhibition of the T cells; conversely, the small pain afferents inhibit the I cells, leaving the T cells in an excitatory state. Melzack and Wall emphasized that pain impulses from the dorsal horn must also be under the control of a descending system of fibers from the brainstem, thalamus, and limbic lobes.

At first the gate-control mechanisms seemed to offer an explanation of the pain of ruptured disc and of certain chronic neuropathies (large fiber outfall), and attempts...
were made to relieve pain by subjecting the peripheral nerves and dorsal columns (presumably their large myelinated fibers) to sustained, transcutaneous electrical stimulation. Such selective stimulation would theoretically “close the gate.” In some clinical situations, these procedures have indeed given relief from pain, but not necessarily due to stimulation of large myelinated fibers alone (see Taub and Campbell). And in a number of other instances relating to pain in large- and small-fiber neuropathies, the clinical behavior has been quite out of keeping with what one would expect on the basis of the gate-control mechanism. As with preceding pain theories, flaws have been exposed in the physiologic observations on which the theory is based. These and other aspects of the gate-control theory of pain have been critically reviewed by P. W. Nathan.

During the last few decades there has been a significant accrual of information on cutaneous sensibility, demanding a modification of earlier anatomo-physiologic and clinical concepts. Interestingly, much of this information is still best described and rationalized in the general framework of specificity, as will be evident from the ensuing discussion on pain and on other forms of cutaneous sensibility in the chapter that follows.

Pain Receptors and Peripheral Afferent Pathways

In terms of peripheral pain mechanisms, as already implied, there is indeed a high degree of specificity, though not an absolute specificity in the von Frey sense. It is now well established that two types of afferent fibers in the distal axons of primary sensory neurons respond maximally to nociceptive (i.e., potentially tissue-damaging) stimuli. One type is the very fine, unmyelinated, slowly conducting C fiber (0.4 to 1.1 mm in diameter), and the other is the thinly myelinated, more rapidly conducting A-delta (A-d) fiber (1.0 to 5.0 mm in diameter). The peripheral terminations of both these primary pain afferents, or receptors, are the free, profusely branched nerve endings in the skin and other organs; these are covered by Schwann cells and contain little or no myelin. There is considerable evidence, based on their response characteristics, that a degree of subspecialization exists among these freely branching, noncapsulated endings and their small fiber afferents. Three broad categories of free endings, or receptors, are recognized: mechanoreceptors, thermoreceptors, and polymodal nociceptors. Each ending transduces stimulus energy into an action potential in nerve membranes. The first two types of receptors are activated by innocuous mechanical and thermal stimulation, respectively; the mechanoreceptors are transmitted by both A-d and C fibers and the thermal effects only by C fibers. The polymodal afferents are most effectively excited by noxious or tissue-damaging stimuli, but they can respond as well to both mechanical and thermal stimuli and to chemical mediators such as those associated with inflammation. Moreover, certain A-d fibers respond to light touch, temperature, and pressure as well as to pain stimuli and are capable of discharging in proportion to the intensity of the stimulus. The stimulation of single fibers by intraneuralelectrodes indicates that they can also convey information concerning the nature and location of the stimulus (local sign). These observations on the polymodal functions of A-d and C fibers would explain the earlier observations of Lele and Weddell that modes of sensation other than pain can be evoked from structures such as the cornea, which is innervated solely by fine nerve endings.

The peripheral afferent pain fibers of both A-d and C types have their cell bodies in the dorsal root ganglia; central extensions of these nerve cells project, via the dorsal root, to the dorsal horn of the spinal cord (or, in the case of cranial pain afferents, to the nucleus of the trigeminal nerve, the medullary analogue of the dorsal horn). The pain afferents occupy mainly the lateral part of the root entry zone. Within the spinal cord, many of the thinnest fibers (C fibers) form a discrete bundle, the tract of Lissauer (Fig. 8-1A). That Lissauer's tract is predominantly a pain pathway is shown (in animals) by the ipsilateral segmental analgesia that results from its transection, but it contains deep sensory, or propriospinal, fibers as well. Although it is customary to speak of a lateral and medial division of the posterior root (the former contains small pain fibers and the latter, large myelinated fibers), the separation into discrete functional bundles is not complete, and in humans the two groups of fibers cannot be differently interrupted by selective rhizotomy.

Dermatometric Distribution of Pain Fibers

Each sensory unit (the sensory nerve cell in the dorsal root ganglion, its central and peripheral extensions, and cutaneous and visceral endings) has a unique topography that is maintained throughout the system from the periphery to the sensory cortex. The discrete segmental distribution of the sensory units permits the construction of sensory maps, so useful to clinicians. This aspect of sensory anatomy is elaborated in the next chapter, which includes maps of the sensory dermatomes and cutaneous nerves. However, as a means of quick orientation to the topography of peripheral pain pathways, it is useful to remember that the facial structures and anterior cranium lie in the fields of the trigeminal nerves; the back of the head, second cervical; the neck, third cervical; the eaulpeut area, fourth cervical; the deltoid area, fifth cervical; the radial forearm and thumb, sixth cervical; the index and middle fingers, seventh cervical; the little finger and ulnar border of hand and forearm, eighth cervical–first thoracic; the nipple, fifth thoracic; the umbilicus, tenth thoracic; the groin, first lumbar; the medial side of the knee, third lumbar; the great toe, fifth lumbar; the little toe, first sacral; the back of the thigh, second sacral; and the genital areas, the third, fourth, and fifth sacral. The distribution of pain fibers from deep structures, though not fully corresponding to those from the skin, also follows a segmental pattern. The first to fourth thoracic nerve roots are the important sensory pathways for the heart and lungs; the sixth to eighth thoracic, for the upper abdominal organs; and the lower thoracic and upper lumbar, for the lower abdominal viscera.

The Dorsal Horn

The afferent pain fibers, after traversing Lissauer's tract, terminate in the posterior gray matter or dorsal horn, predominantly in the marginal zone. Most of the fibers terminate within the segment of their entry into the cord; some extend ipsilaterally to one or two adjacent rostral and caudal segments; and some project, via the ascending tracts to the contralateral dorsal horn. Although the electrophysiologic studies of REXED (the same organization persists in primates and probably in humans) have shown that second-order neurons, the sites of synapse of afferent sensory fibers in the dorsal horn, are arranged in a series of six layers or laminae (Fig. 8-1B). Fine, myelinated (A-d) fibers terminate principally in lamina I of REXED (marginal cell layer of Waldeyer) and also in the outermost part of lamina II; some A-d pain fibers penetrate the dorsal gray matter and terminate in the lateral part of lamina V. Unmyelinated (C) fibers terminate in lamina II (substantia gelatinosa). Yet other cells that respond to painful cutaneous stimulation are located in ventral horn laminae VII and VIII. The latter neurons are responsive to descending impulses from brainstem nuclei as well as segmental sensory impulses. From these cells of termination, second-order axons connect with ventral and lateral horn cells in the same and adjacent spinal segments and subserve both somatic and autonomic reflexes. The main bundle of secondary neurons subserving pain sensation projects contralaterally (and to a lesser extent ipsilaterally) to higher levels.

In recent years, a number of important observations have been made concerning the mode of transmission and modulation of pain impulses in the dorsal horn and brainstem. Excitatory amino acids (glutamate, aspartate) and nucleotides such as adenosine triphosphate (ATP) are the putative transmitters at terminals of primary A-d sensory afferents. Also, A-d pain afferents, when stimulated, release several neuromodulators that play a role in the transmission of pain sensation. Slower neurotransmission by C neurons involves other substances, of which the most important is the 11–amino acid peptide known as substance P. In animals, substance P has been shown to excite nociceptive dorsal root ganglion and dorsal horn neurons; furthermore, destruction of substance P fibers produces analgesia. In patients with the rare condition of congenital neuropathy and insensitivity to pain, there is a marked depletion of dorsal horn substance P.

A large body of evidence indicates that opiate are important modulators of pain impulses that are relayed through the dorsal horn and centers in the medulla and pons. Thus, opiates have been noted to decrease substance P; at the same time, flexor spinal reflexes, which are evoked by segmental pain, are reduced. Opiate receptors of three types are found on both presynaptic primary afferent terminals and postsynaptic dendrites of small neurons in lamina II. Moreover, lamina II of the dorsal horn...
neurons, when activated, release enkephalins, endorphins, and dynorphins—all of which are endogenous, morphine-like peptides that bind specifically to opiate receptors and inhibit pain transmission at the dorsal horn level. The subject of pain modulation by opiates and endogenous morphine-like substances is elaborated further on.

**Spinal Afferent Tracts for Pain**

**Lateral Spinothalamic Tract** As indicated above, axons of secondary neurons that subserve pain sensation originate in laminae I, II, V, VII, and VIII of the spinal gray matter. The principal bundle of these axons decussates in the anterior spinal commissure and ascends in the anterolateral fasciculus to terminate in several brainstem and thalamic structures (Fig. 8-2). It is of clinical consequence that the axons from each dermatome decussate one to three segments above the level of root entry; in this way a discrete lesion of the lateral spinal cord creates a loss of pain and thermal sensation of the contralateral trunk, the dermatomal level of which is *two to three segments below that of the spinal cord lesion*. As the ascending fibers cross the cord, they are added to the inner side of the *spinothalamic tract* (the principal afferent pathway of the anterolateral fasciculus), so that the longest fibers from the sacral segments come to lie most superficially and fibers from successively more rostral levels occupy progressively deeper positions (Fig. 8-3). This somatotopic arrangement is of importance to the neurosurgeon insofar as the depth to which the funiculus is cut will govern the level of analgesia that is achieved; for the neurologist, it provides an explanation of the “sacral sparing” of sensation created by centrally placed lesions of the spinal cord.

**Other Spinocerebral Afferent Tracts** In addition to the lateral spinothalamic tract—the fast-conducting pathway that projects directly to the thalamus—the anterolateral fasciculus of the cord contains several more slowly conducting, medially placed systems of fibers. One such group of fibers projects directly to the reticular core of the medulla and midbrain and then to the medial and intralaminar nuclei of the thalamus; this group of fibers is referred to as the *spinoreticulothalamic pathway* (Fig. 8-4). At the level of the medulla, these fibers synapse in the nucleus gigantocellularis; more rostrally, they connect with nuclei of the parabrachial region, midbrain reticular formation, periaqueductal gray matter, and hypothalamus. A second, more medially placed pathway ascends to the brainstem reticular core via a series of short interneuronal links. It is not clear whether these spinoreticular fibers are collaterals of the spinothalamic tracts, as Cajal originally stated, or whether they represent an independent system, as more recent data seem to indicate. Probably both statements are correct. There is also a third, direct spinopreticular pathway. All three spinoreticular fiber systems lie in the posteromedial part of the lateral column. The conduction of diffuse, poorly localized pain arising from deep and visceral structures (gut, peristem) has been ascribed to these pathways. Melzack and Casey have proposed that this fiber system (which they refer to as *paramedian*), with its diffuse projection via brainstem and thalamus to the limbic and frontal lobes, subserves the affective aspects of pain, i.e., the unpleasant feelings engendered by pain. It is evident that these spinoreticulothalamic pathways continue to evoke the psychic experience of pain even when the direct (anterolateral) spinothalamic pathways have been interrupted. However, it is the lateral pathway, which projects to the ventroposterolateral (VPL) nucleus of the thalamus and thence to discrete areas of the sensory cortex, that subserves the *sensory-discriminative* aspects of pain, i.e., the processes that underlie the localization, quality, and possibly the intensity of the noxious stimulus. Also, the pathways for visceral pain from the esophagus, stomach, small bowel, and proximal colon are carried largely in the vagus nerve and terminate in the nucleus of the solitary tract (NTS) before projecting to the thalamus, as described below. Other abdominal viscera still activate the NTS when the vagus is severed in animals, probably passing through the splanchnic plexus.

It should be emphasized that the foregoing data concerning the cells of termination of cutaneous nociceptive stimuli and the cells of origin of ascending spinal afferent pathways have all been obtained from studies in animals (including monkeys). In humans, the cells of origin of the long (direct) spinothalamic tract fibers have not been fully identified. Information about this pathway in humans has been derived from the study of postmortem material and from the examination of patients subjected to anterolateral cordotomy for intractable pain. As mentioned above, unilateral section of the anterolateral funiculus produces a relatively complete loss of pain and thermal sense on the opposite side of the body, extending to a level two or three segments below the lesion. After a variable period of time, pain sensation.

---

**Figures**

*Figure 8-2* The main somatosensory pathways. Offsets from the ascending anterolateral fasciculus (spinothalamic tract) to nuclei in the medulla, pons, and mesencephalon and nuclear terminations of the tract are indicated in Fig. 8-4.

*Figure 8-3* Spinal cord showing the segmental arrangement of nerve fibers within major tracts. On the left side are indicated the “sensory modalities” that appear to be mediated by the two main ascending pathways. Note the broad zone close to the gray matter occupied by propriospinal fibers. C, cervical; L, lumbar; S, sacral; Th, thoracic. (Adapted by permission from Brodal A: Neurological Anatomy, 3rd ed. New York, Oxford University Press, 1981.)

*Figure 8-4* The paleospinothalamic tract is illustrated on the right. This is a slow-conducting multineuron system that mediates poorly localized pain from deep somatic and visceral structures. On the left is the major descending inhibitory pathway, derived mainly from the periaqueductal gray matter and brainstem raphe nuclei. It modulates pain input at the dorsal horn level.
usually returns, probably being conducted by pathways that lie outside the entorolateral quadrants of the spinal cord and which gradually increase their capacity to conduct pain impulses. One of these is a longitudinally polysynaptic bundle of small myelinated fibers in the center of the dorsal horn (the dorsal intracolumnar tract); another consists of axons of lamina I cells that travel in the dorsal part of the lateral funiculus.  

Thalamic Terminus of Pain Fibers  
The direct spinothalamic fibers separate into two bundles as they approach the thalamus. The lateral division terminates in the ventrobasal and posterior groups of nuclei. The medial contingent terminates mainly in the intralaminar complex of nuclei and in the nucleus submedius. Spinoreticulothalamic (paleospinothalamic) fibers project onto the medial intralaminar (primarily parasubiculum and centrolateral) thalamic nuclei; i.e., they overlap with the terminations of the medially projecting direct spinothalamic pathway. Projections from the dorsal column nuclei, which have a modulating influence on pain transmission, are mainly to the ventrobasal and ventroposterior group of nuclei. Each of the four thalamic nuclear groups that receives nociceptive projections from the spinal cord has a distinct cortical projection, and each is thought to play a different role in pain sensation (see below).  

One practical conclusion to be reached from these anatomic and physiologic studies is that at thalamic levels, fibers and cell stations transmitting the nociceptive impulses are not organized into discrete loci. In general, neurophysiologic evidence indicates that as one ascends from peripheral nerve to spinal, medullary, mesencephalic, thalamic, and limbic levels, the predictability of neuron responsive to noxious stimuli diminishes. Thus it comes as no surprise that neurosurgical procedures for interrupting different pathways become less and less successful at progressively higher levels of the brainstem and thalamus.  

Thalamocortical Projections  
The ventrobasal thalamic complex and the ventroposterior group of nuclei project to two main cortical areas: the primary sensory (postcentral) cortex (a small number terminate in the precentral cortex) and the upper bank of the sylvian fissure. These cortical areas are described more fully in Chap. 9, but it can be stated here that they are concerned mainly with the reception of tactile and proprioceptive stimuli and with all discriminative sensory functions, including pain. The extent to which either cortical area is activated by thermal and painful stimuli is uncertain. Certainly, stimulation of these (or any other) cortical areas in a normal, alert human being does not produce pain. The intralaminar nuclei, which also project to the hypothalamus, amygdaloid nuclei, and thalamic cortex, probably mediate the arousal and affective aspects of pain and the autonomic responses.  

Thalamic and cerebral cortical localization of visceral sensation is not well known. However, cerebral evoked potentials and increased cerebral blood flow (by PET studies) have been demonstrated in the thalamus and pre- and postcentral gyri of patients undergoing rectal balloon distention (Silverman et al; Rothstein et al).  

Descending Pain-Modulating Systems  
Of great importance was the discovery of a system of descending fibers and way stations that modulate activity in nociceptive pathways. The one system that has been studied most extensively emanates from the frontal cortex and hypothalamus and projects to cells in the periaqueductal region of the midbrain and then passes to the ventrolateral medulla. From there it descends in the dorsal part of the lateral fasciculus of the spinal cord. From there it passes to the posterior horns (laminae I, II, and V; see further discussion under “Endogenous Pain-Control Mechanisms” and Fig. 8-5). Several other descending pathways, noradrenergic and serotonergic, arise in the locus ceruleus, dorsal raphe nucleus, and nucleus reticularis gigantocellularis and are also important modifiers of the nociceptive response. The significance of these pain-modulating pathways is discussed further on.  

PHYSIOLOGIC ASPECTS OF PAIN  
The stimuli that activate pain receptors vary from one tissue to another. As pointed out above, the adequate stimulus for skin is one that has the potential to injure tissue, i.e., pricking, cutting, crushing, burning, and freezing. These stimuli are ineffective when applied to the stomach and intestine, where pain is produced by an engorged or inflamed mucosa, distention or spasm of smooth muscle, and traction on the mesenteric attachment. In skeletal muscle, pain is caused by ischemia (the basis of intermittent claudication), necrosis, hemorrhage, and injection of irritating solutions, as well as by injuries of connective tissue sheaths. Prolonged contraction of skeletal muscle evokes an aching type of pain. Ischemia is also the most important cause of pain in cardiac muscle. Joints are insensitive to pricking, cutting, and cautery, but pain can be produced in the synovial membrane by inflammation and by exposure to hypotonic saline. The stretching and tearing of ligaments around a joint can evoke severe pain. Injuries to the periosteum give rise to pain but probably not to other sensations. Arteries are a source of pain when pierced by a needle or involved in an inflammatory process. Distention of arteries, as occurs with thrombotic or embolic occlusion, and excessive arterial pulsation, as in migraine, may be sources of pain; other mechanisms of headache relate to traction on arteries and the meningeal structures by which they are supported (see Chap. 10). Pain due to intraneural lesions probably arises from the sheaths of the nerves. Nerve root(s) and sensory ganglia, when compressed (e.g., by a ruptured disc), give rise to pain.  

With damage to tissue, there is a release of proteolytic enzymes, which act locally on tissue proteins to liberate substances that excite peripheral nociceptors. These pain-producing substances—which include histamine, prostaglandins, serotonin, and similar polypeptides as well as potassium ions— elicited pain when they are injected intra-arterially or applied to the base of a blister. Other pain-producing substances such as kinins are released from sensory nerve endings or are carried there by the circulation. Also, vascular permeability may be increased by these substances.  

In addition, direct stimulation of nociceptors releases polypeptide mediators that enhance pain perception. The best-studied of these is substance P, which is released from the nerve endings of C fibers in the skin during peripheral nerve stimulation. It causes erythema by dilating cutaneous vessels and edema by releasing histamine from mast cells; it also acts as a chemotactic for leukocytes. This reaction, called neurogenic inflammation by White and Helme, is mediated by antidromic action potentials from the small nerve cells in the spinal ganglia and is the basis of the axon reflex of Lewis. This reaction is abolished in certain peripheral nerve diseases and can be studied electrophysiologically as an aid to clinical localization.  

Perception of Pain  
The threshold for perception of pain, i.e., the lowest intensity of a stimulus recognized as pain, is approximately the same in all persons. It is lowered by inflammation, a process that is called sensitization; and is clinically important because in sensitized tissues ordinarily innocuous stimuli can produce pain. The pain threshold is, of course, raised by local anesthetics and by certain lesions of the nervous system as well as by centrally acting analgesic drugs. Mechanisms other than lowering or raising the pain threshold are important as well. Placebos reduce pain in about one-third of the groups of patients in which such effects have been recorded. Acupuncture at sites anatomically remote from painful operative fields apparently reduces the pain in some individuals. Distraction and suggestion, by turning attention away from the painful part, reduce the awareness of and response to pain. Strong emotion (fear or rage) suppresses pain, presumably by activation of the above-described descending adrenergic system. The experience of pain appears to be lessened in manic states and enhanced in depression. Neurotic patients in general have the same pain threshold as normal subjects, but their reaction may be excessive or abnormal. The pain thresholds of frontal lobotomized subjects are
also unchanged, but they react to painful stimuli only briefly or casually if at all. The degrees of emotional reaction and verbalization (complaint) also vary with the personality and character of the patient.

The conscious awareness or perception of pain occurs only when pain impulses reach the thalamocortical level. The precise roles of the thalamus and cortical sensory areas in this mental process are not fully understood, however. For many years it was taught that the recognition of a noxious stimulus as such is a function of the thalamus and that the parietal cortex is necessary for appreciation of the intensity, localization, and other discriminatory aspects of sensation. This traditional separation of sensation (in this instance awareness of pain) and perception (awareness of the nature of the painful stimulus) has been abandoned in favor of the view that sensation, perception, and the various conscious and unconscious responses to a pain stimulus comprise an indivisible process. That the cerebral cortex governs the patient’s reaction to pain cannot be doubted, however. It is also likely that the cortex can suppress or otherwise modify the perception of pain in the same way that corticofugal projections from the sensory cortex modify the rostral transmission of other sensory impulses from thalamic and dorsal column nuclei. It has been shown that central transmission in the spinothalamic tract can be inhibited by stimulation of the sensorimotor areas of the cerebral cortex, and, as indicated above, a number of descending fiber systems have been traced to the dorsal horn laminae from which this tract originates.

**Endogenous Pain-Control Mechanisms**

In recent years, the most important contribution to our understanding of pain has been the discovery of a neuronal analgesia system, which can be activated by the administration of opiates or by naturally occurring brain substances with the pharmacologic properties of opiates. This endogenous system was first demonstrated by Reynolds, who found that stimulation of the ventrolateral periaqueductal gray matter in the rat produced a profound analgesia without altering behavior or motor activity. Subsequently, stimulation of other discrete sites in the medial and caudal regions of the diencephalon and rostral bulbar nuclei (nucleus raphe magnus and paragigantocellularis) were shown to have the same effect. Under the influence of such electrical stimulation, the animal could be operated upon without anesthesia and move around in an undisturbed manner despite the administration of noxious stimuli. Investigation disclosed that the effect of stimulation-produced analgesia (SPA) is to inhibit the neurons of laminae I, II, and V of the dorsal horn, i.e., the neurons that are activated by noxious stimuli. In human subjects, stimulation of the midbrain periaqueductal gray matter through stereotactically implanted electrodes has also produced a state of analgesia, though not consistently. Other sites in which electrical stimulation is effective in suppressing nociceptive responses are the rostral ventromedial medulla (nucleus raphe magnus and adjacent reticular formation) and the dorsolateral pontine tegmentum. These effects are relayed to the dorsal horn gray matter via a pathway in the dorsolateral funiculus of the spinal cord. Ascending pathways from the dorsal horn, conveying noxious somatic impulses, are also important in activating the modulatory network. These connections are illustrated in Fig. 8-6.

As indicated earlier, opiates also act pre- and postganglionically on the neurons of laminae I and V of the dorsal horn, suppressing afferent pain impulses from both the A-d and C fibers. Furthermore, these effects can be reversed by the narcotic antagonist naloxone. Interestingly, naloxone can reduce some forms of stimulation-produced analgesia. Levine and colleagues have demonstrated that not only does naloxone enhance clinical pain but it also interferes with the pain relief produced by placebo. These observations suggest that the heretofore mysterious beneficial effects of placebo (and perhaps of acupuncture) may be due to activation of an endogenous system that shuts off pain through the release of pain-relieving endogenous opioids, or endorphins (see below). Prolonged pain and fear are the most powerful activators of this endogenous opioid-mediated modulating system. The same system is probably operative under a variety of other stressful conditions; for example, some soldiers, wounded in battle, require little or no analgesic medication (“stress-induced analgesia”). The opiates also act at several loci in the brainstem, at sites corresponding with those producing analgesia when stimulated electrically and generally conforms to areas in which neurons with endorphin receptors are localized.

Soon after the discovery of specific opiate receptors in the central nervous system (CNS), several naturally occurring peptides, which proved to have a potent analgesic effect and to bind specifically to opiate receptors, were identified (Hughes et al). These endogenous, morphine-like compounds are generically referred to as endorphins, meaning “the morphines within.” The most widely studied of these compounds are b-endorphin, a peptide sequence of the pituitary hormone b-lipotropin, and two other peptides, enkephalin and dynorphin. They are found in greatest concentration in relation to opiate receptors in the midbrain. At the level of the spinal cord, opiate receptors are essentially enkephalin receptors. A theoretical construct of the roles of enkephalin (and substance P) at the point of entry of pain fibers into the spinal cord is illustrated in Fig. 8-6. A subgroup of dorsal horn interneurons also contain enkephalin; they are in contact with spinothalamic tract neurons.

Figure 8-6 Theoretical mechanism of action of enkephalin (endorphin) and morphine on the transmission of pain impulses from the periphery to the CNS. Spinal interneurons containing enkephalin synapse with the terminals of pain fibers and inhibit the release of the presynaptic transmitter, substance P. As a result, the receptor neuron in the dorsal horn receives less excitatory (pain) impulses and transmits fewer pain impulses to the brain. Morphine binds to unoccupied enkephalin receptors, mimicking the pain-suppressing effects of the endogenous opiate enkephalin.

Thus it would appear that the central effects of a painful condition are determined by many ascending and descending systems utilizing a variety of transmitters. A deficiency in a particular region would explain persistent or excessive pain. Opiate addiction might conceivably be accounted for in this way, and also the discomfort that follows withdrawal of the drug. Indeed, it is known that some of these peptides not only relieve pain but suppress withdrawal symptoms. It has been speculated that in the limbic regions, disturbances in the formation of neurotransmitters could be the basis of unpleasant and distressing emotional states (e.g., depression).

Finally it should be noted that the descending pain-control systems probably contain noradrenergic and serotonergic as well as opiates links. A descending noradrenaline-containing pathway, as mentioned, has been traced from the dorsolateral pons to the spinal cord, and its activation blocks spinal nociceptive neurons. The rostral ventromedial medulla contains a large number of neurons. Destruction of the latter site inhibits dorsal horn cells concerned with pain transmission, perhaps providing a rationale for the use of certain serotonin agonists in patients with chronic pain.

**CLINICAL AND PSYCHOLOGIC ASPECTS OF PAIN**

**Terminology** Several terms related to the experience of altered sensations and pain are often used interchangeably, but each has specific meaning. Hypersensitivity is a general term for heightened cutaneous sensitivity. The term hyperalgesia refers to an increased sensitivity and a lowered threshold to painful stimuli. Inflammation and burns of the skin are common causes of hyperalgesia. The term hyperalgesia, or hyperalgesia, refers to the opposite state—i.e., a decreased sensitivity and a raised threshold to painful stimuli. A demonstrable defect in pain perception (i.e., an elevated threshold) in the affected part, associated with an increased reaction to the stimulus once it is perceived, is sometimes referred to as hypoaesthesia (subtly different from hyperalgesia). In this circumstance there is an excessive reaction to all stimuli, even those (such as light touch) that normally do not evoke pain, a symptom termed allodynia. The elicited allodynic pain may have unusual features, being diffuse, modifiable by fatigue, emotion, etc., and often mixed with other sensations. The mechanism of these abnormalities is not clear, but both hyperalgesia and allodynia are common features of neuropathic or neurogenic pain, i.e., pain generated by peripheral neuropathy. These features are exemplified by causalgia, a special type of burning pain that results from interruption of a peripheral nerve (see page 1438).

**Skin Pain and Deep Sensibility** As indicated earlier, the nerve endings in each tissue are activated by different mechanisms, and the pain that results is characterized by its quality, locale, and temporal attributes. Skin pain is of two types: a pricking pain, evoked immediately on penetration of the skin by a needle point, and a stinging or burning pain, which follows in a second or two. Together they constitute the “double response” of Lewis. Both types of dermal pain can be localized...
with precision. Ichthemia of nerve by the application of a tourniquet to a limb abolishes pricking pain before burning pain. The first (fast) pain is thought to be transmitted by the larger (A-d) fibers and the second (slow) pain, which is somewhat more diffuse and longer-lasting, by the thinner, unmyelinated C fibers.

Deep pain from visceral and skeletonomuscular structures is basically aching in quality; if intense, it may be sharp and penetrating (knife-like). Occasionally there is a burning type of pain, as in the "heartburn" of esophageal irritation and rarely in angina pectoris. The pain is felt as being deep to the body surface. The pain is diffuse and poorly localized, and the margins of the painful zone are not well delineated, presumably because of the relative paucity of nerve endings in viscera.

Referred Pain The localization of deep pain raises a number of problems. Although deep pain has indefinite boundaries, its location always bears a fixed relationship to the area to which it is referred, a rule that is in sharp contrast to that governing the course of the somatic afferents, such as those from the skin, which may be transmitted to distant sensory centers. The central somatic structures are thought to be the pain centers that relay the input of visceral pain fibers into the nervous system and thence to the brain. It is from the brain that the pain arises. The pain referred to the skin is transmitted to the skin in reverse of the normal pathway, but is not transmitted to areas of the skin innervated by the same spinal segment (or segments). This pain, projected to some fixed site as a consequence of the distance, is called referred pain. Small-caliber pain afferents from deep structures project to a wide range of lamina V neurons in the dorsal horn, as do cutaneous afferents. The convergence of deep and cutaneous afferents on the same dorsal horn cells, coupled with the fact that cutaneous afferents are far more numerous than visceral afferents and have direct connections with the thalamus, probably explains the phenomenon of referred pain.

Since the nociceptive receptors and nerves of any given visceral or skeletal structure may project upon the dorsal horns of several adjacent spinal or brainstem segments, the pain may be fairly widely distributed. For example, afferent pain fibers from cardiac or brainstem structures, distributed over several segments, can be projected superficially to the inner side of the arm and the ulnar border of the hand and arm (T1 and T2) as well as the pectoralis (T3 and T4). Once this pool of sensory neurons in the dorsal horns of the spinal cord is activated, additional noxious stimuli may heighten the activity in the whole sensory field ipsilaterally and, to a lesser extent, contralaterally.

Another peculiarity of segmental pain is aberrant representation, explained by an alteration of the physiologic status of the pools of neurons in adjacent segments of the spinal cord. For example, cervical arthrosis or gallbladder disease, causing low-grade discomfort by constantly activating their particular segmental neurons, may induce a shift of cardiac pain cephalad or caudad from its usual locale. Any pain, once it becomes chronic, may spread quite widely in a vertical direction on one side of the body. On the other hand, painful stimuli arising from a distant site exert an inhibitory effect upon segmental nociceptive flexion reflexes in the leg (DeBroucker et al.). Yet another clinical peculiarity of segmental pain is the reduction in power of muscle contraction that it may cause (reflex paralysis, or algiesic weakness).

In an injured nerve, the unmyelinated sprouts of A-d and C fibers become capable of spontaneous ectopic excitation and afterdischarge and susceptible to ephaptic activation (Rasminsky). They are also sensitive to locally applied or intravenous catecholamines because there are adrenergic receptors on the regenerating fibers. Either this mechanism or ephaptic (nerve-to-nerve cross-activation) is thought to be the basis of causalgia and other forms of reflex sympathetic dystrophy; either mechanism would explain the relief afforded by sympathetic block. This subject is discussed in greater detail in relation to peripheral nerve injuries (see page 1438).

Central sensory structures, e.g., sensory neurons in the dorsal horns of the spinal cord or thalamus, if chronically bombarded with pain impulses, may become autonomously overactive (being maintained in this state perhaps by excitatory amino acids) and may remain so after the peripheral pathways have been interrupted. Peripheral nerve injuries have been shown to induce enduring degenerations of central (spinal cord) processing (Frustomer and Lundblad.). Axonal loss of nerves or nerve roots may cause chronic pain even in anesthesia dolorosa areas (anesthetic, dolorous or "deafferentation pain"). In experimentally deafferented animals, neurons of lamina V begin to discharge irregularly in the absence of stimulation. Later the abnormal discharge subsides in the spinal cord but can still be recorded in the thalamus. Hence, painful states such as causalgia, spinal cord pain, and phantom pain are not abolished simply by cutting spinal nerves or spinal tracts.

Pain has several other singular attributes. It does not appear to be subject to negative adaptation—i.e., pain may persist as long as the stimulus is operative—whereas other somatic stimuli, if applied continuously, soon cease to be effective. Furthermore, prolonged stimulation of pain receptors sensitizes them, so that they become responsive to even lower levels of stimulation, such as touch (allodynia). Another remarkable characteristic of pain is the strong feeling or affect with which it is endowed, nearly always unpleasant. Since pain has this affective element, psychologic conditions assume great importance in all persistent painful states. It is of interest that despite this strong affective aspect of pain, it is difficult to recall precisely, or to re-experience from memory, a previously experienced acute pain. Also, the patient's tolerance of pain and capacity to experience it without verbalization are influenced by race, culture, and religion. Some individuals—by virtue of training, habit, and phlegmatic temperament—remain stoic in the face of pain, and others react in an opposite fashion. Pain may be the presenting or predominant symptom in a depressive illness (Chop. 57).

Finally, a comment should be made about the devastating behavioral effects of chronic pain. To quote from Ambroise Paré, a sixteenth-century French surgeon, "There is nothing that abates so much the strength as pain." Continual pain increases irritability and fatigue, disturbs sleep, and impairs appetite. Ordinarily strong persons can be reduced to a whimpering, pitiable state that may arouse the scorn of healthy observers. Patients in pain may seem irrational about their illness and make unreasonable demands on family and physician. Characteristic also is an unwillingness to engage in or continue any activity that might enhance their pain. They withdraw from the main current of daily affairs. Their thoughts and speech come to be dominated by the pain. Once a person is subjected to the tyranny of chronic pain, depressive symptoms are practically always added. The demand for and dependence on narcotics often complicate the clinical problem.

**APPROACH TO THE PATIENT WITH PAIN AS THE PREDOMINANT SYMPTOM**

One learns quickly in dealing with such patients that not all pain is the consequence of serious disease. Every day, healthy persons of all ages have pains that must be taken as part of normal sensory experience. To mention a few, there are the "growing pains" of children; the momentary hard pain over an eye or in the temporal or occipital regions, which strikes with such suddenness as to raise the suspicion of a ruptured intracranial aneurysm; the more persistent ache in the fleshy part of the shoulder, hip, or extremity that subsides spontaneously or in response to a change in position; the fluctuant precordial discomfort of gastrointestinal origin, which can be caused by myocardial disease; the breathing "stitch in the side," due to intercostal or diaphragmatic cramp. These normal pains, as they should be called, tend to be brief and to depart as obscurely as they came. Such pains come to notice only when elicited by an inquiring physician or when experienced by a patient given to worry and introspection. They must always be distinguished from the pain of disease.

Whenever pain—by its intensity, duration, and the circumstances of its occurrence—appears to be abnormal or when it constitutes the chief complaint or one of the principal symptoms, the physician must attempt to reach a tentative decision as to its mechanism and cause. This is accomplished by a thorough interrogation of the patient, with the physician carefully seeking out the main characteristics of the pain in terms of:

1. Location
2. Mode of onset
3. Provoking and relieving factors
4. Quality and time-intensively attributes
5. Duration
6. Severity

Knowledge of these factors in every common disease is the lore of medicine. The severity of pain is often difficult to assess. Extreme degrees of pain are betrayed by the patient's demeanor, but lesser degrees can be roughly estimated by the extent to which the pain has interfered with the patient's sleep, work, and other activities or by the patient's need for bed rest. Some physicians find it helpful, particularly in gauging the effects of analgesic agents, to use a "pain scale," i.e., to have the patient rate the intensity of his pain on a scale of zero (no pain) to ten (worst pain) or to mark it on a line. Needless to say, this general approach is put to use every day in the practice of internal medicine. Together with the physical examination, including tests designed to reproduce and relieve the pain, and ancillary diagnostic procedures, it enables the physician to identify the source of most pains and the diseases of which they are a part.

Once the pains due to the more common and readily recognized diseases of each organ system are eliminated, there remain a significant number of chronic pains that fall into one of four categories: (1) pain from an obscure medical disease, the nature of which has not yet been disclosed by diagnostic procedures; (2) pain associated with disease of the central or peripheral nervous system (i.e., neurogenic or neuropathic pain); (3) pain associated with psychiatric disease; and (4) pain of unknown cause.

**Pain due to Undiagnosed Medical Disease**

Here the source of the pain is usually peripheral and caused by a lesion that irritates and destroys nerve endings. Hence the term nociceptive pain is often used, but it is ambiguous. It usually means an involvement of structures bearing the termination of pain fibers. Carcinomatosis is the most frequent example. Osseous...
metastases, pituitary tumors, invasion of retroperitoneal tissues or the hilum of the lung, and implication of nerves of the brachial or lumbosacral plexuses can be extremely painful, and the origin of the pain may remain obscure for a long time. Sometimes it is necessary to repeat all diagnostic procedures after an interval of a few months, even though at first they were negative. From experience one learns to be cautious about reaching a diagnosis from insufficient data. Treatment is directed to the relief of pain, at the same time instilling in the patient a need to cooperate with a program of expectant observation.

**Neurogenic, or Neuropathic, Pain**

These terms are generally used interchangeably to designate pain that arises from direct stimulation of nervous tissue itself, central or peripheral, exclusive of pain due to granulocytic inflammation or ischemia of sensory C fibers (i.e., sensitization of afferent nerve fibers). Neurogenic pain, which may arise in association with conditions such as neoplasms, infections, surgery, injury, trauma, and metabolic disturbances, may be felt as dull, aching, burning, or shooting pain. It may be well localized and correspond with the dermatome and myotome supplied by a single sensory root. On the other hand, it may be referred to more distant parts of the body, including the head, in which case it is often clouded by sensory, motor, and autonomic disturbances. The exact localization of the source of the injury is unknown in many cases, and the pain may be diffuse or ill-defined. It is often pernicious and is usually described as burning, aching, or cramping. Neurogenic pain may be of an acute, subacute, or chronic nature, depending on the cause and the nature of the injury. It may be accompanied by other symptoms such as weakness, paresthesia, hyperesthesia, allodynia, and autonomic dysfunction. The pain may be exacerbated by movement, temperature changes, or contact with the skin. It may be relieved by rest, heat, or cold. The pain may be constant or intermittent, and it may be triggered by specific stimuli such as touch, pressure, or movement. The pain may be referred to distant parts of the body, and it may be accompanied by other symptoms such as weakness, paresthesia, hyperesthesia, and autonomic dysfunction.

**Peripheral Nerve Pain**

Painful states that fall into this category are in most cases related to disease of the peripheral nerves, and it is to pain from this source that the term neurogenic is more strictly applicable. Pain states of peripheral nerve origin far outnumber those due to spinal cord, brainstem, thalamic, and cerebral disease. Although the pain is localized to a sensory territory supplied by a nerve plexus or nerve root, it often radiates to adjacent areas. Sometimes the onset of pain is immediate on receipt of injury, or more commonly it appears at some point during the evolution or regression of the disorder. The disease of the nerve may be obvious, expressed by the usual sensory, motor, reflex, and autonomic changes, or these changes may be undetectable by standard tests. In the latter case, the term neurogenic is the preferred term.

**Postherpetic Neuralgia**

This condition is more strictly applicable. Pain states of peripheral nerve origin far outnumber those due to spinal cord, brainstem, thalamic, and cerebral disease. The pain is usually localized to a sensory territory supplied by a nerve plexus or nerve root, and it often radiates to adjacent areas. Sometimes the onset of pain is immediate on receipt of injury, or more commonly it appears at some point during the evolution or regression of the disorder. The disease of the nerve may be obvious, expressed by the usual sensory, motor, reflex, and autonomic changes, or these changes may be undetectable by standard tests. In the latter case, the term neurogenic is the preferred term.

**Central Pain**

Central pain occurs in patients with deafferentation of secondary neurons in the posterior horns or of sensory ganglion cells that terminate on them. The deafferentation may cause the deafferented cells to become continuously active and, if stimulated by a microelectrode, to reproduce pain. In the patient whose spinal cord has been transected, there may be intolerable pain in regions below the level of the lesion. It may be exacerbated or provoked by movement, fatigue, or emotion and projected to areas disconnected from suprasegmental structures (akin to the phantom pain in the missing part of an amputated limb). Here, and in the rare cases of intractable pain with metastases, peritoneal implants, invasion of retroperitoneal tissues or the hilum of the lung, and implication of nerves of the brachial or lumbosacral plexuses can be extremely painful, and the origin of the pain may remain obscure for a long time. Sometimes it is necessary to repeat all diagnostic procedures after an interval of a few months, even though at first they were negative. From experience one learns to be cautious about reaching a diagnosis from insufficient data. Treatment is directed to the relief of pain, at the same time instilling in the patient a need to cooperate with a program of expectant observation.

**Pain in Association with Psychiatric Diseases**

It is not unusual for patients with endogenous depression to have pain as the predominant symptom. Most patients with chronic pain of all types are depressed. Wells and colleagues, in a survey of a large number of depressed and chronic pain patients, have convincingly corroborated this clinical impression. Fields has elaborated a theoretical explanation of the overlap of pain and depression. In such cases one is faced with an extremely difficult clinical problem—that of determining whether a depressive state is primary or secondary. In some instances the diagnostic criteria cited in Chap. 57 provide the answer, but in others it is impossible to make this distinction. The empirical use of antidepressant medication or, failing this, with electroconvulsive therapy is one way out of the dilemma.

**Intractable Pain**

Intractable pain may be the leading symptom of either hysteria or compensation nervous. Every experienced physician is familiar with the “battle-scarred abdomen” of the woman with hysteria (so-called Briquet disease) who has demanded and yielded to one surgical procedure after another, losing appendix, ovaries, fallopian tubes, uterus, gallbladder, etc., in the process ("diagnosis by evisceration"). The recognition and management of hysteria are discussed in Chap. 56.

Compensation pain is often colored by persistent complaints of headaches, neck pain (whiplash injuries), low-back pain, etc. The question of ruptured disc is often a patient’s fear and is associated with psychological stress. The pain is often disabling and may interfere with normal activities. It may be due to local inflammation, muscle spasm, or nerve root irritation. Treatment may include pain medication, physical therapy, and surgery. In some cases, chronic pain may be due to underlying medical conditions such as cancer, diabetes, or chronic inflammatory diseases. Treatment may include pain medication, physical therapy, and surgery.

**Chronic Pain of Indeterminate Cause**

This is the most difficult group of all—pain in the thorax, abdomen, flank, back, face, or other part that cannot be traced to any visceral abnormality. Despite all neurologic sources, such as a spinal cord tumor, have been excluded by repeated examinations and imaging procedures. A psychiatric disorder to which the patient’s symptoms and behavior might be attributed cannot be discerned. Yet the patient complains continuously of pain, is disabled, and spends a great deal of effort and money seeking medical aid.

In such a circumstance, some physicians and surgeons, rather than concede their helplessness, may resort to extreme measures such as exploratory thoracotomy, laparotomy, or laminectomy. Or they may injudiciously attempt to alleviate the pain and avoid drug addiction by severing roots and spinal tracts, often with the result that the pain moves to an adjacent segment or to the other side of the body.

This type of patient should be seen frequently by the physician. All the medical facts should be reviewed and the clinical and laboratory examinations repeated if some time has elapsed since they were last done. Tumors in the hilum of the lung or mediastinum, in the retroperitoneal space, and paravertebral spaces, or in the uterus, testicle, kidney, and prostate offer special difficulty in diagnosis, often being undetected for many months. Neurofibroma causing pain in an unusual site, such as one side of the rectum or vagina, is another type of tumor that may defy diagnosis for a long time. Neurogenic pain is almost invariably accompanied by alterations in cutaneous sensation and other neurologic signs, the finding of which facilitates diagnosis; the appearance of the neurologic signs may be long delayed, however. The possibility of drug addiction as a motivation should be eliminated. It is impossible to assess pain in the addicted individual, for the patient’s complaints are woven into his need for medication. Temperament and mood should be evaluated carefully from day to day; the physician must remember that the depressed patient often denies being depressed and may occasionally smile. When no medical, neurologic, or psychiatric disease can be established, one must be resigned to managing the painful state by the use of nonnarcotic medications and frequent clinical re-evaluations. Such a course, though not altogether satisfactory, is preferable.
to prescribing excessive opioids or subjecting the patient to ablative surgery.

Because of the complexity and difficulty in diagnosis and treatment of chronic pain, most medical centers have found it advisable to establish pain clinics. Here a staff of internists, anesthesiologists, neurologists, neurorogues, and psychiatrists are able to review each patient in terms of drug dependence, neurologic disease, and psychiatric problems. Success is achieved by treating each aspect of chronic pain, with emphasis on increasing the patient's tolerance of pain by means of biofeedback, meditation and related techniques, by using special invasive anesthetic special procedures (discussed later in the chapter), by establishing a regimen of pain medication, and by controlling depressive illness.

Rare and Unusual Disturbances of Pain Perception

Lesions of the parieto-occipital regions of one cerebral hemisphere sometimes have peculiar effects on the patient's capacity to feel and react to pain. Under the title of pain hemianopia, Hecaen and Ajaraguerra described several cases of left-sided paralysis from a right parietal lesion which, at the same time, rendered the patient hypersensitive to noxious stimuli. When pinched on the affected side, the patient, after a delay, became agitated, started to cry, and seemed dazed but made no effort to fend off the painful stimulus with the other hand or to withdraw from it. In contrast, if the good side was pinched, the patient reacted normally and moved the normal hand at once to the site of the stimulus to remove it. The motor responses seem no longer to be guided by sensory information from one side of the body.

There are also two varieties of rare individuals who from birth are totally indifferent to pain ("congenital insensitivity to pain") or are incapable of feeling pain ("universal analgesia"). The former have an uncertain congenital deficiency of a neurotransmitter or an equally obscure peculiarity of the central receptive apparatus (see Chap. 9), and the second group suffers from either a congenital lack of pain neurons in dorsal root ganglia, a polynoepathy, or a lack of pain receptors in the primary afferent neuron.

The phenomenon of asymbolia for pain is another rare and unusual condition, wherein the patient, although capable of distinguishing the different types of pain stimuli from one another and from touch, is said to make none of the usual emotional, motor, or verbal responses to pain. This patient seems totally unaware of the painful or hurtful nature of stimuli delivered to any part of the body, whether on one side or the other. The current interpretation of asymbolia for pain is that it represents a particular type of agnosia (analagnosia) or apraxagnosia (cf. Chap. 22), in which the organism loses its ability to adapt its emotional, motor, and verbal actions to the consciousness of a nociceptive impression. "Le sujet a perdu la compréhension de la signification de la douleur." We have been unable to corroborate the existence of this syndrome from our own clinical experience.

Treatment of Intractable Pain

Once the nature of the patient's pain and underlying disease have been determined, therapy must include some type of pain control. Initially, of course, attention is directed to the underlying disease, with the idea of eliminating the source of the pain by appropriate medical, surgical, or radiotherapeutic measures.

If the patient is ridden with disease and will not live more than a few weeks or months, is opposed to surgery, or has widespread pain, surgical measures are out of the question. However, pain from widespread osseous metastases, even in patients with hormone-insensitive tumors, may be relieved by radiation therapy or by hypophysectomy. Pain confined to a restricted area of the jaw or face may be relieved by nerve root blocks; by radiofrequency destruction of the trigeminal nerve, roots, or ganglion; or in some cases by decompressive surgery of an aberrant vascular loop that abuts a root in the posterior fossa. Usually, nerve section is not a satisfactory way of relieving restricted pain of the trunk and limbs because the overlap of adjacent nerves prevents complete denervation. Another procedure to be considered before undertaking such a section of several contiguous sensory roots is the regional delivery of narcotic analogues, such as fentanyl or ketamine, by means of an external pump and a catheter that is implanted percutaneously in the epidural space in proximity to the dorsal nerve roots in the affected region; this device can be used safely at home.

If radiation therapy and other medical and surgical measures are not feasible or fail to relieve the pain, a program utilizing analgesic medication must be undertaken. Central to such a program is the use of opioids, which to this day represent the most effective analgesic agents for the management of severe chronic pain due to medical disease.

A useful way in which to undertake the management of chronic pain that affects several parts of the body, as in the patient with metastases, is with codeine, oxycodone, or propoxyphene taken together with aspirin, acetaminophen, or another nonsteroidal anti-inflammatory agent. The analgesic effects of these two types of drugs are additive, which is not the case when narcotics are combined with dexameth, or phenothion. Antidepressants may have a beneficial effect on pain, even in the absence of depression or other neurotic symptomatology. This is true particularly in cases of neuropathic pain (painful polyneuropathy and some types of radicular pain). Sometimes these nonnarcotic agents may in themselves or in combination with other treatment modalities be sufficient to control the patient's pain, and the use of narcotics can be kept in reserve.

Use of Opioids and Opiates

Should the foregoing measures prove to be ineffective, one must turn to more potent narcotic agents. Methadone and levorphanol are the most useful drugs with which to begin, because of their effectiveness by mouth and the relatively slow development of tolerance. The oral route should be utilized whenever possible, since it is more comfortable for the patient than the parenteral route. Also, the oral route is associated with less side effects, except for nausea and vomiting, which tend to be worse than with parenteral administration. Should the latter become necessary, one must be aware of the ratios of oral to parenteral dosages required to produce equivalent analgesia. These are indicated in Table 8-1.

Table 8-1 Common drugs for the management of chronic pain

If oral medication fails to control the pain, the parenteral administration of codeine or more potent opioids becomes necessary. Again, one may begin with methadone, dihydromorphine (Dilaudid), or levorphanol, given at intervals of 4 to 6 h, because of their relatively long duration of action (particularly in comparison to meperidine). Alternatively, one may first resort to the use of transdermal patches of drugs such as fentanyl, which provide relief for 24 to 72 h and which we have found particularly useful in the treatment of pain from brachial or lumbosacral plexus invasion by tumor. Long-acting morphine preparations are useful alternatives. Should long-continued injections of opiates become necessary, the optimal dose for the relief of pain should be established and the drug then given at regular intervals around the clock, rather than "as needed." The administration of morphine (and other narcotics) in this way represents a laudable shift in attitude among physicians. For many years it was taught that the drug should be given in the smallest possible doses, spaced as far apart as possible, and repeated only when severe pain reasserted itself. It has become clear that such usage of the drug results in unnecessary discomfort and, in the end, the need to use larger doses. The fear of creating narcotic dependence and the expected phenomenon of increasing tolerance must be balanced against the overriding need to relieve pain. The most pernicious aspect of addiction, that of compulsive drug-seeking behavior and self-administration of the drug, occurs only rarely in this setting and usually in patients with a previous history of addiction or alcoholism, with depression as the primary problem, or with certain character defects that have been loosely referred to as "addiction proneness." Even in patients with severe acute or postoperative pain, the best results are obtained by allowing the patient to determine the dose and frequency of intravenous medication, so-called patient-controlled analgesia, or PCA. Again, the danger of producing addiction is minimal.

Excellent guidelines for the use of orally and parenterally administered opioids for cancer-related pain are contained in the article of Cherny and Foley.
The regimen outlined above conforms with current information about pain-control mechanisms. Aspirin and other nonsteroidal anti-inflammatory analgesics are believed to prevent the activation of nociceptors by inhibiting the synthesis of prostaglandins in skin, joints, viscera, etc. Morphine and meperidine given orally, parenterally, or by intrathecal routes, competitively block the stimulation of pain by acting as "false" neurotransmitters at receptor sites on the posterior horn cells of the spinal cord—sites that are normally activated by endogenous opioid peptides (see Fig. 8-5). The separate sites of action of nonsteroidal analgesics and opioids provide an explanation for the therapeutic usefulness of combining these drugs. Yet another mechanism, described earlier in this chapter, consists of the physiologic activation of the intrinsic analgesic system (descending pathways from brain to spinal cord) by electrical stimulation, administration of placebo, and possibly acupuncture; short bursts of transcutaneous electrical stimulation may also suppress pain in this way. Not only do opioids act directly on the central pain-conducting sensory systems but they also exert a powerful action on the affective component of pain. Serotonergic neurons are also thought to play a role in pain modulation.

Other Supplemental Medications Tricyclic antidepressants, especially the methylated forms (imipramine, amitriptyline, and doxepin), block serotonin reuptake and thus enhance the action of this neurotransmitter at synapses and putatively facilitate the action of the intrinsic opiate analgesic system. As a general rule, relief is afforded with tricyclic antidepressants in the equivalent dose range of 75 to 125 mg daily of amitriptyline, but little benefit accrues with higher doses. The newer serotoninergic antidepressants seem not to be as effective for the treatment of chronic neuropathic pain (see review by McQuay and colleagues), but these agents have not yet been extensively investigated in this clinical condition.

Anticonvulsants have a beneficial effect on many central and peripheral neuropathic pain syndromes but are generally less effective for causalgic pain due to partial injury of a peripheral nerve. The mode of action of phenytoin, carbamazepine, and anticonvulsants in suppressing the lancinating pains of tic douloureux, and certain other neuropathies as well as pain after spinal cord injury and myelitis is not understood. The biphosphate compound pamidronate, known to relieve several painful bone disorders, is being adopted increasingly for the treatment of causalgic pain, but the precise indications for its use remain to be defined.

The use of analgesic (nonnarcotic and narcotic), anticonvulsant, and antidepressant drugs in the management of chronic pain is summarized in Table 8-1.

Treatment of Neuropathic Pain

The treatment of pain induced by nerve root compression or intrinsic peripheral nerve disease utilizes several special techniques, some of which fall in the province of the anesthesiologist. If the pain is regional and has a predominantly burning quality, a capsaicin cream can be applied locally, caring being taken to avoid contact with the eyes and mouth. The irritative effect of this chemical seems in some cases to mute the pain. Concoctions of "eucetic" mixtures of local anesthetic creams (EMLA) and the simpler lidocaine gel preparation may provide relief in postherpetic neuralgia and painful peripheral neuropathies.

Injections of epidural corticosteroids or mixtures of analgesics and steroids are helpful in selected cases of lumbar or thoracic nerve root pain and occasionally in painful peripheral neuropathy, but precise criteria for the use of this measure are not well established. Root blocks with lidocaine or with longer-acting local anesthetics are helpful at times in establishing the precise source of radicular pain. Their main therapeutic use in our experience has been for thoracic radiculitis from shingles, chest wall pain after thoracotomy, and diabetic radiculopathy. Similar local injections are used in the treatment of occipital neuralgia.

The infusion of lidocaine has a brief beneficial effect on many types of pain, including neuropathic varieties, localized headaches, and facial pain, and it is said to be useful in predicting the response to longer-acting agents such as its oral analogue, mexiletine, although this relationship has been erratic in our experience (see Table 8-1). Mexiletine is given in an initial dose of 150 mg per day and slowly increased to a maximum of 300 mg three times daily; it should be used very cautiously in patients with heart block.

Finally, reducing sympathetic activity within somatic nerves by direct injection of the sympathetic ganglia in affected regions of the body (stellate ganglion for arm pain and lumbar ganglia for leg pain) has met with mixed success in neuropathic pain, including that of causalgia and reflex sympathetic dystrophy. A variant of this technique utilizes regional intravenous infusion of a sympathetic blocking drug (bretylum, guanethidine, reserpine) into a limb that is isolated from the systemic circulation by the use of a tourniquet. It is known as a "Bar block," after the developer of regional anesthesia for single-limb surgery. The use of these techniques, and the regional block infusion of the adrenergic blocker phentolamine, on the concept of "sympathetically maintained pain," meaning pain that is mediated by the interaction of sympathetic and pain nerve fibers ("false synapse" or "epaphsis") or by the sprouting of adrenergic axons in partially damaged nerves. This form of treatment is still under study, but the most consistent responses to sympathetic blockade are obtained in cases of true causalgia that results from partial nerve injury and in reflex sympathetic dystrophy. These pain syndromes have been referred to by a number of different names, most recently as the "complex regional pain syndrome," but all refer to the same constellation of burning or "shooting" pain (see page 1438). A number of other treatments have proven successful in some patients with reflex sympathetic dystrophy, but the clinician should not be sanguine about their chances of success over the long run. Perhaps the most novel and promising of these has been the use of bisphosphonates (pamidronate, alendronate), which have been beneficial in painful disorders of bone, e.g., Paget disease and metastatic bone lesions. Another treatment of last resort is the epidural infusion of drugs such as ketamine; sometimes this has a lasting effect on causalgic pain.

The therapeutic approaches enumerated here are usually undertaken in sequence. They reflect the general ineffectiveness of currently available treatments and our uncertainty as to the mechanisms of neuropathic pain. There are occasional successes, most of them temporary. Further references can be found in the article by Katz.

Use of Ablative Surgery in the Control of Pain

It is the authors' considered opinion that a program of medical therapy should always precede ablative surgical measures. Only when a variety of analgesic medications (including opioids) combined with phenothiazines and anticonvulsants, and only when certain practical measures, such as regional analgesia or anesthesis, have completely failed should one turn to neurosurgical procedures. Also, one should be very cautious in suggesting a procedure of last resort for pain that has no established cause, as, for example, limb pain that has been incorrectly identified as causalgic because of a burning component of the pain but in which there has been no nerve injury.

The least destructive procedure consists of implantation of an electrical stimulator, usually adjacent to the posterior columns. This procedure, which enjoyed a brief period of popularity, affords only incomplete relief and is difficult to maintain in place; it is now little used. The use of nerve section and dorsal rhizotomy as definitive measures for the relief of regional pain has already been discussed, under "Treatment of Intractable Pain;," above.

Spinothalamic tractotomy, in which the anterior half of the spinal cord on one side is sectioned at an upper thoracic level, effectively relieves pain in the opposite leg and lower trunk. This may be done as an open operation or as a transcutaneous procedure in which a radiofrequency lesion is produced by an electrode. The analgesia and thermoanesthesia may last a year or longer, after which the level of analgesia tends to descend and the pain to return. Bilateral cordotomy is also feasible, but with greater risk of loss of sphincteric control and, at higher levels, of respiratory paralysis. Motor power is nearly always spared because of the position of the posterior column tracts in the posterior part of the lateral funiculus.

Pain in the arm, shoulder, and neck is more difficult to relieve surgically. High cervical transcutaneous cordotomy has been used successfully, with achievement of analgesia up to the chin. Commissural myelotomy by longitudinal incision of the anterior or posterior commissure of the spinal cord over many segments has also been performed, with variable success. Lateral medullary tractotomy is another possibility but must be carried almost to the midline to relieve cervical pain. The risks of this latter procedure and also of lateral mesencephalic tractotomy (which may actually produce pain) are so great that neurosurgeons have to all intents abandoned these operations.

Stereotactic surgery on the thalamus for one-sided chronic pain is still used in a few clinics, and the results have been instructive. Lesions placed in the ventroposterior nucleus are said to diminish pain and thermal sensation over the contralateral side of the body while leaving the patient with all the misery or affect of pain. The postcentral or parafascicular-centromedian nuclei relieve the painful state without altering sensation (Matthies). Since these procedures have not yielded predictable benefits to the patient, they are now seldom practiced. The same unpredictability pertains to cortical ablations. Patients in whom a severe depression of mood is associated with a chronic pain syndrome have been subjected to bilateral stereotactic cingulotomy or the equivalent, subcaudate tractotomy. A considerable degree of success has been claimed for these operations, but the results are difficult to evaluate. Orbitalfrontal leukotomy has been virtually discarded because of the personality change that it produces (see Chap. 22).
Unconventional Methods for the Treatment of Pain

Included under this heading are certain techniques such as biofeedback, meditation, imagery, acupuncture, some forms of spinal manipulation, as well as transcutaneous electrical stimulation. Each of these may be of value in the context of a comprehensive pain management program, conducted usually in a pain clinic, as a means of providing relief from pain and suffering, reducing anxiety, and diverting the patient’s attention, even if only temporarily, from the painful body part. Attempts to quantify the benefits of these techniques—judged usually by a reduction of drug dosage in response to a particular form of treatment—have given mixed results. Nevertheless, it is unwise for physicians to dismiss these methods out of hand, since well-motivated and apparently well-balanced persons have reported subjective improvement with one or another of these methods and, in the final analysis, this is what really matters. Conventional psychotherapy in combination with the use of medication and, at times, of electroconvulsive therapy can be of great benefit in the treatment of associated depressive symptoms, as discussed above (under “Pain in Association with Psychiatric Disease”).

CHAPTER REFERENCES

Under normal conditions, sensory and motor functions are interdependent, as was dramatically illustrated by the early animal experiments of Claude Bernard and Sherrington, in which practically all effective movement of a limb was abolished by eliminating only its sensory innervation (sectioning of posterior roots). Interruption of other sensory pathways and destruction of the parietal cortex also have a profound effect upon motility. Sensory and motor neurons are intimately connected at all levels of the nervous system, from the spinal cord to the cerebrum. To a large extent, human motor activity depends upon a constant influx of sensory impulses (most of them not consciously perceived). Truly, in a physiologic sense, “movement is sensation.”

However, under conditions of disease, motor or sensory function may be affected independently. There may be loss or impairment of sensory function, and this may represent the main manifestation of neurologic disease. The logic of this is clear enough, since the major anatomical pathways of the sensory system are distinct from those of the motor system and can be selectively disturbed by disease. The analysis of sensory symptoms involves the use of special tests, designed to elicit the nature of the sensory alteration and its location, and it is from this point of view that disorders of sensory function are considered here.

This chapter deals with general somatic sensation, i.e., afferent impulses that arise in the skin, muscles, or joints. One form of somatic sensation—pain—has already been discussed (Chap. 8). Because of its overriding clinical importance, pain has been accorded a chapter of its own, but the two chapters are of one piece and should be read together. The special senses—vision, hearing, taste, and smell—are considered in the next section (Chap. 12, Chap. 13, Chap. 14 and Chap. 15), and visceral (interoceptive) sensation, most of which does not reach consciousness, is considered with the disorders of the autonomic nervous system (Chap. 26).

**ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS**

An understanding of sensory disorders depends upon a knowledge of functional anatomy. It is necessary to be familiar with the sensory receptors in the skin and deeper structures, the distribution of the peripheral nerves and roots, and the pathways by which sensory impulses are conveyed from the periphery and through the spinal cord and brainstem to the thalamus and cerebral cortex. These aspects of sensory anatomy and physiology have already been touched upon in Chap. 8, in relation to the perception of pain, and are elaborated here to include all forms of somatic sensation. Charts showing the cutaneous distribution of the peripheral nerves are included (Fig. 9-1).

**Figure 9-1** The cutaneous fields of peripheral nerves. (From Haymaker W, Woodhall B: Peripheral Nerve Injuries, 2nd ed. Philadelphia, Saunders, 1953, by permission.)

All sensation depends on impulses that are excited by adequate stimulation of receptors and conveyed to the central nervous system by afferent, or sensory, fibers. Sensory receptors are of two general types: those in the skin, mediating superficial sensation (exteroceptors), and those in the deeper somatic structures (proprioceptors). The skin receptors are particularly numerous and transduce four types of sensory experience: warmth, cold, touch, and pain; these are conventionally referred to as sensations or senses, e.g., tactile sensation or sense of touch. The proprioceptors inform us of the position of our body or parts of our body; of the force, direction, and range of movement of the joints (kinesthetic sense); and of a sense of pressure, both painful and painless. Histologically, a wide variety of sensory receptors has been described, varying from simple, free axon terminals to highly branched and encapsulated structures, the latter bearing the names of the anatomists who first described them (see below).

**Mechanisms of Cutaneous Sensation**

As indicated in the preceding chapter, it was common teaching for many years that each of the primary modalities of cutaneous sensation is subserved by a morphologically distinct end organ, each with its separate peripheral nerve fibers. According to this formulation, traditionally associated with the name of von Frey, each type of end organ was thought to respond only to a particular type of stimulus and to subserve a specific modality of sensation: Meissner corpuscles, touch; Merkel discs, pressure; Ruffini plumes, heat; Krause end bulbs, cold, pacinian corpuscles, vibration and tickle; and freely branching endings, pain.

This specificity theory, as it came to be called, has held up best in respect to the peripheral mechanisms for pain, insofar as certain primary afferent fibers, namely the C and A-d fibers and their free nerve-ending type of receptors, respond maximally to noxious stimuli. But even these freely branching receptor endings and their so-called pain fibers convey considerable nonnoxious information; that is, their specificity as pain fibers is not absolute (Chap. 8). Nor has it been possible to ascribe a specific function to each of the many other types of receptors. Thus, Merkel discs, Meissner corpuscles, nerve plexuses around the hair follicles, and free nerve endings can all be activated by moving or stationary tactile stimuli. Conversely, a single type of receptor seems capable of generating more than one sensory modality. Lele and Weddell found that with appropriate stimulation of the cornea, each of the four primary modalities of somatic sensibility (touch, warmth, cold, pain) could be recognized, even though the cornea contains only fine, freely ending nerve filaments. In the outer ear, which is also sensitive to these four modalities, only two types of receptors—freely ending and perifollicular—are present. The lack of organized receptors—e.g., the end bulbs of Krause and Ruffini—in the cornea and...
ear makes it evident that these types of receptors are not essential for the recognition of cold and warmth, as von Frey and other early anatomists had postulated.

 Particularly instructive in this regard are the observations of Kibler and Nathan, who studied the responses of warm and cold spots to different stimuli. (Warm and cold spots are those small areas of skin that respond most consistently to thermal stimuli with a sensation of warmth or cold.) They found that a cold stimulus applied to a warm spot gave rise to a sensation of cold and that a noxious stimulus applied to a warm or cold spot gave rise only to a painful sensation; they also noted that mechanical stimulation of these spots gave rise to a sensation of touch or pressure. These observations indicate that cutaneous receptors, some not easily distinguishable from one another on morphologic grounds, are probably endowed with a degree of specificity, in the sense that each responds preferentially (i.e., has a lower threshold) to one particular form of stimulation. Even among the freely branching nociceptors there is some degree of specialization, as discussed in Chap. 8 (page 136). Such end organs can then be classed as mechanoreceptors, thermoreceptors, or nociceptors, depending on their selective sensitivity to mechanical, thermal, or noxious stimuli, respectively (Sinclair; Light and Perl).

 Recent physiologic studies have shown that the quality of sensation depends on the type of nerve fiber that is activated. Different diseases therefore evoke a variety of sensory deficits. Microstimulation of single sensory fibers in a peripheral nerve of an awake human subject arouses different sensations, depending on which fibers are stimulated and not on the frequency of stimulation. On the other hand, the frequency of stimulation does govern the intensity of sensation, as does the number of sensory units that are stimulated. Stated somewhat differently, afferent impulse frequency (temporal summation) is encoded by the brain in terms of magnitude or intensity of sensation. In addition, as the intensity of stimulation increases, more sensory units are activated (spatial summation).

 Localization of a stimulus was formerly thought to depend on the simultaneous activation of overlapping sensory units. Tower defined a peripheral sensory unit as a monopolar dorsal root ganglion cell, its central and distal axon extensions, and all the sensory endings in the territory supplied by the distal extension (receptive field). In the very sensitive pulp of the finger, where the error of localization is less than 1.0 mm, there are 240 overlapping, low-threshold mechanoreceptors per square centimeter. Highly refined physiologic techniques have demonstrated that activation of a single sensory unit is sufficient to localize the point stimulated and that the body map in the parietal lobe is capable, by its modular columnar organization, of encoding such information. Noteworthy also is the fact that each point in the skin that is stimulated may involve more than one type of receptor. It is possible, therefore, that a stimulus of increased intensity, e.g., a mechanical one, will activate a related pain ending.

 A stimulus, in order to gain access to its receptor, must pass through the skin and possess sufficient energy to transduce, i.e., depolarize, the nerve ending. Not only does the threshold of stimulation vary but the nerve impulse that is generated is a graded one, not an all-or-none phenomenon like an action potential in nerve. This poorly understood peripheral generator potential determines the frequency of impulse in the nerve and to what degree it is sustained or fades out (i.e., adapts to the stimulus orfatigues). The mechanism by which a stimulus is translated into a sensory experience, i.e., is encoded, is obscure. It is probably fair to say that each type of specialized ending has a membrane structure that facilitates the transductive process for a particular type of stimulus. In general, the encapsulated endings are more deeply situated, are of low-threshold type, are variably adaptable to continued stimulation (the Meissner and pacinian corpuscles are rapidly adapting; the Merkel disc and Ruffini endings are slowly adapting) and are connected to large sensory fibers (see Lindblom and Ochoa). Pain receptors lie deeper in the skin than those for touch.

 Sensory Pathways

 Sensory Nerves Fibers that mediate superficial sensation are located in cutaneous sensory or mixed sensorimotor nerves. In cutaneous nerves, unmyelinated pain and autonomic fibers exceed myelinated fibers by a ratio of 3 or 4:1. The myelinated fibers are of two types, small, lightly myelinated, A-β fibers for pain and cold, as already mentioned, and larger, faster-conducting A-α fibers for touch and pressure. The nonmyelinated autonomic fibers are efferent (postganglionic) and innervertebral plexus, sweat glands, and blood vessels. Proprioceptive fibers are located in deeper, predominantly motor nerves. In addition, these nerves contain afferent and efferent spindle and Golgi tendon organ fibers and thinner pain afferents. The differing conduction velocities of these fibers are discussed in Chap. 45.

 A single cutaneous (touch, pain, and temperature) axon connects to several receptors, all of one type, which are irregularly distributed in the skin and account for sensory spots. Stimulation of one particular type of fiber is sufficient to transduce, i.e., to depolarize, the nerve ending. The proprieceptive fibers subserve pressure sensation and, with endings in articular structures, the sense of position and movement; they enable one to discriminate the form, size, texture, and weight of objects. Sensations of tickle, itch, and wetness are believed to arise from combinations of several types of receptors. The efferent impulses from these receptors are transmitted to the spinal cord to give rise to the spinal reflex arcs, to the brainstem to evoke muscular responses, and to the cerebral cortex to give rise to conscious perceptions of sensation. The pathophysiolog of itching has been discussed by Greaves and Wall.

 Spinal Roots All the sensory neurons have their cell bodies in the dorsal root ganglia. The peripheral extensions of these cells constitute the sensory nerves; the central projections of these same cells form the posterior (dorsal) roots and enter the spinal cord. Each dorsal root contains all the fibers from skin, muscles, connective tissue, ligaments, tendons, joints, bones, and viscera that lie within the distribution of a single body segment, or somite. This segmental innervation has been amply demonstrated in humans and animals by observing the effects of lesions that involve one or two spinal nerves, such as (1) herpes zoster, which also involves sensory nerves; (2) a sensory nerve lesion (e.g., cervical root avulsion); or (3) a large, transverse lesion of the spinal cord (e.g., cervical myelotomy). In the case of these lesions, the body map in the parietal lobe is capable, by its modular columnar organization, of encoding such information. Noteworthy also is the fact that each point in the skin that is stimulated may involve more than one type of receptor. It is possible, therefore, that a stimulus of increased intensity, e.g., a mechanical one, will activate a related pain ending.

 A stimulus, in order to gain access to its receptor, must pass through the skin and possess sufficient energy to transduce, i.e., depolarize, the nerve ending. Not only does the threshold of stimulation vary but the nerve impulse that is generated is a graded one, not an all-or-none phenomenon like an action potential in nerve. This poorly understood peripheral generator potential determines the frequency of impulse in the nerve and to what degree it is sustained or fades out (i.e., adapts to the stimulus or fatigues). The mechanism by which a stimulus is translated into a sensory experience, i.e., is encoded, is obscure. It is probably fair to say that each type of specialized ending has a membrane structure that facilitates the transductive process for a particular type of stimulus. In general, the encapsulated endings are more deeply situated, are of low-threshold type, are variably adaptable to continued stimulation (the Meissner and pacinian corpuscles are rapidly adapting; the Merkel disc and Ruffini endings are slowly adapting) and are connected to large sensory fibers (see Lindblom and Ochoa). Pain receptors lie deeper in the skin than those for touch.

 Sensory Pathways

 Sensory Nerves Fibers that mediate superficial sensation are located in cutaneous sensory or mixed sensorimotor nerves. In cutaneous nerves, unmyelinated pain and autonomic fibers exceed myelinated fibers by a ratio of 3 or 4:1. The myelinated fibers are of two types, small, lightly myelinated, A-β fibers for pain and cold, as already mentioned, and larger, faster-conducting A-α fibers for touch and pressure. The nonmyelinated autonomic fibers are efferent (postganglionic) and innervertebral plexus, sweat glands, and blood vessels. Proprioceptive fibers are located in deeper, predominantly motor nerves. In addition, these nerves contain afferent and efferent spindle and Golgi tendon organ fibers and thinner pain afferents. The differing conduction velocities of these fibers are discussed in Chap. 45.

 A single cutaneous (touch, pain, and temperature) axon connects to several receptors, all of one type, which are irregularly distributed in the skin and account for sensory spots. Stimulation of one particular type of fiber is sufficient to transduce, i.e., to depolarize, the nerve ending. The proprieceptive fibers subserve pressure sensation and, with endings in articular structures, the sense of position and movement; they enable one to discriminate the form, size, texture, and weight of objects. Sensations of tickle, itch, and wetness are believed to arise from combinations of several types of receptors. The efferent impulses from these receptors are transmitted to the spinal cord to give rise to the spinal reflex arcs, to the brainstem to evoke muscular responses, and to the cerebral cortex to give rise to conscious perceptions of sensation. The pathophysiolog of itching has been discussed by Greaves and Wall.

 Spinal Roots All the sensory neurons have their cell bodies in the dorsal root ganglia. The peripheral extensions of these cells constitute the sensory nerves; the central projections of these same cells form the posterior (dorsal) roots and enter the spinal cord. Each dorsal root contains all the fibers from skin, muscles, connective tissue, ligaments, tendons, joints, bones, and viscera that lie within the distribution of a single body segment, or somite. This segmental innervation has been amply demonstrated in humans and animals by observing the effects of lesions that involve one or two spinal nerves, such as (1) herpes zoster, which also causes visible vesicles in the corresponding area of skin; (2) the effects of a prolapsed intervertebral disc, which causes hypalgnesia in a single root zone; and (3) surgical section of several roots on each side of an intact root (method of remaining sensibility). Maps of the dermatomes derived from these several types of data are shown in Fig. 9-2. It should be noted that there is considerable overlap from one dermatomal segment to the other, more so for touch than for pain. By contrast, there is little overlap between branches of the trigeminal nerve. Also, the maps differ somewhat according to the methods used in constructing them. In contrast to most dermatomal charts, those of Keegan and Garrett (based on the injection of local anesthetic into single dorsal root ganglia) show bands of hypalgnesia to be continuous longitudinally from the periphery to the spine (Fig. 9-3). The distribution of pain fibers from deep structures, though not exactly corresponding to that of pain fibers from the skin, also follows a segmental pattern.

 Figure 9-2 Distribution of the sensory spinal roots on the surface of the body. (Reproduced by permission from Sinclair.)

 Figure 9-3 Dermatomes of the upper and lower extremities, outlined by the pattern of sensory loss following lesions of single nerve roots. (Reproduced by permission from Keegan and Garrett.)
In the dorsal roots, the sensory fibers are first rearranged and function. Large and myelinated fibers enter the cord just medial to the dorsal horn and divide into ascending and descending branches. The ascending fibers and some of the ascending ones enter the gray matter of the dorsal horn within a few segments. They synapse with wide-sense relay cells that subserve segmental reflexes. Some of the ascending fibers run uninterruptedly in the dorsal columns of the same side of the spinal cord, terminating in the gracile and cuneate nuclei. The central axons of the primary sensory neurons are joined in the posterior columns by other secondary neurons whose cell bodies lie in the posterior horns of the spinal cord (see below).

The fibers in the posterior columns are displaced medially as new fibers from each successively higher root are added (Fig. 8-1 and Fig. 8-3).

**Posterior Columns**

Of the long ascending posterior column fibers, which are activated by mechanical stimuli of skin and subcutaneous tissues and by movement of joints, only about 25 percent (from the lumbar region) reach the gracile nuclei. The rest give off collaterals to or terminate in the dorsal horns of the spinal cord, at least in the cat (Davidoff). An estimated 20 percent of ascending fibers originate from cells in Rexed layers IV and V of the posterior horns and convey impulses from low-threshold mechanoreceptors that are sensitive to hair movement, to skin pressure, or to noxious stimuli. There are also descending fibers in the posterior columns, including fibers from cells in the dorsal column nuclei.

The posterior columns contain a portion of the sensory input of which the sense of touch as well as the fibers mediating the senses of touch-pressure, vibration, direction of movement and position of joints, stereesthesia—recognition of surface texture, shape, numbers and figures written on the skin, and two-point discrimination—all of which depend on patterns of touch-pressure (Fig. 8-3). However, the fiber pathways in the posterior columns are not the sole mediators of proprioception in the spinal cord (see "Posterior Column Syndrome," further on). The nerve cells of the nuclei gracilis and cuneatus and accessory cuneate nuclei give rise to a secondary afferent path, which crosses the midline in the medulla and ascends as the medial lemniscus to the posterior thalamus (see further on).

In addition to these well-defined posterior column pathways, there are cells in the "reticular" part of the dorsal column nuclei that receive secondary ascending fibers from the dorsal horns of the spinal cord and from ascending fibers in the posterolateral columns. These dorsal column fibers project to brainstem nuclei, cerebellum, and thalamic nuclei. Many other cells of the dorsal column nuclei are interneurons, with both excitatory and inhibitory effects on local reflexes or on the primary ascending neurons. They are under the influence of the sensorimotor cortex. Some act on descending corticospinal motor neurons. The functions of many of the extrathalamic projections of dorsal column cells are unknown (Davidoff).

Thiny myelinated or unmyelinated fibers enter the cord on the lateral aspect of the dorsal horn and synapse with dorsal horn cells, mainly within a segment or two of their point of entry into the cord. The dorsal horn cells, in turn, give rise to sensory secondary fibers, some of which may ascend ipsilaterally but most of which decussate and ascend in the spinothalamic tracts, as described in Chap. 8 (Fig. 8-1 and Fig. 8-2). Observations based on surgical interruption of the anterolateral funiculi indicate that these fibers mediating pain and temperature occupy the funiculus (lateral spinothalamic tract), and those conveying deep pressure occupy the ventromedial part (anteromedial spinothalamic tract). Also, as remarked in Chap. 8, an ascending tract of secondary sensory axons lies in or medial to the descending corticospinal system.

**Trigeminal Connections**

The pathways mediating cutaneous sensation from the face and head, especially touch, pain, and temperature, are conveyed to the brainstem by the trigeminal nerve. After entering the pons, the pain and temperature fibers turn caudally and run through the medulla as the ascending trigeminal tract, terminating in a long, vertically oriented nucleus that lies below it and extends to the second or third cervical segment of the cord, where it becomes continuous with the posterior horn of the spinal gray matter. Axons from the neurons of this nucleus cross the midline and ascend as the trigeminal lemniscus along the lateral border of the spinal cord.

Ascending fibers from the reticular nuclei, medial lemniscus, trigeminal lemniscus, and spinothalamic pathways merge in the midbrain and terminate in the posterior complex of the thalamus, particularly in the ventral posterior complex nucleus (VPL).

**Thalamocortical Connections**

The posterior thalamic complex projects mainly to two somatosensory cortical areas. The first area (S1) corresponds to the postcentral cortex or Brodmann's area 3, 1, and 2. S1 afferents are derived primarily from VPL and VPM (ventral postero medial—thalamus—the terminus of trigeminal filaments) and from the medial lemniscus, somatotopically, with the leg represented uppermost (face and hand are juxtaposed). Electrical stimulation of this area yields sensations of tingling, numbness, and warmth in specific regions on the opposite side of the body. The information transmitted to S1 is tactile and proprioceptive, derived mainly from the dorsal column—medial lemniscus system and concerned mainly with sensory discrimination. The second somatosensory area (S2) lies on the upper bank of the sylvian fissure, adjacent to the insula. Localization of function is less discrete in S2 than in S1, but S2 is also organized somatotopically, with the face rostrally and the leg caudally. The sensations evoked by electrical stimulation of S2 are much the same as those of S1 but, in distinction to the latter, may be felt bilaterally. Of note is the failure of cortical stimulation to evoke pain sensation.

Undoubtedly, the perception of sensory stimuli involves more of the cerebral cortex than the two discrete areas described above. Some sensory fibers probably project to the precentral gyrus and others to the superior parietal lobule. Moreover, S1 and S2 are not purely sensory in function; motor effects can be obtained by stimulating them electrically. It has been shown that sensory neurons in VPL, cuneate and gracile nuclei, and sensory neurons in the dorsal horns of the spinal cord also project to extrathalamic cortical projections as well as ascending ones. This reciprocal arrangement probably influences movement and the transmission and interpretation of pain, as discussed in Chap. 8.

Provided that the subcortical structures, especially the thalamus, are intact, certain sensations such as pain, touch, pressure, and extremes of temperature can reach consciousness. Their accurate localization, however, as well as the patient's ability to make other fine sensory discriminations, depends to a large extent on the integrity of the sensory cortex. This clinical distinction is elaborated in the discussion of the sensory syndromes, further on.

From this brief account of the various channels of sensory information, the conclusion is inevitable that at every level there is the possibility of feedback control from higher levels. Most external and some internal stimuli are highly complex and induce activity in more than one sensory system. In every system, there is sufficient redundancy to allow lesser used systems to compensate for the deficits incurred by disease.

**EXAMINATION OF SENSATION**

Most neurologists would agree that sensory testing is the most difficult part of the neurologic examination. For one thing, test procedures are relatively crude and inadequate and are unlike natural modes of stimulation with which the patient is familiar. It is also fair to say that few diagnoses are made solely on the basis of the sensory examination; more often it serves to complement the motor examination. Embarrassingly often, no objective sensory loss can be demonstrated despite symptoms that suggest the presence of such an abnormality. Rarely, the opposite persists, i.e., one sometimes discovers a sensory deficit when there has been no complaint of sensory symptoms. In the former instance, sensory symptoms in the nature of paresthesias or dysesthesias may be generated along axons of nerves not sensed. In the latter, may be felt bilaterally. Of note is the failure of cortical stimulation to evoke pain sensation.

Before proceeding to sensory testing, the physician should question patients about their symptoms, and this too poses special problems. Patients are confronted with questions addressing aspects of their everyday life. In the former instance, sensory symptoms in the nature of paresthesias or dysesthesias may be generated along axons of nerves not sensed. In the latter, may be felt bilaterally. Of note is the failure of cortical stimulation to evoke pain sensation.

If nerves, sensory roots, or spinal tracts are damaged or partially interrupted, the patient may complain of tingling or prickling feelings ("like Novocain" or like the feelings in a limb that has "fallen asleep," the common colloquialism for nerve compression), cramp-like sensations, or burning or cutting pain occurring either spontaneously or in response to stimulation.
Experimental data support the view that partially damaged touch, pressure, thermal, and pain fibers become hyperexcitable and generate ectopic impulses along their course, either spontaneously or in response to a natural volley of stimulus-evoked impulses (Ochoa and Torebjörk). These abnormal sensations are called *paresthesias,* or *dysesthesias* if they are severe and distressing. Another positive sensory symptom is *allodynia,* referring to a phenomenon in which one type of stimulus evokes another type of sensation—e.g., touch may induce pain.

The clinical characteristics of a sensation may divulge the particular sensory fibers that are involved. It has been shown that stimulation of touch fibers gives rise to a sensation of tingling and buzzing; of muscle proprioceptors, to pseudocram; of thermal fibers, to hotness and coldness; and of A-d fibers, to prickling and pain. Paresthesias arising from ectopic discharges in large sensory fibers can be induced by compression, by hypocalcemia, and by diverse diseases of the nerves.

The presence of persistent paresthesias should always raise the suspicion of a lesion involving sensory pathways in nerves, spinal cord, or higher structures. Evasive paresthesias, of course, may be of no significance. Every person has had the experience of resting a limb on the ulnar, scapial, or peroneal nerve and having the extremity "fall asleep." This is due to a demyelinating and not to ischemic interruption of axonal transport of the limb, as is commonly assumed. The hyperventilation of anxiety may cause paresthesias of the lips and hands (sometimes unilateral) from diminution of 
\[ \text{CO}_2 \] and thereby of ionized calcium; tetany may also occur, with carpopedal spasms. Severe acral and peripheral paresthesias with perversity of hot and cold sensations are characteristic of certain neurotoxic shellfish poisonings (ciguatera).

**Effect of Age on Sensory Function** A matter of importance in the testing of sensation is the progressive impairment of sensory perception that occurs with advancing age. This requires that sensory thresholds, particularly in the feet and legs, always be assessed in relation to age standards. The effect of age is most evident in relation to vibratory sense, but proprioception, touch, and fast pain are also diminished with age. Sweating and vasomotor reflexes are reduced as well.

The changes may be confirmed by dragging a pin lightly over the parts in question. If an area of diminished or absent touch or pain sensation is encountered, its boundaries should be demarcated to determine whether it has a segmental or peripheral nerve distribution or is lost below a certain level on the trunk. Such areas are best delineated by proceeding from the region of impaired sensation toward the normal. If an area of diminished or absent touch or pain sensation is encountered, its boundaries should be determined to decide whether it has a segmental or peripheral nerve distribution or is lost below a certain level on the trunk. Such areas are best delineated by proceeding from the region of impaired sensation toward the normal.

**Testing of Tactile Sensation** The detail with which sensation is tested is determined by the clinical situation. If the patient has no sensory complaints, it is sufficient to test vibration and position sense in the fingers and toes and the perception of pin-prick over the face, trunk, and extremities, and to determine whether the findings are the same in symmetrical parts of the body. A rough survey of this sort occasionally detects sensory defects of which the patient was unaware. On the other hand, more thorough testing is in order if the patient has complaints referable to the sensory system or if one finds localized atrophy or weakness, ataxia, trophic changes of joints, or painless ulcers.

A few other general rules should be mentioned. One should not press the sensory examination in the presence of fatigue, for an inattentive patient is a poor witness. Also, the examiner must avoid suggesting symptoms to the patient. After explaining in the simplest terms what is required, the examiner interposes as few questions and remarks as possible. Consequently, patients should not be asked, "Do you feel that?" each time they are touched; they are simply told to say "yes" or "sharp" each time that they feel pain. Reticence should be avoided, since it may make inexact and inaccurate responses. In patients who may be interpreting subtle changes in pinprick, differentiating between warm and cold is often more informative than differentiating between "sharp" and "dull." The patient should not see the part under examination. However, a cooperative patient may, if asked to use a pin or his fingertips, outline an analgesic or anesthetic area or determine if there is a graduated loss of sensation in the distal parts of a leg or arm. Finally, the findings of the sensory examination should be accurately recorded on a chart by shading affected regions on a preprinted figure of the body or a sketch of a hand, foot, face, or limb.

Described below are the usual bedside methods of testing sensory function. With attention to certain details of procedure, these tests are quite sufficient for most clinical purposes. For clinical investigation and research into the physiology of pain, which require the detection of threshold values and quantification of sensory impairment, a wide range of instruments are available. Their use has been described by Dyck et al (see also Lindblom and Ochoa, and Bertelsmann et al).

**Testing of Tactile Sensation** This is usually done with a wipe of cotton. Patients are first acquainted with the nature of the stimulus by applying it to a normal part of the body. When they respond, "yes", each time various other parts are touched. A patient who is simulating sensory loss may say "no" in response to a tactile stimulus. Cornified areas of skin, such as the soles and palms, will require a heavier stimulus than other areas and the hair-clad parts a lighter stimulus. As a rule, the sense of pain is the least sensitive, with corneal sensitivity to pin-prick, although it may be evoked by a great diversity of noxious stimuli. Patients must understand that they are to report the feeling of sharpness, not simply the feeling of contact or pressure of the pin point. If pinpricks are applied rapidly in one area, their effect may be summated and a heightened perception of pain may result; therefore, they should be delivered about one per second, and not over the same spot.

It is almost impossible, using an ordinary pin, to apply each stimulus with equal intensity. A pinwheel is sometimes more effective because it allows the application of a more constant pressure. This difficulty can be overcome to some extent by the use of an algometer, which enables one to deliver stimuli of constant intensity and also to grade the intensity and determine threshold values. Even with this instrument, an isolated stimulus may be reported as being excessively sharp, apparently because of direct contact with a pain spot.

If an area of diminished or absent touch or pain sensation is encountered, its boundaries should be demarcated to determine whether it has a segmental or peripheral nerve distribution or is lost below a certain level on the trunk. Such areas are best delineated by proceeding from the region of impaired sensation toward the normal. The changes may be confirmed by dragging a pin lightly over the parts in question.

**Testing of Deep Pressure-Pain** One can estimate this modality simply by lightly pinching or pressing deeply on the tendons, muscles, or bony prominences. Pain can often be elicited by heavy pressure even when superficial sensation is diminished; conversely, in some diseases, such as tarsal neurofibromata, loss of deep pressure-pain may be more striking than loss of superficial pain.

**Testing of Thermal Sense** A rough but quick way to assess thermal loss (or to corroborate a previously found zone of hypalgesia) is to apply alternate sides of a tuning fork to the skin, one side of which has been warmed by rubbing it briskly against the palm. Usually more careful examination is required, in which case the areas of skin to be tested should be exposed to room air for a brief time before the examination. The test objects should be large, preferably two stoppered test tubes containing hot (45°C) and cold (20°C) tap water. Thermometers, which extend into the water through the flask stoppers, indicate the temperature of the water at the moment of testing. At first, extreme degrees of heat and cold (e.g., 10 and 45°C) are employed to delineate roughly an area of thermal sensory impairment. The side of each tube is applied successively to the skin for a few seconds and the patient is asked to report whether the flap feels "less hot" or "less cold" over an area of suspected impairment in comparison to a normal part. The qualitative change should then be quantitated as far as possible by estimating the differences in
temperature that the patient is able to recognize. The difference in temperature between the two tubes is gradually reduced. A normal person can detect a difference of 1°C or even less when the temperature of the tubes is in the range of 28 to 32°C; in the warm range, differences between 35 and 40°C can be recognized, and in the cold range, between 10 and 20°C. If the temperature of the test object is below 10°C or above 50°C, sensations of cold or heat become confused with pain.

**Testing of Proprioceptive Sense**

Awareness of the position and movements of our limbs, fingers, and toes is derived from receptors in the muscles, tendons (Golgi tendon organs, according to Roland et al.), and joints and is probably facilitated by activation of skin receptors (Moberg). The two modalities comprised by proprioception, i.e., sense of movement and of position, are usually lost together, although clinical situations do arise in which perception of the position of a limb or digits is lost while that of passive and active movement (kinesthesia) of these parts is retained. The opposite has also been said to occur but must be very rare.

Abnormalities of position sense may be disclosed in several ways. When the patient has his arms outstretched and eyes closed, the affected arm will wander from its original position; if the fingers are spread apart, they may undergo a series of changing postures (“piano-playing” movements, or pseudostheteosis); in attempting to touch the tip of his nose with his index finger, the patient may miss the target repeatedly, but he corrects his performance with the eyes open.

The lack of position sense in the legs is demonstrated by displacing the limb from its original position and having the patient, with eyes closed, place the other leg in the same position or point to the great toe. If position sense is defective in both legs, the patient will be unable to maintain his balance with feet together and eyes closed (Romberg sign). The latter term is often used imprecisely. In the Romberg position, even a normal person whose eyes are closed will sway slightly, and the patient who lacks balance due to cerebellar ataxia or vestibulopathy or to some other motor disorder will sway considerably more if his visual cues are removed. In performing this test, the patient should optimally be barefoot. Only a marked discrepancy in balance with eyes open and with eyes closed qualifies as a Romberg sign.

The best indication of abnormality is the need to step to the side in order to avoid falling. Mild degrees of unsteadiness in nervous or suggestible patients may be omitted in seeing their attention, e.g., by having them touch the index finger of each hand alternately to the nose while they are standing with eyes closed or by following the examiner’s finger with their eyes.

Perception of passive movement is first tested in the fingers and toes, since the defect, when present, is reflected maximally in these parts. It is important to grasp the digit firmly at the sides perpendicular to the plane of movement; otherwise the pressure applied by the examiner in displacing the digit may allow the patient to identify the direction of movement. This applies as well to testing of the more proximal segments of the limb. Also, the patient should be instructed to report each movement as being “up” or “down” from the previous position (directional kinesthesia). It is useful to demonstrate the test with a large and easily identified movement, but once the idea is clear to the patient, the smallest detectable changes should be determined. The sensitivity of testing is enhanced by using the third and fourth fingers and toes. The part being tested should be moved rapidly. Normally, a very slight degree of movement is appreciated in the digits (as little as 1 degree of an arc). The test should be repeated enough times to enable chance (50 percent of responses). Defective perception of passive movement is judged by comparison with a normal limb. Spontaneous movements (e.g., through experience with daily activities). Slight impairment of passive movement may be overlooked.

**Testing of Vibration Sensation**

Vibration sense is tested by placing a tuning fork with a low rate and long duration of vibration (128 Hz) over the bony prominences, making sure that the patient responds to the vibration, not simply to the pressure of the fork, and that he is not trying to listen to it. There are mechanical devices to quantitate vibration sense, but it is sufficient for clinical purposes to compare the point tested with a normal part of the patient or the examiner. The examiner may detect the vibration after it ceases for the patient to feel it, but the test is usually performed with the tuning fork being placed on a bony prominence (e.g., the iliac crest and the lateral aspect of the ankle). The vibrating object is allowed to run down until the moment that vibration is no longer perceived, at which point the fork is transferred quickly to the corresponding part of the examiner and the time to extinction is noted. There is a small degree of accommodation to the vibration stimulus, so that slight asymmetries detected by rapidly shifting from a body part on one side to the other should be interpreted with caution. The perception of vibration at the tibial tuberosity after it has disappeared at the ankle or at the anterior iliac spine after it has disappeared at the tibial tuberosity is indicative of a peripheral neuropathy. The approximate level of a spinal cord lesion can be corroborated by testing vibratory sensation over the iliac crests and successive vertebral spines.

**Testing of Discriminative Sensation**

Damage to the sensory cortex or to the thalamocortical projections results in a special type of disturbance—namely, an inability to make sensory discriminations. Lesions in these structures usually disturb position sense but leave the so-called primary modalities (touch, pain, temperature, and vibration sense) relatively little affected. In such a situation, or if a cerebral lesion is suspected on other grounds, discriminative function should be tested further by the following tests:

**Two-Point Discrimination**

The ability to distinguish two points from one is tested by using a compass, the points of which should be blunt and applied simultaneously and painlessly. The distance at which such stimuli can be recognized as double varies but is roughly 1 mm at the tip of the tongue, 2 to 3 mm on the lips, 3 to 5 mm at the fingertips, 8 to 15 mm on the palm, 20 to 30 mm on the dorsa of the hands and feet, and 4 to 7 cm on the body surface. It is characteristic of the patient with a lesion of the sensory cortex to mistake two points for one, although occasionally the opposite occurs.

**Cutaneous Localization and Figure Writing** (Graphesthesia)

Localization of cutaneous tactile or painful stimuli is tested by touching various points on the body and asking the patient to place the tip of his index finger on the point stimulated or on the corresponding point of the examiner’s limb. Recognition of numbers or letters (these should be larger than 4 cm on the palm) or the direction of lines drawn on the skin also depends on localization of tactile stimuli. Normally, traced numbers as small as 1 cm can be detected on the pulp of the fingers if drawn with a sharp pencil. According to Wall and Noordenbos, these are also the most useful and simplest tests of posterior column function.

**Appreciation of Texture, Size, and Shape**

Appreciation of texture depends mainly on cutaneous impressions, but the recognition of the shape and size of objects is based on impressions from deeper receptors as well. The lack of recognition of shape and form is frequently a manifestation of cortical disease, but a similar clinical effect will occur if tracts that transmit proprioceptive and tactile sensation are interrupted by lesions of the spinal cord and brainstem (and, of course, of the peripheral nervous system). Sensory defects in the tactile and discriminative forms of astereognosis are not uncommon in multiple cerebral infarctions and as an aspect of cerebellar disease and as the result of injury by palpation, even though the primary sense data (touch, pain, temperature, and vibration) are intact. In practice, a pure astereognosis is rarely encountered, and the term is employed when the impairment of superficial and vibratory sensation in the hands seems to be of insufficient severity to account for the defect in tactile object identification. For this reason, astereognosis is either right- or left-sided and may be associated with the qualifications mentioned above, is the product of a lesion in the opposite hemisphere, involving the sensory cortex, particularly S2, or the thalamoparietal operations.

The classic doctrine that somatic sensation is represented only in the contralateral parietal lobe is not absolute. Beginning with Oppenheim in 1906, there have been sporadic reports of patients who showed bilateral astereognosis or loss of tactile sensation as a result of an apparently unilateral cerebral lesion. The correctness of these observations was corroborated by Semmes and colleagues, who tested a large series of patients with traumatic lesions involving either the right or left cerebral hemisphere. They found that the impairment of sensation (particularly discriminative sensation) following right- and left-sided lesions was not strictly comparable; the left hemisphere was as much as twice as often defective as the right hemisphere.

This is a composite sensation comprising touch and rapid alterations of deep-pressure sense. The only cutaneous structure capable of registering such rapid stimuli is the rapidly adapting pacinian corpuscle. The conduction of vibratory sense depends on both cutaneous and deep afferent fibers that ascend in separate but combined columns of the spinal cord but will be disturbed in patients with disease of multiple peripheral nerves, dorsal columns, medial lemniscus, and thalamus. Vibration and position sense are usually lost together, although one of them (most often vibration sense) may be affected disproportionately. With advancing age, vibration is the sensation most commonly diminished, at the toes and ankles.

**Temperature Discrimination**

Temperature discrimination is tested by using a two-tube apparatus, one containing water at 45°C and the other at 25°C. The tubes are covered with tubes of rubber or plastic (and labeled with the appropriate temperature if necessary) to mask the patient’s view and prevent him from determining which tube contains the warmer water. The tubes are arranged so that the patient cannot see the examiner’s hand as he places them on the back of the patient’s hand (or foot). The examiner should place the tube containing the warmer water on the corresponding point of the examiner’s hand (or foot) and the tube containing the colder water on the ipsilateral hand (or foot) of the patient. The examiner should heat and cool the tubes slowly to abolish the possible effect of temperature on the patient’s movements. If the patient is unable to discriminate a difference of 15°C, he is considered to have no temperature discrimination.

Finally, there is a distinction to be made between astereognosia and tactile agnosia. Some authors (e.g., Caselli) have defined tactile agnosia as a strictly unilateral disorder, right or left, in which the impairment of tactile object recognition is unencumbered by a disturbance of the primary sensory modalities. Such a disorder would be designated by others as a pure form of tactile agnosia (see above). In our view, tactile agnosia is a disturbance in which a one-sided lesion lying posterior to the postcentral gyrus of the dominant parietal lobe results in an inability to recognize an object by touch in both hands. According to this view, tactile agnosia is a disorder of apperception of stimuli and of translating them into symbols, akin to the defect in naming parts of the body, visualizing a plan or a route, understanding their effect, etc., by having them touch the index finger of each hand alternately to the nose while they are standing with eyes closed or by following the examiner’s finger with their eyes.
meaning of the printed or spoken word (visual or auditory verbal agnosia). These and other agnosias are discussed in Chap. 22.

The traditional concept of left hemispheric dominance in respect to tactile perception has been questioned by Carmon and Benton, who found that the right hemisphere is particularly important in perceiving the direction of tactile stimuli. Also, Corinck observed that patients with right-hemisphere lesions show a controversial gradient of tactile-learning than those with left-sided lesions, pointing to a relative dominance of the right hemisphere in the mediation of tactile performance involving a spatial component. Certainly the phenomenon of sensory inattention or extinction is more prominent with right than with left parietal lobe lesions and is most informative if the primary and secondary sensory cortical areas are spared. These matters are considered further on in this chapter and in Chap. 22.

SENSORY SYNDROMES

Sensory Changes due to Interruption of a Single Peripheral Nerve

These changes will vary, depending on whether the nerve involved is predominantly muscular, cutaneous, or mixed. Following division of a cutaneous nerve, the area of sensory loss is always less than its anatomic distribution because of overlap from adjacent nerves. That the area of tactile loss is greater than the one for pain relates both to a lack of collateralization (regeneration) from adjacent tactile fibers (in contrast to rapid collateral regeneration of pain fibers) and to a greater overlap of pain fibers of tactile-maze learning than those with left-sided lesions, pointing to a relative dominance of the right hemisphere in the mediation of tactile performance involving a spatial component. Certainly the phenomenon of sensory inattention or extinction is more prominent with right than with left parietal lobe lesions and is most informative if the primary and secondary sensory cortical areas are spared. These matters are considered further on in this chapter and in Chap. 22.

Sensory Changes due to Interruption of a Single Peripheral Nerve (Radiculopathy)

Because of considerable overlap from adjacent roots, division of a single sensory root does not produce complete loss of sensation in any area of skin. However, compression of a single sensory cervical or lumbar root (e.g., by a herniated intervertebral disc) can cause a segmental impairment of cutaneous sensation. When two or more contiguous roots have been completely divided, a zone of sensory loss can be demonstrated, surrounded by a narrow zone of partial loss, in which a raised threshold accompanied by excessive sensitivity (dysesthesia) may or may not be evident. For reasons not altogether clear, partial sensory loss from root lesions is easier to demonstrate by the use of a painful stimulus than by a tactile or pressure stimulus. Tendon and cutaneous reflexes (abdominal, cremasteric) may be lost. If pain is present, it may be intensified by movement of the spine and radiates in a proximal-distal direction. Disease of the nerve roots frequently gives rise to “shooting pains” and burning sensations that project down the course of their sensory nerves. The common examples are sciatica, from lower lumbar or upper sacral root compression, and sharp pain radiating from the shoulder and down the upper arm, from cervical disc protrusion.

When multiple roots are affected (polyradiculopathy) by an infiltrative, inflammatory, or compressive process, the syndrome is more complex and needs to be differentiated from polyneuropathy. Its distinguishing features are an asymmetrical muscle weakness, the differential involvement of proximal and distal limb parts, and pain and sensory loss consistent with affection of several roots, not necessarily contiguous ones. Details will be found in Chap. 46.

Sensory Changes due to Involvement of Additional Nerve Roots

Because of considerable overlap from adjacent roots, division of a single sensory root does not produce complete loss of sensation in any area of skin. However, compression of a single sensory cervical or lumbar root (e.g., by a herniated intervertebral disc) can cause a segmental impairment of cutaneous sensation. When two or more contiguous roots have been completely divided, a zone of sensory loss can be demonstrated, surrounded by a narrow zone of partial loss, in which a raised threshold accompanied by excessive sensitivity (dysesthesia) may or may not be evident. For reasons not altogether clear, partial sensory loss from root lesions is easier to demonstrate by the use of a painful stimulus than by a tactile or pressure stimulus. Tendon and cutaneous reflexes (abdominal, cremasteric) may be lost. If pain is present, it may be intensified by movement of the spine and radiates in a proximal-distal direction. Disease of the nerve roots frequently gives rise to “shooting pains” and burning sensations that project down the course of their sensory nerves. The common examples are sciatica, from lower lumbar or upper sacral root compression, and sharp pain radiating from the shoulder and down the upper arm, from cervical disc protrusion.

When multiple roots are affected (polyradiculopathy) by an infiltrative, inflammatory, or compressive process, the syndrome is more complex and needs to be differentiated from polyneuropathy. Its distinguishing features are an asymmetrical muscle weakness, the differential involvement of proximal and distal limb parts, and pain and sensory loss consistent with affection of several roots, not necessarily contiguous ones. Details will be found in Chap. 46.

Sensory Changes due to Involvement of Sensory Ganglia (Sensory Neuronopathy)

Widespread disease of the dorsal root ganglia (paraneoplastic, toxic, and inflammatory, as in Sjögren syndrome and other connective tissue diseases) produces many of the same sensory defects as disease of the roots but is unique in that proximal areas of the body show pronounced sensory loss; the face, oral mucosa, scalp, trunk, and genitilia may be sites of hypesthesia and hypalgesia. Proprioception is diminished or lost in distal and, to some extent, proximal body parts. Tendon reflexes are lost. Often there are features of dysautonomia, but strength is entirely spared. Recognition of this unusual pattern of paresthesia loss is of considerable diagnostic importance, since it raises for consideration a number of underlying diseases that might otherwise be missed; these are discussed in Chap. 46. The tabetic syndrome, described below, may also be considered a special type of polyradiculopathy or ganglionopathy.

Sensory Neuronal Syndromes

(Fig. 9-4; see also Chap. 44)
Figure 9-4 Some of the sites of lesions that produce characteristic spinal cord syndromes (shaded areas indicate lesions).

**Tabetic Syndrome** This results from damage to the large proprioceptive and other fibers of the posterior lumbosacral (and sometimes cervical) roots. It is typically caused by neurosyphilis but also by diabetes mellitus and other diseases that involve the posterior roots and/or dorsal root ganglia. Nummberness or paresthesias and lightning or lancinating pains are frequent complaints; areflexia, abnormalities of gait (page 125), and hypotonia without significant muscle weakness are found on examination. The sensory loss may involve only vibration and position senses in the lower extremities, but in severe cases, loss or impairment of superficial or deep pain sense or of touch may be added. Romberg's sign is prominent. The feet and legs are most affected, much less often the arms and trunk. Frequently, atonicity of the bladder with retention of urine and trophic joint changes (Charcot joints) are associated.

**Complete Spinal Sensory Syndrome** With a complete transverse lesion of the spinal cord, all forms of sensation are abolished below a level that corresponds to the lesion. There may be a narrow zone of hyperesthesia at the upper margin of the anesthetic zone. Loss of pain, temperature, and touch sensation begins one or two segments below the level of the lesion; vibratory and position senses have less discrete levels. The sensory (and motor) loss in spinal cord lesions that involve both gray and white matter is expressed in patterns corresponding to body segments or dermatomes. These are shown in Fig. 9-2 and Fig. 9-3 and are most obvious on the trunk, where each intercostal nerve has a transverse distribution.

Also, it is important to remember that during the subacute and chronic evolution of a transverse spinal cord lesion, there may be a greater discrepancy between the level of the lesion and that of the sensory loss. This can be understood if one envisions a lesion evolving from the periphery to the center of the cord, affecting first the outermost fibers carrying pain and temperature sensation from the legs. Conversely, a lesion advancing from the center of the cord will affect these modalities in the reverse order, with so-called sacral sparing.

**Hemisection of the Spinal Cord (Brown-Séquard Syndrome)** In rare instances, disease is confined to or predominates on one side of the spinal cord; pain and thermal sensation are affected on the opposite side of the body, and proprioceptive sensation is affected on the same side as the lesion. The loss of pain and temperature sensation begins one or two segments below the lesion. An associated spastic motor paralysis on the side of the lesion completes the syndrome (Fig. 9-4). Tactile sensation is not affected, since the fibers from one side of the body are distributed in tracts (posterior columns, anterior and lateral spinothalamic) on both sides of the cord.

**Syringomyelic Syndrome (Lesion of the Central Gray Matter)** Since fibers conducting pain and temperature sensation cross the cord in the anterior com-missure, a lesion of considerable vertical extent in this location will characteristically abolish these modalities on one or both sides over several segments (dermatomes) but will spare tactile sensation (Fig. 9-4). The most common cause of such a lesion in the cervical region is developmental syringomyelia; less common causes are intramedullary tumor, trauma, and hemorrhage. This type of dissociated sensory loss usually occurs in a segmental distribution, and since the lesion frequently involves other parts of the gray matter, varying degrees of segmental amyotrophy and reflex loss are usually present as well. If the lesion has spread to the white matter, corticospinal, spinothalamic, and posterior column signs will be conjoined. A pseudosyringomyelic syndrome has been alluded to above (see also page 1376).

**Posterior Column Syndrome** Loss of vibratory and position sense occurs below the lesion, but the perception of pain and temperature is affected relatively little or not at all. Since posterior column lesions are due to the interruption of central projections of the dorsal root ganglia cells, they may be difficult to distinguish from an affection of large fibers in sensory roots (tabetic syndrome). In some diseases that involve the dorsal columns, vibratory sensation may be involved predominantly, whereas in others position sense is more affected. With complete posterior column lesions, only a few of which have been verified by postmortem examinations (see Nathan et al for a review of the literature), not only is the patient deprived of knowledge of movement and position of parts of the body below the lesion, but all types of sensory discrimination are impaired as well. If the lesion is in the high cervical region, there is clumsiness in the palpation of objects and an inability to recognize the qualities of objects by touch, even though touch-pressure sensation is relatively intact. The stereoaesthesia is expressed also by impaired graphesthesia, tactile localization, and ability to detect the direction of lines drawn on the skin. There may be unusual disturbances of touch and pressure, manifest as lability of threshold, persistence of sensation after removal of the stimulus, and sometimes tactile and postural hallucinations. Nathan and colleagues have confirmed older observations that lesions of the posterior columns cause only slight defects in touch and pressure sensation and that lesions of the anterolateral spinothalamic tracts cause minimal or no defects in these modalities. However, a combined lesion in both pathways causes a total loss of tactile and pressure sensibility below the lesion.

The loss of sensory functions that follows a posterior column lesion—such as impaired two-point discrimination; figure writing; detection of size, shape, weight, and texture of objects; and ability to detect the direction and speed of a moving stimulus on the skin—may simulate a parietal "cortical" lesion but differs in that vibratory sense is also lost in the spinal cord lesion. Paresthesias in the form of tingling and pins-and-needles sensations or girdle- and band-like sensations are common complaints with posterior column disease, and in some cases pinprick may produce a diffuse, burning, unpleasant sensation.

In several cases on record, interruption of the posterior columns by surgical incision or other type of injury did not cause a permanent loss of the sensory modalities thought to be subserved by these pathways (Cook and Browder, Wall and Noordenbos). Since postmortem studies of these cases were not carried out, it is possible that some of the posterior column fibers had been spared. Also, it should be realized that not all proprioceptive fibers ascend to the gracile and cuneate nuclei; some proprioceptive fibers leave the posterior columns in the lumbar region and synapse with secondary neurons in the spinal gray matter and ascend in the ipsilateral posterolateral funiculus. Only cutaneous fibers continue to the gracile and cuneate nuclei. The proposition of Wall and Noordenbos, which is debatable, is that such fibers are spared. Also, it should be realized that not all proprioceptive fibers ascend to the gracile and cuneate nuclei; some proprioceptive fibers leave the posterior columns in the lumbar region and synapse with secondary neurons in the spinal gray matter and ascend in the ipsilateral posterolateral funiculus. Only cutaneous fibers continue to the gracile and cuneate nuclei. The proposition of Wall and Noordenbos, which is debatable, is that such fibers are spared.

**Anterior Myelopathy (Anterior Spinal Artery Syndrome)** With infarction of the spinal cord in the territory of supply of the anterior spinal artery or with other destructive lesions affecting the ventral posterior columns due to causes other than those discussed so far, there is usually a sensory level that is most prominent, as in some cases of myelitis, one finds a loss of pain, temperature sensation below the level of the lesion and a relative or absolute sparing of proprioceptive sensation (see also page 1317). Since the corticospinal tracts and the ventral grey matter also lie within the area of distribution of the anterior spinal artery, spastic paralysis is a prominent part of this syndrome (Fig. 9-4).

**Disturbances of Sensation due to Lesions of the Brainstem**

A characteristic feature of medullary lesions is the occurrence, in many instances, of a crossed sensory disturbance, i.e., a loss of pain and temperature sensation on one side of the face and on the opposite side of the body. This is accounted for by involvement of the descending trigeminal tract or its nucleus and the crossed lateral spinothalamic tract on one side of the brainstem and is nearly always caused by a lateral medullary infarction (Wallenberg syndrome). In the upper medulla, pons, and midbrain, the crossed trigeminothalamic and lateral spinothalamic tracts run together, and a lesion at these levels causes loss of pain and temperature sensation on the opposite half of the face and body. There are no tactile paresthesias, only thermal or painful dysesthesias. In the upper brainstem, the spinothalamic pons, and midbrain, the crossed trigeminothalamic and lateral spinothalamic tracts run together, and a lesion at these levels causes loss of pain and temperature sensation on the opposite half of the face and body. There are no tactile paresthesias, only thermal or painful dysesthesias. In the upper brainstem, the spinothalamic tract on one side of the brainstem and is nearly always caused by a lateral medullary infarction (Wallenberg syndrome). In the upper medulla, pons, and midbrain, the crossed trigeminothalamic and lateral spinothalamic tracts run together, and a lesion at these levels causes loss of pain and temperature sensation on the opposite half of the face and body. There are no tactile paresthesias, only thermal or painful dysesthesias. In the upper brainstem, the spinothalamic tract on one side of the brainstem and is nearly always caused by a lateral medullary infarction (Wallenberg syndrome).

**Sensory Loss due to a Lesion of the Thalamus (Syndrome of Déjerine-Roussy)** Involvement of the ventral posterolateral (VPL) and posteromedial (VPM) nuclei of the thalamus, usually due to a vascular lesion, less often to a tumor, causes loss or diminution of all forms of sensation on the opposite side of the body. Position sense is affected more frequently than any other sensory function and is usually but not...
always more profound than loss of touch and pinprick. With partial recovery of sensation, spontaneous pain or discomfort (thalamic pain), sometimes of the most distressing type, may appear on the affected side of the body, and any stimulus may then have a diffuse, unpleasant, lingering quality (page 840). Thermal, especially cold, stimuli, emotional disturbance, loud sounds, and even certain types of music may aggravate the painful state. In spite of this overresponse to pinprick, or to thermal or other stimuli, the patient usually shows an elevated pain threshold, i.e., a stronger stimulus than normal is necessary to produce a sensation of pain (hyperalgiesia with hyperpathia). The same type of pain syndrome may occasionally accompany lesions of the white matter of the parietal lobe or the medial lemniscus or even the posterior columns of the spinal cord.

**Sensory Loss due to Lesions of the Parietal Lobe**

In the best-known anterior parietal lobe syndrome, that of Verger-Déjerine, there are disturbances mainly of discriminative sensory functions of the opposite leg, arm, and side of face without impairment of the primary modalities of sensation (unless the lesion is deep). Loss of position sense and sense of movement, impaired ability to localize touch and pain stimuli (topagnosia), widening of two-point threshold, and astereognosis are the most prominent findings, as described earlier in this chapter and on page 483.

Another characteristic manifestation of parietal lobe lesions is sensory inattention, extinction, or neglect. In response to bilateral simultaneous testing of symmetrical parts, using either tactile or painful stimuli, the patient may acknowledge only the stimulus on the sound side; or, if the face and hand or foot on the affected side is touched or pricked, only the stimulus to the face may be noticed. Apparently, cranial structures command more attention than other less richly innervated parts. A similar phenomenon occurs when visual stimuli are simultaneously delivered to both right and left peripheral fields. Yet each stimulus, when applied separately to each side or to each part of the affected side, is properly perceived and localized. In sensory neglect, the patient ignores one side of the body and extrasensory space, contralateral to the parietal lesion, which is usually in the nondominant hemisphere. Left parietal lesions may also cause (right) sensory neglect, but less frequently. This type of sensory neglect, or extinction, which may also occur occasionally with posterior column and medial lemniscus lesions, may be detected in persons who disclaim any sensory symptoms. These phenomena and other features of parietal lobe lesions are considered further in Chap. 22.

Yet another parietal lobe syndrome (Déjérine-Mouzon) is featured by a severe impairment of the primary modalities of sensation (pain, thermal, tactile, and vibratory sense) over half of the body. Motor paralysis is variable and, with partial recovery, there may be a clumsiness that resembles cerebellar ataxia. Since the sensory disorder simulates that due to a thalamic lesion, it was called pseudothermal by Foix and coworkers. Hyperpathia, much like that of the Déjerine-Roussy syndrome (see above), has also been observed in patients with cortical-subcortical parietal lesions. The pseudothermal syndrome was related by Foix and colleagues to a syrinx infantil; Bogousslavsky and associates traced it to a parietal infarct due to occlusion of the ascending parietal branch of the middle cerebral artery. In each of the aforementioned parietal lobe syndromes, if the dominant hemisphere is involved, there may be an aphasia, a bimodal tactileagnosia, or a Gerstmann syndrome; with nondominant lesions, there may be anosognosia (page 485).

Often with parietal lesions, the patient's responses to sensory stimuli are variable. A common mistake is to attribute this abnormality to hysteresis. A lesion confined to only a part of the parietal cortex (the best examples have been due to glancing bullet or shrapnel wounds of the skull) may result in a circumscribed loss of superficial sensation in an opposite limb, mimicking a root or peripheral nerve lesion.

**Sensory Loss due to Suggestion and Hystera**

The possibility of suggesting sensory loss to a patient is a very real one, as has already been indicated. Hysterical patients rarely complain spontaneously of cutaneous sensory loss, although they may use the term numbness to indicate paralysis of a limb. Examination, on the other hand, may disclose a complete hemianesthesia—often with reduced hearing, sight, smell, and taste—as well as impaired vibration sense over only half the skull, most being anatomic impossibilities. Anesthesia of an entire limb or a sharply defined sensory loss over part of a limb, not conforming to the distribution of a root or cutaneous nerve, may also be observed. The diagnosis of hysterical hemianesthesia is best made by eliciting the other relatively specific symptoms of hystera or, if this is not possible, by noting the discrepancies between this type of sensory loss and that which occurs as part of the known, anatomically verified sensory syndromes. Sometimes, in a patient with no other neurologic abnormality or in one with a definite neurologic syndrome, one is dismayed by sensory findings that are completely inexplicable and discordant. In such cases one must try to reason through to the diagnosis by disregarding the sensory findings.

**Diagnosis of Somatosensory Syndromes**

Affirmation of the clinical sensory syndromes is often possible by the application of electrophysiologic testing. Slowing and reduced amplitude of sensory nerve conduction is found with lesions of nerve, but only if the lesion lies distal to the sensory ganglion. Severe sensory loss in a neuropathic pattern with preserved sensory nerve action potentials therefore points to a radiculopathy. Loss of or slowing of H and F responses corroborates the presence of lesions in proximal parts of nerves, plexuses, and roots. By the use of somatosensory evoked potentials, it is possible to demonstrate slowing of conduction in the peripheral nerve, in the spinal cord to a point of lesion, in the medullary tract in the central sensory pathways, and in the pathway from the thalamus to the cerebral cortex. These tests require little cooperation on the part of the patient and can be employed in the analysis of sensory systems even in patients who are comatose. (See Chap. 2 for further discussion.)

In practice, it is seldom necessary to examine all modalities of sensation and perception. With single peripheral nerve lesions, touch and pinprick testing are the most informative. With spinal cord disease, pinprick and thermal stimuli are most revealing of lateral column lesions; testing the senses of vibration, position, and movement, particularly the sense of direction of a dermal stimulus, reliably indicates posterior column lesions. Touch is the least useful. In brainstem lesions, all modes of sensation including touch are regularly affected, and this applies in general to thalamic lesions. Thus, one is guided in the selection of tests by the locale of the disease.

**CHAPTER REFERENCES**

Chapter 10

HEADACHE AND OTHER CRANIOFACIAL PAINS

GENERAL CONSIDERATIONS

In the introductory chapter on pain, reference was made to the necessity, when dealing with any painful state, of determining its quality, severity, location, duration, and time course as well as the conditions that produce, exacerbate, or relieve it. When headache is considered in these terms, a certain amount of useful information is obtained, but often less than one might expect. Auscultation of the skull may disclose a bruit (with large arteriovenous malformations) and palpation may disclose the tender, hardened arteries of temporal arteritis, sensitive areas overlying a cranial metastasis, an inflamed sinus, or a tender occipital nerve. However, apart from such special instances, examination of the head itself, though always necessary, is seldom revealing.

As to the quality of cephalic pain, the patient's description may or may not be helpful. Persistent questioning on this point may even occasion surprise, for the patient often assumes that the word headache should have conveyed enough information to the examiner about the nature of the discomfort. Most headaches, regardless of type, tend to be dull, aching, and not sharply localized, as is usually the case with disease of structures deep to the skin. Seldom does the patient describe the precise or slitting type of pain that arises from the skin. When asked to compare the pain to some other sensory experience, the patient may allude to tightness, pressure, bursting, sharpness, or stabbing. The most important information to be obtained is whether the headache throbs, indicating a vascular sensitivity. But one must keep in mind that patients often use the word throbbing to refer to a waxing and waning of the headache, without any relation to the pulse, whereas authentic pulsatile throbbing, especially if hemicranial, is highly characteristic of migraine.

Similarly, statements about the intensity of the pain must be accepted with caution, since they reflect as much the patient's attitudes and customary ways of experiencing and reacting to pain as its true severity. By temperament, some persons tend to minimize discomfort and others to dramatize it. A better index of severity is the degree to which the pain has incapacitated the patient, especially if he is not prone to illness. A severe migraine attack seldom allows performance of the day's work. Another rough index of the severity of headache is its propensity to awaken the patient from sleep or to prevent sleep. The most intense cranial pains are those associated with meningitis and subarachnoid hemorrhage, which have grave implications, and with migraine, cluster headache, or tic douloureux, which do not.

Data regarding the location of a headache are apt to be more informative. Inflammation of an extracranial artery causes pain localized to the site of the vessel. Lesions of paranasal sinuses, teeth, eyes, and upper cervical vertebrae induce a less sharply localized pain, but still one that is referred to the head itself, though usually necessary, is seldom revealing.

Throughout the body, the occurrence of电源that are markedly unusual or perception of specific pains tend to be more interpretable and are significant only for reason of their benignity. Migraine of the classic type has its onset in the early morning hours or daytime, reaches its peak of severity rapidly or gradually, and lasts, unless treated, for 4 to 24 h, occasionally for as long as 72 h. Often it is terminated by sleep. More than a single attack of migraine every few weeks is exceptional. A migrainous patient having several attacks per week usually proves to have a combination of migraine and tension headaches, an analgesic “rebound headache” or, rarely, some new, unexpected intracranial lesion. By contrast, the headaches of ocular migraine are apt to be more informative. Inflammation of an extracranial artery causes pain localized to the site of the vessel.

In the case of meningitis, it may come on more gradually, over several hours or days. Brief sharp pain, lasting a few seconds, in the eyeball (ophthalmodynia) or cranium (“icepick”) pains; “ice-cream headache,” due to pharyngeal cooling, are more common in migraineurs, with or without the characteristic headache, but otherwise are uninterpretable and are significant only for reason of their benignity. Migraine of the classic type has its onset in the early morning hours or daytime, reaches its peak of severity rapidly or gradually, and lasts, unless treated, for 4 to 24 h, occasionally for as long as 72 h. Often it is terminated by sleep. More than a single attack of migraine every few weeks is exceptional. A migrainous patient having several attacks per week usually proves to have a combination of migraine and tension headaches, an analgesic “rebound headache” or, rarely, some new, unexpected intracranial lesion. By contrast, the occurrence of an otherwise severe unilateral orbitotemporal pain coming on within an hour or two after falling asleep or at predictable times during the day and recurring nightly or daily for a period of several weeks to months is typical of cluster headache; usually an individual attack dissipates in 30 to 45 min. The headaches of intracranial tumor may appear at any time of day or night, interrupt sleep, vary in intensity, and last a few minutes to hours; as the tumor raises intracranial pressure, or with posterior fossa masses, the headache tends to be worse in the morning on awakening. Tension headaches, described further on, may persist with recurring nightly or daily for a period of several weeks to months is typical of cluster headache; usually an individual attack dissipates in 30 to 45 min. The headaches of intracranial tumor may appear at any time of day or night, interrupt sleep, vary in intensity, and last a few minutes to hours; as the tumor raises intracranial pressure, or with posterior fossa masses, the headache tends to be worse in the morning on awakening. Tension headaches, described further on, may persist with
The more or less constant relationship of headache to certain biologic events and also to certain precipitating or aggravating (or relieving) factors must always be noted. Headaches that occur regularly in the premenstrual period are usually generalized and mild in degree ("premenstrual tension"), but attacks of migraine may also be induced in certain subtypes of migraine that have their origin in cranial sinuses, disease are most typically intense after a period of inactivity, such as after a night’s sleep, and the first movements of the neck are stiff and painful. Headache from infection of the nasal sinuses may appear, with clocklike regularity, upon awakening or in the midst of sleep; it is characteristically stopped by stopping and changing in atmospheric pressure. Eyestrain headaches, of course, follow prolonged use of the eyes, as after long-sustained periods of reading, peering into glaring headlights, or exposure to the glare of video displays. In certain individuals, alcohol, intense exercise (such as weight-lifting), stooping, straining, coughing, and sexual intercourse are known to initiate a special type of bursting headache, lasting a few seconds to a few minutes. If the headache is made worse by sudden movement or by coughing or straining, an intracranial source is suggested. Anger, excitement, or worry may initiate migraine in certain disposed persons. In other patients, migraine occurs several hours or a day following a period of intense activity and stress ("weekend migraines"); they have discovered that their migraine is relieved dramatically by gentle compression of the carotid or superficial temporal artery on the painful side, and others have noted that the carotid itself is tender during the headache.

**Headache of Ocular Origin**

Another type of headache of ocular origin is located as a rule in the orbit, forehead, or temple, is of the steady, aching type and tends to follow prolonged use of the eyes in close work. This is accompanied by pain over the affected maxillary or frontal sinuses. Usually it is associated with tenderness of the skin.

**Pain-Sensitive Cranial Structures**

Understanding of headache has been greatly augmented by observations made during operations on the brain (Ray and Wolff). These observations inform us that only certain cranial structures are sensitive to pain: (1) skin, subcutaneous tissue, muscles, extracranial arteries, and periosteum of the skull; (2) delicate structures of the eye, ear, nasal cavities, and sinuses; (3) intracranial venous sinuses and their large tributaries, especially pericavernous structures; (4) parts of the dura at the base of the brain, and the arteries within the dura and pia-arachnoid, particularly the proximal parts of the anterior and middle cerebral arteries and the intracranial segment of the internal carotid artery; (5) the middle meningeal and superficial temporal arteries; and (6) the optic, oculomotor, trigeminal, glossopharyngeal, vagus, and first three cervical nerves. Interestingly, pain is practically the only sensation produced by stimulation of these structures; the pain arises in the walls of small blood vessels containing pain fibers (the nature of vascular pain is discussed further on).

Of importance also are the reference sites of pain from the aforementioned structures. Pain impulses that arise from distention of the middle meningeal artery are projected to the back of the eye and temporal area. Pain from the intracranial segment of the internal carotid artery and proximal parts of the middle and anterior cerebral arteries is felt in the eye and orbitotemporal regions. The bony skull, much of the pia-arachnoid and dura over the convexity of the brain, the parenchyma of the brain, and the ependyma and choroid plexuses lack sensitivity.

The pathways whereby sensory stimuli, whatever their nature, are transmitted to the central nervous system (CNS) are the trigeminal nerves, particularly the first and second divisions of the trigeminal nerve. Converging impulses from the meningeal vessels, from the carotid and temporal arteries, and from the orbit, eye, and sinuses, enter the cranial cavity through the foramen ovale, the foramen spinosum, and the foramen lacerum, and enter the dura mater through the foramen magnum. These impulses travel up the trigeminal nerves and their branches to the first and second divisions of the trigeminal nerve, which terminate in the brainstem and thalamus. The pain impulses from the meningeal and arterial structures are then transmitted to the thalamus and thence to the cerebral cortex, where the pain sensation is perceived.

To summarize, pain from supratentorial structures is referred to the anterior two-thirds of the head, i.e., to the territory of sensory supply of the first and second divisions of the trigeminal nerve; pain from infratentorial structures is referred to the vertex and back of the head and neck by the upper cervical roots. The seventh, ninth, and tenth cranial nerves refer pain to the naso-oral region, ear, and throat. There may be local tenderness of the scalp at the site of the referred pain. Dental or temporomandibular joint pain may also have cranial reference. With the exception of the cervical portion of the internal carotid artery, from which pain is referred to the eyebrow and supraorbital region, and the upper cervical spine, from which pain may be referred to the occiput, pain due to disease in extracranial parts of the body is not referred to the head.

**Mechanisms of Cranial Pain**

The studies of Ray and Wolff have also demonstrated that relatively few mechanisms are operative in the genesis of cranial pain. More specifically, intracranial mass lesions cause headache only if in a position to deform, displac, or exert traction on vessels and dural structures at the base of the brain, and this may happen long before intracranial pressure rises. In fact, artificially raising the intraspinal and intracranial pressure by the subarachnoid or intraventricular injection of sterile saline solution does not consistently result in headache. This has been interpreted to mean that raised intracranial pressure does not cause headache—a questionable conclusion when one considers the relief of headache that follows lumbar puncture and lowering of the cerebrospinal fluid (CSF) pressure in some patients. Actually, most patients with high intracranial pressure complain of biocapillary and biffontal headaches that fluctuate in severity, probably because of traction on vessels or dura.

**Dilatation of intracranial or extracranial arteries (and possibly sensitization of these vessels), of whatever cause, is likely to produce headache. The headaches that follow seizures, infusion of histamine, and ingestion of alcohol are probably all due to cerebral vasodilatation. Nitroglycerine, nitrates in cured meats (‘hot-dog headache’), and monosodium glutamate in Chinese food may cause headache by the same mechanism. It seems probable that the throbbing or steady headache that attends subarachnoid hemorrhage is the result of transient dilatation of meningeal vessels, which results from the increased pulsation of these vessels in the brain. Certain infectious agents, enumerated further on, seem to have a proclivity to cause severe headache. The febrile headache may be generalized or predominant in the frontal or occipital regions and is much like histamine headache in being relieved on one side by carotid or superficial temporal artery compression and on both sides by jugular vein compression. It, like migraine, is increased by shaking the head.

A similar mechanism may be operative in the severe, bilateral, throbbing headaches associated with extreme rises in blood pressure, as occurs with pheochromocytoma, malignant hypertension, sexual activity, and in patients being treated with monoamine oxidase inhibitors. Patients should be informed that mild to moderate degrees of hypertension do not cause headaches. So-called cough and exertional headaches may also have their basis in distention of intracranial vessels and their surrounding structures. Activation of the trigeminovascular system (the trigeminal nerves and the blood vessels they supply), leading to “sterile inflammation,” has also been assigned a role in the genesis of migraine headache. These and other theories of causation are discussed further on in this chapter.

Extracranial temporal and occipital arteries, when involved in giant-cell arteritis (cranial or “temporal” arteritis), give rise to severe, persistent headache, at first located in the temporal region. The pain may be mild at first, but with occlusion or dissection of the vertebral artery, the pain is postauricular. With involvement of the occipital artery in the posterior circulation, there is severe pain over the scalp and face. The pain may be described as aching or stabbing, and is accompanied by tenderness of the scalp overlying the involved arteries. The pain is relieved by rest, elevation of the head, and sometimes by the application of cold packs. The pain may be intense and may be associated with fever, chills, and malaise. The condition is usually self-limited, but it may recur. The diagnosis of giant-cell arteritis is confirmed by histologic examination of tissue obtained by biopsy of the temporal artery. The disease is treated with corticosteroids, which may relieve the symptoms and prevent recurrence. In some cases, the disease may progress to involve other organs, including the heart, lungs, and kidneys.

Infection or blockage of paranasal sinuses is accompanied by pain over the affected maxillary or frontal sinuses. Usually it is associated with tenderness of the skin in the same distribution. Pain from the ethmoid and sphenoid sinuses is localized deep in the midline behind the root of the nose or occasionally at the vertex (especially with disease of the sphenoethmoid sinus) or opposite part of the cranium. The mechanism in these cases involves changes in pressure and infection of the paranasal sinuses. Sinus pain recurs and subsides periodically, depending on drainage from the sinus. With frontal and ethmoidal sinusitis, the pain tends to be worse on awakening and gradually subsides when the patient is upright; the opposite pertains with maxillary and sphenoidal sinusitis. These relationships are believed to disclose their mechanism; pain is ascribed to filling of the sinuses and its relief to their emptying, induced by the dependent position of the ostia. Bending over intensifies the pain by causing changes in pressure, as does blowing the nose if the ostium of the infected sinus is patent, during air travel, both earache and sinus congestion may be exacerbated. Pain from the sphenopalatine ganglia is mixed with the trigeminal and other sensory fibers. The tentorially roughened trigeminal and cervical innervation zones. The central sensory connections, which ascend through the cervical spinal cord and brainstem to the thalamus, have been described in the preceding chapter.

**Infection or Blockage of Paranasal Sinuses**

Infection or blockage of paranasal sinuses is accompanied by pain over the affected maxillary or frontal sinuses. Usually it is associated with tenderness of the skin in the same distribution. Pain from the ethmoid and sphenoid sinuses is localized deep in the midline behind the root of the nose or occasionally at the vertex (especially with disease of the sphenoethmoid sinus) or opposite part of the cranium. The mechanism in these cases involves changes in pressure and infection of the paranasal sinuses. Sinus pain recurs and subsides periodically, depending on drainage from the sinus. With frontal and ethmoidal sinusitis, the pain tends to be worse on awakening and gradually subsides when the patient is upright; the opposite pertains with maxillary and sphenoidal sinusitis. These relationships are believed to disclose their mechanism; pain is ascribed to filling of the sinuses and its relief to their emptying, induced by the dependent position of the ostia. Bending over intensifies the pain by causing changes in pressure, as does blowing the nose if the ostium of the infected sinus is patent, during air travel, both earache and sinus congestion may be exacerbated. Pain from the sphenopalatine ganglia is mixed with the trigeminal and other sensory fibers. The tentorially roughened trigeminal and cervical innervation zones. The central sensory connections, which ascend through the cervical spinal cord and brainstem to the thalamus, have been described in the preceding chapter.
forehead. As for headache in general, it is important that the eyes be refracted, but eyestrain is probably not as frequent a cause as one would expect from the wholesale dispensing of eyeglasses for its relief.

Headaches that accompany disease of ligaments, muscles, and apophyseal joints in the upper part of the spine are referred to the occiput and nape of the neck on the same side and sometimes to the temple and forehead. These headaches have been reproduced in part by the injection of hypertonic saline solution into the affected ligaments, muscles, and zygapophyseal joints. Such pains are especially frequent in late life because of the prevalence of degenerative changes in the cervical spine and tend also to occur after whiplash injuries or other forms of sudden flexion, extension, or torsion of the head on the neck. If the pain is arthritic in origin, the first movements after being still for some hours are stiff and painful. The pain of fibromyalgia, evidenced by tender areas near the cranial insertion of cervical and other muscles, is a controversial entity. There are no pathologic data as to the nature of these vaguely palpable lesions, and it is uncertain whether the pain actually arises in them. They may represent only the deep tenderness felt in the region of referred pain or the involuntary secondary protective spasm of muscles. Sleep disturbance is often associated, as is depression. Massage of muscles, heat, and injection of the tender spots with local anesthetic have unpredictable effects but relieve the pain in some cases. Unilateral occipital headache is often misinterpreted as occipital neuralgia (see further on).

The headache of meningeal irritation (infection or hemorrhage) is acute in onset, usually severe, generalized, deep-seated, constant, and associated with stiffness of the neck, particularly on forward bending. It has been ascribed to increased intracranial pressure; indeed, the withdrawal of CSF may afford some relief. However, dilatation and inflammation of meningeal vessels and the chemical irritation of pain receptors in the large vessels and meninges by chemical agents, particularly serotonin and plasma kinins, are probably more important factors in the production of pain and spasm of the neck extensors. In the chemically induced meningitis from rupture of an epidermoid cyst, for example, the spinal fluid pressure is usually normal but the headache is severe.

Lumbar puncture (LP) headache is characterized by a steady occipitonalchial and frontal pain coming on within a few minutes after arising from a recumbent position and relieved within a minute or two by lying down. Its cause is a persistent leakage of CSF into the lumbar tissues through the needle track. The CSF pressure is low (often zero in the lateral decubitus position), and the injection of sterile isotonic saline solution intrathecally or the placing of an epidural “blood patch” relieves the headache. Usually this type of headache is increased by compression of the jugular veins but is unaffected by digital obliteration of one carotid artery. It seems probable that, in the upright position, a low intraspinal and negative intracranial pressure permits caudal displacement of the brain, with traction on dural attachments and dural sinuses. Pannullo and colleagues, with magnetic resonance imaging, have demonstrated this downward displacement of the cranial contents.

Understandably, then, headache following cisternal puncture is less frequent. As soon as the leakage of CSF stops and CSF pressure is restored (usually within hours or a few days), the headache disappears. “Spontaneous” low-pressure headache may follow a sneeze, strain, or athletic injury, presumably because of rupture of the arachnoid sleeve along a nerve root (page 671). Less frequently, lumbar puncture is complicated by severe stiffness of the neck and pain over the back of the neck and occiput (page 670); a second spinal tap in some instances discloses slight pleocytosis but no decrease in glucose—a sterile or chemical meningitis. This benign reaction must be distinguished from the rare occurrence of bacterial meningitis due to introduction of bacteria by the LP needle.

Headaches that are aggravated by lying down occur with chronic subdural hematoma and some tumors, especially with those in the posterior fossa. The headaches of pseudotumor cerebri are also generally worse in the supine position.

The identification of a number of neurotransmitters has helped in the understanding of headache mechanisms. These are considered below in the section on migraine, since they have been best studied in this form of headache.

PRINCIPAL VARIETIES OF HEADACHE

There should be little difficulty in recognizing the acute headaches of glaucoma, purulent sinusitis, subarachnoid hemorrhage, and bacterial or viral meningitis and the subacute or more chronic headache of brain tumor provided that these sources of headache are kept in mind. A fuller account of these types of headache may be found in later chapters of this book, where the underlying diseases are described. When the headache is chronic, recurrent, and unattended by other symptoms and signs of neurologic disease, the physician faces a more difficult diagnostic problem.

The following types of headaches should then be considered (see Table 10-1). In general, the classification of these headaches and other types of craniofacial pain follow those of the International Headache Society (see Olesen). One area of controversy in classification concerns the status (and indeed the existence) of tension headache. A currently held view, with which the authors do not entirely agree, is that there is a continuum between migraine and tension headache. This relationship is considered further on.

Table 10-1 Common types of headache

MIGRAINE

Migraine is a ubiquitous familial disorder characterized by periodic, commonly unilateral, often pulsatile headaches which begin in childhood, adolescence, or early adult life and recur with diminishing frequency during advancing years.

Two closely related clinical syndromes have been identified. The first is called migraine with aura and the second, migraine without aura (terminology of the International Headache Society). For many years the first syndrome was referred to as classic or neurologic migraine, and the second, as common migraine. The ratio of classic to common migraine is 1.5. Either type may be preceded by vague premonitory changes in mood and appetite (a prodrome). Migraine with aura, the term now used to denote classic migraine, is ushered in by an evident disturbance of nervous function, most often visual, followed in a few minutes by hemispheric or, in about one-third of cases, by bilateral headache, nausea, and sometimes vomiting, all of which last for hours or as long as a day or two. Migraine without aura is characterized by an unheralded onset of hemispheric headache or, less often, by generalized headache with or without nausea and vomiting, which then follows the same temporal pattern as the migraine with aura. Sensitivity to light and noise attends both types and intensification with movement of the head is common. If the pain is severe, the patient prefers to lie down in a quiet, darkened room and tries to sleep. Both headache syndromes usually respond to ergotamine, sumatriptan, and related drugs.

The genetic nature of classic migraine (with an aura) is apparent from its occurrence in several members of the family of the same and successive generations in 60 to 80 percent of cases. Twin and sibling studies have not revealed a consistent mendelian pattern in either the classic or common form, and the inheritance in all likelihood is polygenic. Certain rare forms of migraine, such as familial hemiplegic migraine, appear to be monogenic disorders, but the role of these genes, one of which codes for a calcium channel (see below), in classic and common migraine is speculative.

Migraine, with or without aura, is a remarkably common condition; its prevalence among Caucasians is in the range of 4 to 6 percent among men and 13 to 18 percent among women (see Stewart et al). The numbers are lower in Asians. Migraine may have its onset in childhood but usually begins in adolescence; in more than 80
percent of patients, the onset is before 30 years of age. Both the prevalence and gender ratio vary with age, increasing to about 40 years of age and declining thereafter. The headaches tend to occur during the premenstrual period; in about 15 percent of women migraineurs, the attacks are exclusively perimenstrual ("true menstrual migraine"), although estrogen and progesterone levels throughout the menstrual cycle are the same in normal and migrainous women. Menstrual migraine, discussed further on, is thought to be related to the withdrawal of estradiol rather than progesterone (Somerville). The attacks cease during pregnancy in 75 to 80 percent of women, and in others they continue at a reduced frequency; less often, attacks of migrainous headache occur in the absence of menstruation. Migraine usually diminishes in severity and frequency with age, it may actually worsen in some postmenopausal women, and estrogen therapy may either increase, or, paradoxically, diminish the incidence of headaches. The use of birth control pills has been associated with an increased frequency of migraine and with new cases of permanent neurologic deficit. Some patients link their attacks to certain dietary items—particularly chocolate, cheese, fatty foods, oranges, tomatoes, and onions—but these connections seem to us to be overrated. Some of these foods are rich in tyramine, which has been incriminated as a provocative factor in migraine. Alcohol, particularly red wine or port, regularly provokes an attack in some persons; in others, headaches are consistently induced by exposure to glare or other strong sensory stimuli, sudden jarring of the head ("footballer's migraine"), or by rapid changes in barometric pressure.

Migraine with aura has its onset soon after awakening, but it may occur at any time of day. During the preceding day or so, there may have been mild changes in mood (sometimes a surge of energy or a feeling of well-being), hunger or anorexia, drowsiness, and frequent yawning. Then, abruptly, there is a disturbing visual disturbance consisting usually of unformed lights (photophobia), an enlarging blind spot with an area of scotoma (scintillating scotoma), or formations of dazzling zigzag lines (arranged like the battlements of a castle, hence the term fortification spectra or teichopsia). Some patients complain of blurred or shimmering or cloudy vision, as though they were looking through thick or smoked glass or the wavy distortions produced by heat rising from a luminous hallucination. These attacks may last several minutes and eventually may leave an island of visual loss in their wake (scotomatic defects); the latter are usually bilateral and often homonymous (involving corresponding parts of the field of vision of each eye), pointing to their origin in the visual cortex. Visual abnormalities of retinal and optic nerve origin have also been described (see further on).

Other focal neurologic symptoms, much less common than usual visual ones, include numbness and tingling of the lips, face, and hand (on one or both sides); slight confusion of thinking; weakness of an arm or leg; mild aphasia or dysarthria, dizziness, and uncertainty of gait; or drowsiness. Only one or a few of these neurologic phenomena are present in any given patient, and they tend to occur in more or less the same combination in each attack. If weakness or paresthetic numbness spreads from one part of the body to another or if one neurologic symptom follows another, this occurs relatively slowly over a period of minutes (not over seconds, as in a seizure). These neurologic symptoms last for 1 to 15 min, sometimes longer; as they begin to recede, they are followed by a unilateral dull pain that progresses to a throbbing headache (usually not always on the side of the cerebral disturbance), which slowly increases in intensity. At its peak, within minutes to an hour, the patient is forced to lie down and to shun light and noise. Light is irritating and may be painful to the globs, or it is perceived as very bright (dazzle) and strong odors are extremely offensive. The nausea and vomiting may occur hours and sometines days after the aura, and may occur several times over weeks or months. Although the headache may be an unpleasant feature of the illness. The temporal vessels may be tender and the headache may be worsened by strain or jarring of the body or rapid movement of the head. Pressure on the scalp vessels or carotid artery may momentarily reduce the pain.

Between attacks, the migrainous patient is normal. For a time, when pschomastic medicine was much in vogue, there was insistence on a migrainous personality, characterized by tenseness, rigidity of attitudes and thinking, meticulousness, and perfectionism. Further analyses, however, have not established a particular personality type in the migraineur. Moreover, the fact that the headaches may begin in early childhood, when the personality is relatively amorphous, would argue against the idea of a clear relationship, as there are many statements to the contrary, between migraine and neurosis. Some patients have noted that the attacks of migraine tend to occur during the "let-down period," after many days of hard work or nervous tension, but the temporal relations between headache and the day's or week's activities have not proved to be consistent. The relationship to epilepsy is also tenuous; the incidence of seizures is slightly higher in migrainous patients and their relatives than in the general population. Lance and Anthony find no mechanism common to migraine and epilepsy. There does seem to be in migraines an overrepresentation of motion sickness and of fainting.

Migraine Variants Much variation occurs. The headache may be exceptionally severe and abrupt in onset ("crash migraine"), raising the specter of subarachnoid hemorrhage. The aura or prodrome revealing the attack instantly lasts over several minutes. The headache may accompany rather than follow the neurologic abnormalities. Though typically hemicranial (the French word migraine is said to be derived from megrim, which in turn was derived from the Latin hemiceranica and its corrupted forms hemigranea and migranea), the pain may be frontal, temporal, or generalized.

Migraine without aura Migraine without aura is the most frequent variant of migraine. Migraines may also occur without aura, although the prodrome is usually similar. These attacks are usually very abrupt in onset, often without a prodrome, and often precede a severe headache, or be plunged into a state of confusion, with belligerent and irrational behavior that lasts for hours or several days before clearing. In yet another type, a child or adult may experience unilateral paralysis. In still other cases, monocular blindness is associated with disc edema (optic neuritis). In still yet another case, an infant, child, or adult has episodes of unilateral paralysis that may long outlast the headache.

Migraine with aura A particularly troublesome migraine variant occurs in a child or adolescent who, after a trivial head injury, may lose sight, suffer severe headache, or be plunged into a state of confusion, with belligerent and irrational behavior that lasts for hours or several days before clearing. In yet another variant there is an abrupt onset of either one-sided paralysis or aphasia after virtually every minor head injury (we have seen this condition several times in college athletes, but with any symptom). Although a history of migraine is frequent, it has not been seen in hemiplegic migraine.

Hemiplegic Migraine In a related disorder known as hemiplegic migraine, an infant, child, or adult has episodes of unilateral paralysis that may long outlast the headache. Several families have been described in which this condition was inherited as an autosomal dominant trait (familial hemiplegic migraine). In the latter disorder, linkage-analysis studies have localized the responsible gene to chromosome 19 in one-third of families (Joutel et al), but in others, the gene has been localized to chromosome 19, and in yet others, no linkage has been found. The gene on chromosome 19 codes for a voltage-gated calcium channel protein, which
attacks of migraine, instead of beginning in childhood (see pages 880 and 913) and recurring in
Lauritzen and Lance has suggested that the trigeminal pathways are in a state of persistent hyperexcitability in the migraine patient and that they discharge periodically, perhaps in

depression of Læ, and considerable work since then has corroborated this idea. These observations, however, apply only to migraine with aura; the blood flow during
period. The same dilatation has been inferred to occur in the middle cerebral arteries from observations with transcranial Doppler imaging. The well-established
matter must be regarded as unresolved, but clearly there is an alteration in blood flow during auras and a vascular element is likely in both types of migraine. Iversen
reports of Dorfman and coworkers, in which cerebral infarction was (see below). Cutter et al, using perfusion-weighted MRI, corroborated the finding of diminished occipital cerebral blood flow during the aura in four patients.
showed a reduction in blood flow that started in the occipital cortex and spread slowly forward on both sides, in a manner much like that of the spreading depression
of Leã (see below). The puzzle is how this genetic fault is translated periodically into a regional neurologic deficit, unilateral headache, or both. For many years, our thinking about the pathogenesis of migraine was dominated by the views of Harold Wolff and others—that the headache was due to the
distention and excessive pulsation of branches of the external carotid artery. Certainly the throbbing, pulsating quality of the headache and its relief by compression of
that the basic process has been greatly intensified. However, always to be
considered in the diagnosis of such cases is the possibility that migraine has been combined with tension headache (migraine-tension or mixed-pattern headache) or
transformed to so-called analgesia-rebound headache or ergotamine-dependency headache. Ergot intoxication or narcotic addiction are other diagnostic
considerations. It has been our practice to admit such patients to the hospital, discontinue all ergot and narcotic medication, and administer corticosteroids
intravenously or ergots intravenously in selected patients (see further on for details of treatment).

The relationships between migraine, menses, and pregnancy have already been addressed. In general, headaches can be expected to abate during pregnancy, but—in our experience—a few women have an intensification or the appearance of auras in the third trimester.

Under the title “Pseudomigraine with Temporary Neurological Symptoms and Lymphocytic Pleocytosis,” Gomez-Aranda and colleagues have described what is
possibly yet another migraine variant. Their series comprised 50 adolescents and young adults, predominantly males, who developed several episodes of transient
(hours) neurologic deficits, accompanied by migraine-like headaches and sometimes fever. One-quarter of this group had a history of migraine and a similar number had a viral-illness-like illness within 3 weeks before the onset of the syndrome. The CSF contained from 10 to 780 lymphocytes per cubic millimeter and the total protein was elevated. The authors reported more middle and posterior meningeal arteries had visual symptoms. The patients were asymptomatic between attacks and in none did the entire illness persist beyond 7 weeks. The causation and pathophysiology of this syndrome and its relation to migraine are entirely obscure, although an aseptic inflammation of the leptomeningeal vasculature has been proposed. We have observed several similar cases, presumably parainfectious, and have tentatively
found corticosteroids to be useful.

Cause and Pathogenesis So far, it has not been possible to determine, from the many clinical observations and investigations, a unifying theory as to the cause and
pathogenesis of migraine. Tension and other emotional states, which are claimed by some migraineurs to precede their attacks, are so inconsistent as to be no more than
a coincident factor. Clearly, an identifiable genetic factor is implicated, although it is expressed in a recognizable mendelian pattern (autosomal dominance) in a relatively small number of families (see above). The puzzle is how this genetic fault is translated periodically into a regional neurologic deficit, unilateral headache, or both. Our thinking about the pathogenesis of migraine was dominated by the views of Harold Wolff and others—that the headache was due to the
distention and excessive pulsation of branches of the external carotid artery. Certainly the throbbing, pulsating quality of the headache and its relief by compression of
the common carotid artery supported this view, as did the early observation of Graham and Wolff that the headache and amelioration of pulsation of the extracranial
arteries diminished after the intravenous administration of ergotamine tartrate.

The importance of vascular factors continues to be emphasized by more recent findings. In a group of 11 patients with classic migraine, Olsen and colleagues, using the xenon inhalation method, noted a regional reduction in cerebral circulation during the period when neurologic symptoms appear. They concluded that the reduction in blood flow was sufficient to cause both ischemia and the neurologic deficits and that the latter had a vascular origin. In a subsequent study, Woods and colleagues observed a patient who, during positron emission tomography (PET), fortuitously had an attack of common migraine. Highly sophisticated measurements showed a reduction in blood flow that started on both sides in an occipital lobe and extended forward slowly (2.2 mm/min) as a wave of “spreading oligemia” that does not respect arterial boundaries ( Lauritzen and Olsen). Both of these events are intriguingly similar to the phenomenon of “spreading cortical depression,” first observed by Læ in experimental animals. He demonstrated that a nocuous stimulus applied to the rat cortex was followed by vasoconstriction and slowly spreading waves of inhibition of the electrical activity of cortex. The earliest vascular change was a 50% reduction in the rate of propagation of the electrical impulse. As the spreading depression approached the dura mater, the arterial diameter changed from 65 to 30 μm, matching the experience with both the aura and migraine without aura. This reduction in the arterial diameter caused by spreading cortical depression of Læ, and considerable work since then has corroborated this idea. These observations, however, apply only to migraine with aura; the blood flow during common migraine has generally remained normal.

Another hypothesis linking the aura and the painful phase of migraine has been proposed by Moskowitz. The linkage is based on the fact that the involved vessels, both extracranial and intracranial, are innervated by small unmyelinated fibers, which are derived from the trigeminal nerve and subserve both pain and autonomic functions (trigeminovascular complex). Moskowitz found that activation of these fibers releases substance P and other peptides into the vessel wall. He has postulated that the released peptides serve to dilate the cerebral vessels and increase their permeability, culminating in a throbbing unilateral headache. More recently, nitric oxide that is generated by endothelial cells has been implicated as the cause of migraine headache, but the reason for its release and the relationship to blood flow changes is unclear.

The foregoing observations leave a number of questions unanswered. Is one to conclude that migraine with and without aura are different diseases, involving
extracranial arteries in one instance and intracranial ones in another? Is the circulatory change the primary cause of headache, or is it a secondary or coincidental phenomenon? Is diminished neuronal activity (spreading depression) the primary cause of neurologic symptoms (it seems so) and headache (unclear), or is the
disruption of the trigeminal system secondary to reduced metabolic demand? Why are the posterior portions of the brain so often implicated? Blau and DEXTER and also
Drummond and Lance are confident that the presence or absence of headache does not depend on extracranial vascular factors. These authors point to their findings
that occlusion of blood flow through the scalp or common carotid circulation fails to alleviate the pain of migraine in one-third to one-half the patients. Alternatively, Lance has suggested that the trigeminal pathways are in a state of persistent hypoperfusion in the migraine patient and that they discharge periodically, perhaps in
response to the sensation of pain from the peripheral circulation. Alternatively, there is a considerable body of circumstantial evidence that serotonin acts as a neurotransmitter and humoral mediator in the neural and vascular components of the
migraine headache. This evidence and the role of other factors in the pathogenesis of migraine have been reviewed in detail by Lance and Goodfay. The potential
role of nitric oxide has been mentioned, and its importance in migraine is bolstered by the observation that drugs blocking the production of nitric acid ameliorate the
headache.

No final reconciliation of all these conflicting data is possible at this time and the mechanism of migraine remains incompletely explained. Several aspects seem clear, however. The authors continue to favor the unique mechanism of spreading depression as the best explanation of the neurologic deficit, as well as the view that a triggering factor remains unknown. It is most plausible that spreading depression is the cause of the headache, and that underlie these changes and precisely what is altered by the genetic predisposition to migraine are unresolved. There are consistent vascular changes during the aura (reduced regional flow, mainly in posterior regions of the cerebrum) and, at the same time, dilation of both basal brain and scalp vessels; but the connection of this change in caliber to pain, the traditional explanation for headache, is not certain. Perhaps emotion, fatigue, fasting, mild head injury, and so forth serve, in vulnerable individuals, to activate the neural mechanisms intermittently.

Diagnosis Neurologic migraine should occasion no difficulty in diagnosis if the above facts are kept in mind and a good history is obtained. The difficulties come from a lack of awareness that (1) a progressively unfolding neurologic syndrome may be migrainous in origin, (2) the neurologic disorder may occur without headache, and (3) the neurologic disorder is often out of proportion to the pain. Mild head injury, which may be an unrecognized event, or the occurrence of which may prove difficult to distinguish from the other common types of headache. Some of these problems merit elaboration because of their practical importance.

The neurologic part of the migraine syndrome may resemble focal epilepsy, the clinical effects of a slowly evolving hemorrhage from an arteriovenous malformation or aneurysm, a transient ischemic attack, or a thrombotic or embolic stroke. It is the pace of the neurologic symptoms of migraine, more than their character, that reliably distinguishes the condition from epilepsy.

Ophthalmoplegic migraine will always suggest a carotid aneurysm, but in normotensive children sacular aneurysm is a great rarity, and in very few adult cases has carotid arteriography revealed such an abnormality. There have been many claims that the habitual occurrence of migraine on the same side of the head increases the likelihood of an underlying arteriovenous malformation (AVM). R. D. Adams, who studied more than 1200 patients with AVFs, found that the headaches, which occurred in over 30 percent of cases, usually did not have the other features of either migraine or cluster headache. However, in about 5 percent the headaches were associated with visual aura, indistinguishable from neurologic migraine. Stated somewhat differently, the incidence of classic migraine is more than five times greater in patients with AVMs than in the general population. In most of the patients, the AVM was in the occipital region, on the side of the headache; and in most, there was an initial visual aura. Approximately half of the patients with AVM and migraine had a family history of migraine. Thus, AVM must be regarded as an acknowledged cause of recurrent headache, and the latter may be frequent and troublesome for years before the malformation is revealed by a hemorrhage or discovered by other manifestations.

A special problem relates to paradoxes of throbbing headache that is not hemispheric in distribution, not preceded by a neurologic aura, and not accompanied by other known causes. Are these cases examples of common (noncerebral) migraine or of some other type of cephalalgia? Unfortunately, the available data do not bear directly on the interpretation of the patient's symptoms; and since there is as yet no valid confirmatory laboratory test, the controversy as to where migraine begins and ends is still the armchair type. Favoring the diagnosis of migraine are onset in childhood or adolescence, lifelong history, positive family history, and response of the headache to ergotamine or sumatriptan. The observation that pattern and flash visual stimulation induces fast waves of high amplitude in children with migraine may, if corroborated, prove to be helpful (Mortimer et al).

Treatment of Migraine This topic may logically be subdivided into two parts—control of the individual attack and prevention. The time to initiate treatment of an attack depends upon the visual (prophylactic) provisions of the very onset of the headache (see below). If the headaches are mild, the patient may already have learned that acetosalicylic acid, acetylsalicylic acid, or a nonsteroidal anti-inflammatory drug (the most effective drugs for mild and moderate cases in our experience) will suffice to control the pain. Insofar as one good response may be obtained from one type of nonsteroidal anti-inflammatory drug and not from another, it is advisable to try two or three preparations in successively increasing doses of headache. Rarely, patients can be given small amounts of muscle relaxants, such as cyclobenzaprine with aspirin or acetylsalicylic acid, for limited periods. The combination of aspirin or acetylsalicylic acid, caffeine, and butalbital, though popular with some patients, is usually incompletely effective if the headache is severe, and is capable of causing dependence. Numerous other agents have proved to be effective and each has had a period of popularity among neurologists (Schulman and Silberstein).

Overall, for severe attacks, the ergot alkaloids, ergotamine tartrate, and particularly dihydroergotamine (DHE) and sumatriptan or one of the newer “triptans” (e.g., zolmitriptan, rizatriptan) are probably the most effective forms of treatment and are best administered early in the attack. Ergotamine is an alpha-adrenergic agonist with strong serotonin (5HT) receptor affinity and vasoconstrictor action. The drug is taken as an uncoated 1- to 2-mg tablet of ergotamine tartrate, held under the tongue until dissolved (or swallowed), and repeated every half hour until the headache is relieved or until a total of 8 mg is taken. A single oral dose of promethazine (Phenergan), 50 mg, or of metoclopramide (Reglan), 20 mg, given with the ergotamine, relaxes the patient and allows nausea and vomiting. Patients in whom vomiting prevents oral administration may be given ergotamine by rectal suppository or DHE by nasal spray or inhaler (one puff at onset and another at 30 min) or learn to give themselves a subcutaneous injection of DHE (usual dosage 1 mg). Caffeine, 100 mg, is thought, on slim evidence, to potentiate the effects of ergotamine and other medications for migraine. When ergotamine is administered early in the attack, the headache will be abolished or reduced in severity and duration in some 70 to 75 percent of patients.

A single 6-mg dose of sumatriptan (a selective agonist of 5HT receptors), given subcutaneously, is an equally effective and well-tolerated treatment for migraine attacks. An advantage of this drug is the ease of self-administration using prepackaged injection kits, thus avoiding frequent and inconvenient visits to the emergency department. Sumatriptan can also be given orally in a 50- or 100-mg tablet, zolmitriptan in a 2.5 or 5 mg tablet, and rizatriptan in a 10 mg dose repeated if needed in 2 h, but their latencies are considerably longer than that of the subcutaneous injection. Sumatriptan is available as an intranasal spray, which is particularly useful in patients with nausea and vomiting. The response rate after 2 h is similar to that of the orally administered drug, although the nasal spray acts more rapidly.

For severe cases that arrive in the emergency department or physician's office having failed to obtain relief with the above medications, Raskin has found metoclopramide 10 mg IV, followed by dihydroergotamine 0.5 to 1 mg PO every 8 h for 2 days, to be effective. Intravenous and the concomitant medications have also been useful in some refractory cases and in terminating migraine status, but they should not be given continuously. If a depressive illness emerges as an important problem, as it frequently does, it is treated along the lines described in Chap. 57.

The sympathomimetic drug isometheptene combined with a sedative and acetylsalicylic acid (Midrin) has been useful for some patients and probably acts in a similar way to ergotamine and sumatriptan. A wide array of other drugs have been recommended as therapeutic adjuncts, e.g., metoclopramide, prochlorperazine, chlorpromazine, ketorolac, and intranasal lidocaine. Each of these drugs, given alone, is effective in alleviating the headache in about half of patients. This fact emphasizes the need for blinded placebo trials for any new drug that is introduced for the treatment of headache.

Because of the danger of prolonged arterial spasm in patients who have vascular (particularly coronary) disease or are pregnant, they should not be given ergotamine and DHE. Elderly patients should be carefully observed and blood pressure monitoring during and after administration of the drugs. Even in healthy individuals, major cerebral or cardiac ischaemia or 6 to 8 h may be required before sumatriptan should be repeated. With sumatriptan, the usual dosage is 50 mg and 20 mg. The risk of uncontrolled hypertension or to patients taking serotoninergic and triptocyclic antidepressants. Contraceptive agents taken orally or implanted subcutaneously have had a propensity to induce migraine, but this risk has been reduced greatly with the introduction of low-estrogen agents.

If, in an individual attack, all of the foregoing measures fail, it is best to resort to narcotics, which usually give the patient a restful, pain-free sleep. Halfway measures at this point are usually futile. However, the use of narcotics as the mainstay of acute or prophylactic therapy is to be avoided.

Prophylactic Treatment In individuals with frequent migraine attacks, efforts at prevention are worthwhile. The most effective agents have been beta blockers, antidepressants, and anticonvulsants. Commonly used doses are 20 to 30 mg three times daily and increasing the dosage gradually to as much as 240 mg daily, probably best given as a long-acting preparation in the higher dosage ranges. Underdosage is a major reason for inefficacy. If propranolol is unsuccessful, one of the other beta blockers—atenolol (40 to 160 mg/day), timolol (20 to 40 mg/day), or metoprolol (100 to 200 mg/day)—may prove effective. In patients who do not respond to these drugs over a period of 4 to 6 weeks, valproic acid 250 mg taken three to four times daily or one of the antidepressants (amitriptyline, 75 to 125 mg nightly) may be tried. Calcium channel blockers (verapamil, 320 to 480 mg/day; nifedipine, 90 to 360 mg/day) are also effective in decreasing the frequency and severity of migraine attacks in some patients, but there is typically a lag of several weeks before benefit is attained. Methysergide (Sansert), an ergot-like preparation, in doses of 2 to 6 mg daily for several weeks or months, has proven to be a useful agent in the prevention of migraine. Retroperitoneal and pulmonary fibrosis are rare but serious complications that can be avoided by discontinuing the medication for 3 to 4 weeks after every 5-month course of treatment. Clonidine, 0.05 mg three times daily; Midrin; indomethacin, 150 to 200 mg/day; and cyproheptadine (Periactin), 4 to 16 mg/day, are found to be helpful in some patients and may be particularly useful in preventing predictable attacks of perimeningual migraine. A typical experience is for one of these medications to reduce the number and severity of headaches for several months and then to become less effective, whereupon an increase in the dosage, if
tolerated, may help; or one of the many alternatives can be tried. The newest putative treatment for cluster headache, both migraine and tension, is the injection of botulinum toxin (Botox) into sensitive vessels and other cranial muscles. Elimination of headaches for 2 to 4 months has been reported—a claim that justifies further study.

A group of relatively uncommon headaches respond very well to indomethacin, so much so that some authors have defined a category of indomethacin-responsive headaches. These include organic migraine, chronic paroxysmal hemicrania (see further on), and hemicrania continua, exortional headache, and some instances of premenstrual migraine.

Some patients know or allege to know that certain items of food induce attacks (chocolate, hot dogs, smoked meats, oranges, and red wine are the ones most commonly mentioned), and it is obvious enough that they should avoid these foods if possible. Limiting caffeinated beverages may be helpful. In certain cases the correction of a refractive error, an elimination diet, or behavioral modification is said to have reduced the frequency and severity of migraine and of tension headaches. However, the methods of study and the results are so poorly controlled that it is difficult to evaluate them. All experienced physicians appreciate the importance of establishing a routine for the patient and of teaming up with a psychiatrist. There is no need for the neurologist to be the sole provider of treatment and advice; the patient who is followed by a psychiatrist and a family doctor has an excellent chance of solving this problem.

Psychotherapy has not been helpful, or at least one can say that there is no critical evidence of its value. The claims for sustained improvement of migraine with chiropractic manipulation are similarly unsubstantiated and do not accord with our experience. Meditation, acupuncture, and biofeedback techniques all have their advocates, but again the results, while not to be discounted, are uninterpretable.

Cluster Headache

This type of headache has been described under a variety of names, including paroxysmal nocturnal cephalalgia (Adams), migrainous neuralgia (Harris), histamine cephalalgia (Horton), red migraine, erythrogea, temporal arthralgia, or pachycephalomy. To be distinguished also are the Tolosa-Hunt syndrome of ocular pain and ocular motor paralyses (see further on) and the paragnostic syndrome of Raeder, which consists of paroxysms of pain somewhat like that of tic douloureux in the distribution of the opthalmic and maxillary divisions of the fifth nerve, in association with ocular sympathetic paralysis (pupil and miosis but with preservation of sweating). Loss of sensation in a trigeminal nerve distribution and weakness of muscles innervated by the trigeminal nerve are often added. We have seen instances of head pain, particularly in women, in which the features of both cluster headache and Raeder syndrome could be recognized; no lesion in or near the trigeminal ganglion was found. The cases of the paroxysmal pain behind the eye or nose or in the upper jaw or temple—associated with blocking of the nostril or lacrimation and described under the titles of sphenopalatine (Studer), petrosal, vidian, and ciliary neuralgia (Charlin or Harris, "lower half" headache)—probably represent instances of cluster headache or its variants. There is no evidence to support the separation of these neuralgias as distinct entities.

Chronic paroxysmal hemicrania is the name given by Sjastad and Dale to a unilateral form of headache that resembles cluster headache in some respects but has several distinctive features. Like cluster headache, these are of short duration (2 to 45 min), and usually affect the temporoparietal region of one side, accompanied by conjunctival hyperemia, rhinorrhea, and, in some cases a partial Horner syndrome. Unlike cluster headache, however, the paroxysms occur many times each day, recur daily for long periods (the patient of Price and Posner had an average of more than 40 per day), and most importantly, respond dramatically to the administration of indomethacin, 25 to 50 mg tid. Also unlike the usual form of cluster headache, chronic paroxysmal hemicrania is more common in women than in men, in a ratio of 3:1.

The relationship of the cluster headache to migraine remains conjectural. No doubt the headaches in some persons have some of the characteristics of both, hence the terms migrainous neuralgia and cluster migraine (Kudrow). Lrance and others, however, have pointed out differences that seem important to the authors: flushing of the face and neck is not a prominent feature in cluster headache; the blood pressure is normal in cluster headache, whereas a 10 mm Hg decrease in systolic pressure may occur in migraine; there is an erythema in the region of the sphenopalatine artery in cluster headache, but not in the migrainous form; and decreased temperature over the forehead, temple, and cheek in cluster headache, decreased temperature in migraine; and notable distinctions in sex distribution, age of onset, rhythmicity, and other clinical features, as described above. Cluster has been observed to be triggered in sensitive patients by the use of nitroglycerin; the same occurs rarely in migraine.

The mechanism and cause of the cluster headache syndrome are unknown. Gardner and coworkers originally postulated a paroxysmal parasympathetic discharge mediated through the greater superficial petrosal nerve and sphenopalatine ganglion. These authors obtained consistent results by cutting the nerve, but others (Tillotson et al) have reported that application of cocaine to the region of the sphenopalatine fossa (via the nostril) consistently abolishes attacks of cluster headache. Capsaicin, applied over the affected region of the forehead and scalp, may have the same effect. Stimulation of the ganglion is said to reproduce the mechanism of headache) led to the notion, popular for many years, that this form of headache was caused by the spontaneous release of histamine and to a form of trigemino-carotid hypertension. The fact that cluster headaches could be reproduced by the intravenous injection of 0.1 mg histamine (an early experimental technique for studying the mechanism of headache) is of interest, popular for many years, that this form of headache was caused by the spontaneous release of histamine and to a form of treatment that consisted of "desensitizing" the patient by slow intravenous injections of this drug given daily for several weeks. Experience has shown that this form of treatment is not really anything more than provoking desensitization. It should be noted that the intravenous injection of more than 0.1 mg histamine induces or worsens many forms of focal or generalized headache (due to fever, trauma, brain tumor) that are dependent upon activation of pain-sensitive tissue around the vessels derived from the internal carotid artery.

Treatment of Cluster Headache

The usual nocturnal attacks of cluster headache can be treated with a single anticipatory dose of ergotamine at bedtime (2 mg orally). Inhalation of 100% oxygen for 10 to 15 min at the onset of headache may also abort the attack, but is not always practical. Intranasal lidocaine, or "tripan" drugs (as for migraine, see above) can be used to abort an attack. In other patients, ergotamine has to be given once or twice during the day at times when an attack of the head is surrounded by a band or clamped in a vise) or a feeling that the head is swollen and may burst. On these sensations, waves of aching pain are

Tension Headache

This, the most common variety of headache, is usually bilateral, with occipitotemporal, or frontal predominance or diffuse extension over the top of the cranium. The pain is usually described as dull and aching, but questioning often uncovers other sensations, such as fullness, tightness, or pressure (as though the head were surrounded by a band or clamped in a vise). On these sensations, waves of aching pain are
superimposed. The latter may be interpreted as paroxysmal or throbbing and, if the pain is more on one side, the headache may suggest a migraine without aura. However, it lacks the persistent throbbing quality, nausea, photophobia, and phonophobia of the latter. Nor do most tension headaches seriously interfere with daily activities. The onset is more gradual than that of migraine, and the headache, once established, may persist with only mild fluctuations for days, weeks, months, or even years. In fact, this is the only type of headache that exhibits the peculiarity of being present throughout the day, day after day, for long periods of time. The term chronic tension headache is used to signify this type of chronic daily headache. Although sleep is usually undisturbed, the headache is present when the patient awakens or develops soon afterward, and the common analgesic remedies have little or no beneficial effect if the pain is of more than mild to moderate severity. The incidence of tension headache is certainly greater than that of migraine. However, many patients treat tension headaches themselves and do not seek medical advice. Like migraine, tension headaches are more common in women than in men. Unlike migraine, they infrequently begin in childhood or adolescence but are more likely to occur in middle age and to coincide with anxiety, fatigue, and depression in the trying times of life. In the large series of Lance and Curran, about one-third of patients with tension headaches had readily recognized symptoms of depression. In our experience, chronic anxiety or depression of varying degrees of severity is present in the majority of cases with prolonged headaches. Migraine and traumatic headaches may be complicated by tension headache, which, because of its persistence, often arouses fears of a brain tumor or other intracranial disease. However, as Patten points out, not more than one or two patients out of every thousand with tension headaches will be found to harbor an intracranial tumor.

In a substantial group of patients, the headache, when severe, develops a pulsating quality, to which the term tension-vascular headache has been applied (Lance and Curran). This is particularly the case in patients with protracted and chronic daily headaches. Observations such as these have tended to blur the sharp distinctions between migraine and tension headaches.

For many years it was taught that tension headaches were due to excessive contraction of craniovascular muscles and an associated constriction of the scalp arteries. However, it is not clear that either of these mechanisms contributes to the genesis of tension headache, at least in its chronic form. Until recently it has been felt that in most patients with tension headache, the craniovascular muscles are quite relaxed (by palpation) and show no evidence of persistent contraction when measured by surface electromyographic (EMG) recordings. Anderson and Frank found no difference in the degree of muscle contraction between migraine and tension headache. However, using an ingenious laser device, Sakat et al have reported that the pericranial and trapezius muscles are hardened in patients with tension headaches. Recently, nitric oxide has been implicated in the genesis of tension-type headaches, specifically by creating a central sensitization to sensory stimulation from cranial structures. The strongest support of this concept comes from several reports that an inhibitor of nitric oxide reduces muscle hardness and pain in patients with chronic tension headache (Ashina et al). At present, this is an interesting but speculative idea.

**Treatment of Tension Headache**

Simple analgesics, such as aspirin or acetaminophen or other nonsteroidal anti-inflammatory drugs, may be helpful but only for brief periods. Tension headaches respond best to the cautious use of one of several drugs that relieve anxiety or depression, when the latter symptoms are present. Some patients respond to ancillary measures such as massage, meditation, and biofeedback techniques. Stronger analgesic medication should be avoided. Raskin reports success with calcium channel blockers, phenelzine, or cyproheptadine. Ergotamine and propranolol are not effective unless there are symptoms of both migraine and tension headache. Relaxation techniques may be helpful in teaching patients how to deal with underlying anxiety and stress (Lance).

**Headaches in the Elderly**

In several surveys of an elderly population, headache with onset in this age period was found to be a prominent symptom in as many as one of six persons and more often to have serious implications than headache in a younger population. In one series of such patients reported by Pascual and Berciano, more than 40 percent had tension headaches (women more than men) and there was a wide variety of diseases in the others (posttraumatic headaches, cerebrovascular disease, intracranial tumors, cranial arteritis, severe hypertension). Cough headache and cluster headache were present in some of the men. New-onset migraine in this age group is a rarity.

Raskin has described a headache syndrome in older patients that shares with cluster headache a nocturnal occurrence (hypnic headache). It may occur with daytime naps as well. However, it differs in being bilateral and unaccompanied by lacrimation and rhinorhea. Also, it differs from migraine. Raskin has successfully treated a number of his patients with 300 mg of lithium carbonate at bedtime. The nosologic position of this hypnic headache syndrome is undetermined. Despite these considerations, the most treacherous and neglected cause of headache in the elderly is temporal (cranial) arteritis with or without polymyalgia rheumatica, as discussed further on.

**Headache and Other Craniofacial Pain with Psychiatric Disease**

In our outpatient clinic the most common cause of generalized persistent headache, both in adolescents and adults, is depression or anxiety in one of its several forms. The authors have noted that many seriously ill psychiatric patients complain of frequent headaches that are not typically of the tension type. These patients report unilateral or generalized throbbing cephalic pain lasting for hours every day or two. The nature of these headaches, which in some instances resemble common migraine, is unsettled. Others have delusional symptoms involving physical distortion of cranial structures. As the psychiatric symptoms subside, the headaches usually disappear.

Odd cephalic pains, e.g., a sensation of having a nail driven into the head (clavus hystericus), may occur in hysteria and raise perplexing problems in diagnosis. The bizarre character of these pains, their persistence in the face of every known therapy, the absence of other signs of disease, and the presence of other manifestations of hysteria provide the basis for correct diagnosis. Older children and adolescents sometimes have peculiar behavioral reactions to headache: screaming, looking dazed, clutching the head with an agoniized look. Usually, migraine is the underlying disorder, the additional manifestations responding to therapeutic support and suggestion.

**Posttraumatic Headache**

Severe, chronic, continuous, or intermittent headaches appear as the cardinal symptom of several posttraumatic syndromes, separable in each instance from the headache that immediately follows head injury (i.e., scalp laceration and cerebral contusion with blood in the CSF and increased intracranial pressure) and which may last several days or a week or two.

The headache of chronic subdural hematomata is deep-seated, steady, unilateral or generalized, and usually accompanied or followed by drowsiness, confusion, stupor, and hemiparesis. The head injury may have been minor and forgotten by the patient and family and mild degrees of confusion may be attributed to inattention or drowsiness. Typically the headache and other symptoms increase in frequency and severity over several weeks or months. Diagnosis is usually established by CT and MRI.

Headache is a prominent feature of a complex syndrome comprising giddiness, fatigability, insomnia, nervousness, trembling, irritability, inability to concentrate, and tearfulness—a syndrome that we have called posttraumatic nervous instability. This type of headache and associated symptoms, which resemble the tension headache syndrome, are described fully in Chap. 35, "Craniocebral Trauma." The patient with posttraumatic nervous instability requires supportive therapy in the form of repeated reassurance and explanations of the benign nature of the symptoms, a program of increasing physical activity, and the use of drugs that allay anxiety and depression. The early settlement of litigation, which is often an issue, works to the patient's advantage.

Tenderness and aching pain sharply localized to the scar of a scalp laceration represent in all probability a different problem and raise the question of a traumatic neuralgia. Tender scars from scalp lacerations may be treated by repeated subcutaneous injections of local anesthetics such as 5 mL of 1% procaine.

With whiplash injuries of the neck, there may be unilateral or bilateral retroauricular or occipital pain, due probably to stretching or tearing of ligaments and muscles at the occipitocervical junction or to a worsening of a preexistent cervical arthropathy. Much less frequently, cervical intervertebral discs and nerve roots are involved.

Under the heading of posttraumatic dysautonomic cephalalgia, Vijayan and Dreyfus have described a syndrome comprising severe, episodic, throbbing, unilateral headaches sometimes accompanied by ipsilateral mydriasis and excessive sweating of the face, thus simulating migraine or cluster headache. Between bouts of headache, a few of the patients showed partial plosis and miosis as well as pharmacologic evidence of partial sympathetic denervation. The condition followed injury to the soft tissues of the neck in the region of the carotid artery sheath. The headaches did not respond to treatment with ergotamine, but prompt relief was obtained in

Headaches of Brain Tumor

Headache is said to be a significant symptom in about two-thirds of all patients with brain tumor (Rooke), but it is considerably less frequent in our experience, particularly as the heralding symptom in an adult. The pain has no specific features; it tends to be deep-seated, usually nonthrobbing (occasionally throbbing), and is described as aching or bursting. Attacks of pain last a few minutes to an hour or more and occur once or many times during the day. Physical activity and changes in position of the head may provoke pain, whereas rest diminishes its frequency. Nocturnal awakening because of pain occurs in only a small proportion of patients and is not usually diagnostic. Unexpected forceful (projectile) vomiting may paralyze the illness in its later stages. If unilateral, the headache is nearly always on the same side as the tumor. Pain from supratentorial tumors is felt anterior to the interauricular circumference of the skull; from posterior fossa tumors, it is felt behind this line. Bilateral and bicippital headaches, coming on after unilateral headaches, signify the development of increased intracranial pressure.

Harris described headaches of paroxysmal type with intra- and periventricular brain tumors, and many others have commented on the same type of headache with parenchymal tumors. These are severe headaches that reach their peak intensity in a few seconds, last for several minutes or as long as an hour, and then subside quickly. When they are associated with vomiting, transient blindness, leg weakness with “drop attacks,” and loss of consciousness, there is a high likelihood of brain tumor. With respect to its onset, this headache resembles that of subarachnoid hemorrhage, but the latter is far more long-lasting. In its entirety, this paroxysmal headache is most typical of a colloidal cyst of the third ventricle, but it can occur with other tumors as well, including craniopharyngiomas, pinealomas, and cerebellar masses. One cannot help but be impressed with the frequency of headache as a manifestation of colloid cysts, and we have several times stumbled on the correct diagnosis when an odd, unexplained headache led to brain imaging. The mechanism of headache in cases of colloidal cyst is not simply one of blocking the flow of CSF at the foramina of Monro and is not predicated on the development of hydrocephalus.

Temporal Arteritis (Giant-Cell Arteritis, Cranial Arteritis)

This particular type of inflammatory disease of cranial arteries is an important cause of headache in elderly persons. All of our patients have been more than 50 years of age, most of them more than age 65. From a state of normal health, the patient develops an increasingly intense throbbing or nonthrobbing headache, often with superimposed sharp, stabbing pains. In a few patients the headache has had an almost explosive onset. The headache is usually unilateral, sometimes bilateral, and often localized to the site of the affected vessels. The pain persists to some degree throughout the day and is particularly severe at night. It lasts for many months if untreated (average duration, 1 year). The superficial temporal and other scalp arteries are frequently thickened and tender and without pulsation. Jaw claudication and ischemic nodules on the scalp, with ulceration of the overlying skin, have been described in severe cases. Many of the patients feel generally unwell and have lost weight; some have a low-grade fever and anemia. Usually the sedimentation rate is greatly elevated (>50 mm/h) and a few patients have a neutrophilic leukocytosis. As many as 50 percent of patients have generalized aching of proximal limb muscles, reflecting the presence of polymyalgia rheumatica (see page 230).

The importance of early diagnosis relates to the threat of blindness from thrombosis of the ophthalmic and, less often, of the posterior ciliary arteries. This may be prevented by anticoagulation, which is preventive but is less frequent, and prophylactic, which is not settled. The large intracranial vessels are occasionally affected; once vision is lost, it is seldom recoverable. For this reason the earliest suspicion of cranial arteritis should lead to biopsy of the appropriate scalp artery and the immediate administration of corticosteroids. Microscopic examination discloses an intense granulomatous or “giant-cell” arteritis. If biopsy on one side fails to clarify the situation and there are solid clinical reasons for suspecting the diagnosis, the other side should be sampled. Arteriography of the external carotid artery branches is probably the most sensitive test but is seldom used; ultrasonic examination has recently been introduced to display the irregularly thickened vessel wall of the temporal arteries. This technique, which shows promising, requires further study.

Treatment consists of the administration of prednisone, 45 to 60 mg/day in single or divided doses over a period of several weeks, with gradual reduction to 10 to 20 mg/day and maintenance at this dosage for several months or years if necessary to prevent relapse. The headache can be expected to improve within a day or two of beginning treatment and failure to do so brings the diagnosis into question. When the sedimentation rate or C-reactive protein are elevated, their return to normal is a reliable index of therapeutic response.

Pseudotumor Cerebri (Benign or Idiopathic Intracranial Hypertension)

The headache of pseudotumor cerebri assumes a variety of forms. Typical is a feeling of occipital pressure that is greatly worsened by lying down, but many patients have—in addition or only—headaches of migraine or tension type. Indeed, some of them respond to medications such as propranolol or ergot compounds. None of the proposed mechanisms for pain in pseudotumor cerebri seems to be adequate as an explanation, particularly the idea that cerebral vessels are displaced or compressed, since neither has been demonstrated. It is worth noting that facial pain may also be a feature of the illness, albeit rare. A more complete description can be found on page 667.

Special Varieties of Headache

Low-Pressure and Spinal Puncture Headache

These are commonly known to neurologists and the latter type is an unavoidable part of lumbar punctures. The headache is typically severe and constant and probably caused by traction on the cranial blood vessels. Assuming the supine position almost immediately relieves the cranial pain and eliminates vomiting, but a blood-patch procedure may be required in persistent cases. In a limited number of cases we have had success in aborting the headache by the use of intravenous caffeine injections. The condition and its treatment are discussed on pages 670–671.

Menstrual Migraine and Other Headaches Linked to the Hormonal Cycle

The relation of headache to a drop in estradiol levels has been mentioned on page 182.

Premenstrual headache, taking the form of migraine or a combined tension-migraine headache, usually responds to the administration of a nonsteroidal anti-inflammatory drug begun 3 days before the anticipated onset of the menstrual period; oral sumatriptan (25 to 50 mg q.i.d.) and zolmitriptan (2.5 to 5 mg bid) are equally effective. Manipulation of the hormonal cycle with danazol (a testosterone derivative) or estradiol has also been effective but is rarely necessary.

Cough and Exertional Headache

A patient may complain of very severe, transient cranial pain on coughing, sneezing, laughing heartily, lifting heavy objects, stooping, and straining at stool. Pain is usually felt in the front of the head, sometimes occipitally, and may be unilateral or bilateral. As a rule, it follows the initiating action within a second or two and lasts a few seconds to a few minutes. The pain is often described as having a bursting quality and may be of such severity as to cause the patient to cradle his head in his hands, simulating the headache of acute subarachnoid hemorrhage.

Most often this syndrome takes the form of a benign idiopathic state that recurs over a period of several months to a year or two and then disappears. In a report of 103 patients followed for 3 years or longer, Rooke found that additional symptoms of neurologic disease developed in only 10; Symonds also has attested to the usual benignity of the condition. Its cause and mechanism have not been determined. During the attack, the CSF pressure is normal. Bilateral jugular compression may induce an attack, possibly because of traction on the walls of large veins and dural sinuses. In a few instances, we have observed this type of headache after lumbar puncture or after a hemorrhage from an arteriovenous malformation.

Aside from a rare instance of subarachnoid hemorrhage, patients with cough or strain headache occasionally be found to have serious intracranial disease, most often of the posterior fossa and foramen magnum: arteriovenous malformation, Chiari malformation, platybasia, basilar impression, or tumor. It may be necessary, then, to supplement the neurologic examination by appropriate skull films, CT, and MRI. Far more common, of course, are the temporal and maxillary pains that are due to dental or sinus disease and are induced by coughing.

A special variant of exertional headache is “weight-lifter’s headache.” It occurs either as a single event or repeatedly over a period of several months, but each episode of headache may last many hours or days, and it is associated with the suspicion of subarachnoid hemorrhage. If the pain resolves in an hour or less and there is no meningismus or sign of bleeding on the CT, we have foregone lumbar puncture and angiography but have suggested that weight-lifting not be resumed for several months or years if necessary to prevent relapse. If the headache can be expected to improve within a day or two of beginning treatment and failure to do so brings the diagnosis into question. When the sedimentation rate or C-reactive protein are elevated, their return to normal is a reliable index of therapeutic response.

Indomethacin may be quite effective in controlling exertional headaches, and this has been confirmed in controlled trials. Useful alternatives are nonsteroidal anti-inflammatory agents, ergot preparations, and phenoxyzine. In a few of our cases, lumbar puncture appeared to resolve the problem in some inexplicable way.

Headaches Related to Sexual Activity

Lance has described 21 cases of this type of headache, 16 in males and 5 in females. The headache took one of two forms: one in which headache of the tension type developed as sexual excitement increased and another in which a severe, throbbing, “explosive” headache occurred at the
time of orgasm and persisted for several minutes or hours. The latter headaches were of such abruptness and severity as to suggest a ruptured aneurysm, but the neurologic examination was negative in every instance, as was arteriography in seven patients who were subjected to this procedure. In 18 patients who were followed for a period of 2 to 7 years, no other neurologic symptoms developed. Characteristically, the headache occurred on several consecutive occasions and then inexplicably disappeared. In cases of repeated coital headache, indomethacin is effective. Of course, so-called orgasmic headache is not always benign; a hypertensive hemorrhage, rupture of an aneurysm or vascular malformation, or myocardial infarction may occur during the exertion of sexual intercourse.

**Erythromyalgia** On rare occasions, an intense, generalized, throbbing headache may occur in conjunction with flushing of the face and hands and numbness of the fingers (erythromyalgia). Episodes tend to be present on awakening from sound sleep. This condition has been reported in a number of unusual settings: (1) in mastocytosis (infiltration of tissues by mast cells, which elaborate histamine, heparin, and serotonin); (2) with carcinoid tumors; (3) with serotonin-secreting tumors; (4) with some tumors of the pancreatic islets; and (5) with pheochromocytoma. Seventy-five percent of patients with pheochromocytoma reportedly have vascular-type headaches coincident with paroxysms of hypertension and elaboration of catecholamines (Lance and Hinterberger).

**Headache Related to Medical Diseases**

Severe headache may occur with a number of infectious illnesses caused by banal viral upper respiratory infections, by organisms such as *Mycoplasma*, or *Coxiella* (Q fever), and particularly by influenza. The suspicion of meningitis is raised, even subarachnoid hemorrhage, but almost invariably there is no reaction in the CSF.

About 50 percent of patients with hypertension complain of headache, but the relationship of one to the other is not clear. Minor elevations of blood pressure may be a result rather than the cause of tension headaches. Severe (malignant) hypertension, with diastolic pressures of more than 120 mmHg, is regularly associated with headache, and measures that reduce the blood pressure relieve it. Abrupt elevations of blood pressure, as occur in patients taking monoamine oxidase inhibitors and then ingest tyramine-containing food, can cause headaches that are abrupt and severe enough to simulate subarachnoid hemorrhage. However, it is the individual with moderately severe hypertension and frequent severe headaches who causes the most concern. In some of these patients the headache is of the common migrainous or tension type, but in others they defy classification. According to Wolff, the mechanism of the hypertensive headache is similar to that of migraine, i.e., increased vascular pulsations. The headaches, however, bear no clear relation to modest peaks in blood pressure. Curiously, headaches that occur toward the end of renal dialysis or soon after its completion are associated with a fall in blood pressure (as well as a decrease in blood sodium levels and osmolality). The latter type of headache is bifrontal and throbbing, and is accompanied sometimes by nausea and vomiting. The mechanism of occipital pain that may awaken the hypertensive patient and wear off during the day is not understood.

Headaches frequently follow a seizure, having been recorded in half of one large series of epileptic patients analyzed in Great Britain. In migraineurs, the postictal headache may reproduce a typical migraine attack. Rarely, in patients with a vascular malformation, a migraine-like attack precedes a seizure.

Experienced physicians are aware of many other conditions in which headache may be a dominant symptom. These include fivers of any cause, carbon monoxide exposure, chronic lung disease with hypercapnia (headaches often nocturnal), hypothyroidism. Cushing disease, withdrawal from corticosteroid medication, hypoglycemia, mountain sickness, chronic exposure to nitrates, occasionally adrenal insufficiency, aldosterone-producing adrenal tumors, use of "the pill," and development of acute anemia with hemoglobin below 10 g.

No attempt is made here to discuss the symptomatic treatment of headache that may accompany these many medical conditions. Obviously the guiding principle in management is to uncover and remove the underlying disease or functional disturbance.

**Headache Related to Diseases of the Cervical Spine**

Headaches that accompany diseases of the upper cervical spine are well recognized, but their mechanism is obscure. Recent writings have focused on a wide range of causative lesions, such as synovitis-articular arthropathy, C2 dorsal root entrapment, calcified ligamentum flavum, hypertrophied posterior longitudinal ligament, and rheumatoid arthritis of the atlantoaxial region. CT and MRI have divulged a number of these abnormalities. They are discussed below, under the heading of "Third Occipital Nerve Headache," below, and in Chap. 11.

**OTHER CRANIOFACIAL PAINS**

(See Table 10-2)

<tr>
<td><strong>Trigeminal Neuralgia (Tic Douloureux)</strong></td>
</tr>
<tr>
<td>This is a common disorder of middle age and later life and consists of paroxysms of intense, stabbing pain in the distribution of the mandibular and maxillary divisions (rarely the ophthalmic division) of the fifth cranial nerve. The pain seldom lasts more than a few seconds or a minute or two but may be so intense that the patient involuntarily winces; hence the term tic. It is uncertain whether the tic is reflexive or quasi-voluntary. The paroxysms recur frequently, both day and night, for several weeks at a time. Another characteristic feature of trigeminal neuralgia is the initiation of pain by stimulation of certain areas of the face, lips, or gums, as in shaving or brushing the teeth, or by movement of these parts in chewing, talking, or yawning—the so-called trigger zones. Sensory or motor loss in the distribution of the trigeminal nerve cannot be demonstrated in these cases, though there are minor exceptions to this rule. In addition to the paroxysmal pain, some of the patients complain of a more or less continuous discomfort, itching, and sensitivity of the face, features always regarded as atypical even though not infrequent.</td>
</tr>
<tr>
<td>In studying the relationship between stimuli applied to the trigger zones and the paroxysms of pain, the latter are found to be induced by touch and possibly tickle rather than by a painful or thermal stimulus. Usually a spatial and temporal summation of impulses is necessary to trigger a paroxysm of pain, which is followed by a refractory period of up to 2 or 3 min. This suggests that the mechanism of the paroxysmal pain is in the nature of allodynia, a feature of other neuropathic pains (see page 145).</td>
</tr>
<tr>
<td>The diagnosis of tic douloureux must rest upon the strict clinical criteria enumerated above, and the condition must be distinguished from other forms of facial and cephalic neuralgia and pain arising from diseases of the jaw, teeth, or sinuses. Most cases of trigeminal neuralgia are without assignable cause (idiopathic), in contrast to symptomatic trigeminal neuralgia, in which paroxysmal facial pain is due to involvement of the fifth nerve by some other disease: multiple sclerosis (may be bilateral), aneurysm of the basilar artery, or tumor (acoustic or trigeminal neurona, meningioma, epidermoid) in the cerebellopontine angle. Sometimes it is due to compression of the trigeminal roots by a tortuous blood vessel, as originally pointed out by Dandy. Currently there is some disagreement as to the importance of the vascular lesion and its management. Jannetta has observed it in most of his patients and has relieved their pain by surgical decompression of the trigeminal root. Others declare a vascular compressive causation to be less frequent (Adams et al.). Each of the forms of symptomatic trigeminal neuralgia may give rise only to pain in the distribution of the fifth nerve, or it may produce a loss of sensation as well. This and other disorders of the fifth nerve, some of which give rise to facial pain, are</td>

...
Treatment

Anticonvulsant drugs such as phenytoin (300 to 400 mg/day), valproic acid (800 to 1200 mg/day), clonazepam (2 to 6 mg/day), gabapentin (300 to 900 mg/ day), and particularly carbamazepine (600 to 1200 mg/day), alone or in combination, suppress or shorten the duration and severity of the attacks. Carbamazepine is effective in a large percentage of patients, but half of the patients, and half of the severe cases, will require a combination of medications. Carbamazepine may be useful in patients who cannot tolerate carbamazepine or gabapentin, but it is most effective as an adjunct to one of the anticonvulsant drugs. Capsaicin applied locally to the trigger zones or the topical instillation in the eye of an anesthetic (proparacaine 0.5%) has been helpful in some patients. By temporizing and using these drugs, one may permit a spontaneous remission to occur.

Most of the patients with intractable pain come to surgery. The commonly used procedures are stereotactically controlled thermoocoagulation of the trigeminal roots using a radio-frequency generator and the procedure of vascular decompression, popularized by Jannetta, which requires a posterior fossa craniotomy but leaves no sensory loss. Barker and colleagues have reported that 70 percent of 1185 patients were relieved of pain by repositioning a small branch of the basilar artery that was found to compress the fifth nerve, and this effect persisted, with an annual recurrence rate of less than 1 percent per year for 10 years. The therapeutic efficacy of these two surgical approaches is roughly equivalent; in recent years there has been a preference for microvascular decompression, especially late in the course of the illness.

Glossopharyngeal Neuralgia

This syndrome is much less common than trigeminal neuralgia but resembles the latter in many respects. The pain is intense and paroxysmal; it originates in the throat, approximately in the tonsillar fossa, and is provoked most commonly by swallowing but also by talking, chewing, yawning, laughing, etc. The pain may be localized in the ear or radiate from the throat to the ear, implicating the auricular branch of the vagus nerve. For this reason, White and Sweet suggested the term vagal glossopharyngeal neuralgia. This is the only craniofacial neuralgia that may be accompanied by bradycardia and even by syncope, presumably because of the triggering of cardiovascular reflexes by different pain impulses. There is no demonstrable sensory or motor deficit. Rarely, carotoma or epithelioma of the oropharyngeal-infracranial region or pentonsilar abscesses may give rise to pain clinically indistinguishable from glossopharyngeal neuralgia. For idiopathic glossopharyngeal neuralgia, a trial of carbamazepine, gabapentin, or baclofen may be useful. If these are unsuccessful, the conventional surgical procedure has been to interrupt the glossopharyngeal nerve and upper rootlets of the vagus nerve near the medulla. Recent observations suggest that a vascular decompression procedure similar to the one used for tic directed to a small vascular loop under the ninth nerve relieves the pain in a proportion of patients.

Acute Zoster and Postherpetic Neuralgia

Neuralgia associated with a vesicular eruption due to the herpes zoster virus may affect cranial as well as peripheral nerves. In the region of the cranial nerves, two syndromes are frequent: herpes zoster auriculans and herpes zoster ophthalmicus. Both may be exceedingly painful in the acute phase of the infection. In the former, herpes of the external auditory meatus and pinna and sometimes of the palate and occipital region—with or without deafness, tinnitus, and vertigo—is combined with facial numbness. This syndrome, since its original description by Ramaswami and Hunt, has been known as genculate herpes, despite the lack, to this day, of pathologic proof that it depends solely upon a herpetic infection of the genculate ganglion (see Chap. 47). Pain and herpetic eruption due to herpes zoster infection of the gasserian ganglion and the peripheral and central pathways of the trigeminal nerve are practically always limited to the first division (herpes zoster ophthalmicus). Ordinarily, the eruption will appear within 4 to 5 days after the onset of the pain, and if it does not, some cause other than herpes zoster will almost invariably declare itself. Neurologists, however, a few cases have been reported in which the characteristic localization of pain to a dermatome, with serologic evidence of herpes zoster infection, was not accompanied by skin lesions.

The acute discomfort associated with the herpetic eruption usually subsides after several weeks, or it may linger for several months. Treatment with acyclovir, along the lines indicated in Chap. 33, will shorten the period of eruption and pain, but the drug does not prevent the occurrence of chronic pain. In the elderly the pain often becomes chronic and intractable. It is described as a constant burning, with superimposed waves of stabbing pain, and the skin in the territory of the preceding eruption is exquisitely sensitive to the slightest tactile stimuli, while the threshold of pain and thermal perception is elevated. Alodynia is frequent. This unrelenting postherpetic neuralgia of long duration represents one of the most difficult pain problems with which the physician has to deal. Some relief may be provided by application of capsaicin cream, use of a mechanical vibrator, or administration of phenytoin, gabapentin, or carbamazepine. Antidepressants such as amitriptyline and fluoxetine, are helpful in some patients, and Bowsher has suggested, on the basis of a small placebo-controlled trial, that treatment with amitriptyline during the acute phase may prevent persistent pain. The addition of a phenothiazine to an antidepressant (e.g., amitriptyline 75 mg at bedtime and fluphenazine 1 mg tid) has proved to be a useful measure, but the long-term use of phenothiazines carries with it all the well-known risks, including that of inducing a movement disorder. Probably equivalent results are obtained by a combination of valproic acid and an antidepressant, as reported by Raftery. King has reported that two (5-grain) aspirin tablets crushed and mixed with cold cream or chloroform (15 mL) and spread over the painful zone on the face or trunk relieved the pain for several hours in most patients with postzoster neuralgia. The authors have limited personal experience with this treatment. Extensive trigeminal rhizotomy or other destructive procedures should be avoided, since these surgical measures are not universally successful and may superimpose a diffuse refractory dysesthetic component upon the neuralgia.

Otalgia

Pain localized in and around one ear is occasionally a primary complaint. This can have a number of different causes and mechanisms. During neurosurgical operations in awake patients, stimulation of cranial nerves V, VII, IX, and X causes ear pain, yet interruption of these nerves usually causes no demonstrable loss of sensory or motor function. The neuralgia of herpes zoster is exquisitely sensitive to the slightest tactile stimuli, while the threshold of pain and thermal perception is elevated. Alodynia is frequent. This unrelenting postherpetic neuralgia of long duration represents one of the most difficult pain problems with which the physician has to deal. Some relief may be provided by application of capsaicin cream, use of a mechanical vibrator, or administration of phenytoin, gabapentin, or carbamazepine. Antidepressants such as amitriptyline and fluoxetine, are helpful in some patients, and Bowsher has suggested, on the basis of a small placebo-controlled trial, that treatment with amitriptyline during the acute phase may prevent persistent pain. The addition of a phenothiazine to an antidepressant (e.g., amitriptyline 75 mg at bedtime and fluphenazine 1 mg tid) has proved to be a useful measure, but the long-term use of phenothiazines carries with it all the well-known risks, including that of inducing a movement disorder. Probably equivalent results are obtained by a combination of valproic acid and an antidepressant, as reported by Raftery. King has reported that two (5-grain) aspirin tablets crushed and mixed with cold cream or chloroform (15 mL) and spread over the painful zone on the face or trunk relieved the pain for several hours in most patients with postzoster neuralgia. The authors have limited personal experience with this treatment. Extensive trigeminal rhizotomy or other destructive procedures should be avoided, since these surgical measures are not universally successful and may superimpose a diffuse refractory dysesthetic component upon the neuralgia.

Occipital Neuralgia

Paroxysmal pain may occasionally occur in the distribution of the greater or lesser occipital nerves (suboccipital, occipital, and posterior parietal areas). There may be tenderness where these nerves cross the superior nuchal line, but there is only questionable evidence of an occipital nerve lesion in such cases. Carbamazepine may provide some relief. Blocking the nerves with lidocaine may abolish the pain and encourage attempts to section one or more occipital nerves or the second or third cervical dorsal root, but the results have rarely been successful, and several such patients who had these procedures were later referred to us with disabling anesthesia dolorosa. We have advised repeated injections of local anesthetic agents and the use of steroids, traction, local heat, and analgesics and anti-inflammatory drugs. The pain at times may be difficult to distinguish from that arising in the upper three cervical apophyseal joints, one type of which is discussed below.

Third Occipital Nerve Headache

This condition, a unilateral occipital and suboccipital ache, is a prominent symptom in patients with neck pain, particularly after whiplash injuries (a prevalence of 27 percent, according to Lord et al). Bogduk and Marsland attribute this type of headache to a degenerative or traumatic arthropathy involving the C2 and C3 apophyseal joints with impingement on the third occipital nerve (a branch of the C3 dorsal ramus that crosses the lateral and dorsal aspects of the apophyseal joint). Ablation of the neck pain and headache by percutaneous blocking of the third occipital nerve under fluoroscopic control is a trial of carbamazepine, gabapentin, or baclofen may be useful. If these are unsuccessful, the conventional surgical procedure has been to interrupt the glossopharyngeal nerve and upper rootlets of the vagus nerve near the medulla. Recent observations suggest that a vascular decompression procedure similar to the one used for tic directed to a small vascular loop under the ninth nerve relieves the pain in a proportion of patients.

Carotidynia

This term was coined by Temple Fay in 1927 to designate a special type of cervicofacial pain that could be elicited by pressure on the common carotid arteries ( Sweet and Wespic). This term was coined by Temple Fay in 1927 to designate a special type of cervicofacial pain that could be elicited by pressure on the common carotid arteries. This term was coined by Temple Fay in 1927 to designate a special type of cervicofacial pain that could be elicited by pressure on the common carotid arteries. This term was coined by Temple Fay in 1927 to designate a special type of cervicofacial pain that could be elicited by pressure on the common carotid arteries.
condition is treated with simple analgesics. Yet another variety of carotidynia appears at any stage of adult life and recurs in attacks lasting minutes to hours in association with throbbing headaches indistinguishable from common migraine (Raskin and Prusiner). This form responds favorably to the administration of ergotamine, methysergide, and other drugs that are effective in the treatment of migraine.

**Costen Syndrome (Temporomandibular Joint Pain)**

This is a form of craniofacial pain consequent upon dysfunction of one temporomandibular joint. Malocclusion due to ill-fitting dentures or loss of molar teeth on one side, with alteration of the normal bite, may lead to distortion of and ultimately degenerative changes in the joint and to pain in front of the ear, with radiation to the temple and over the face. The diagnosis is supported by the findings of tenderness over the joint, crepitus on opening the mouth, and limitation of jaw opening. The favored diagnostic maneuver involves palpating the joint from its posterior aspect by placing a finger in the external auditory meatus and pressing forward. The diagnosis can be made with some confidence if this reproduces the patient’s pain. CT and plain films are rarely helpful, but effusions have been shown in the joints by MRI. Management consists of careful adjustment of the bite by a dental specialist and should be undertaken only when the patient meets the strict diagnostic criteria for this condition. In our experience, most of the diagnoses of Costen syndrome that reach the neuroradiologist have been erroneous and the number of headaches and facial pains that are attributed to “temporomandibular joint dysfunction” is excessive, especially if judged by the response to treatment. The temporomandibular joint may also be the source of pain when involved by rheumatoid arthritis.

**Facial Pain of Dental or Sinus Origin**

Maxillary and mandibular discomfort are common effects of nerve irritation from deep caries, dental pulp degeneration, or periodontal abscesses. The pain of dental nerve origin is most severe at night, slightly pulsating, and often associated with local tenderness at the root of the tooth in response to heat, cold, or pressure. It usually responds to denervation of the tooth.

Trigeminal neuritis following dental extractions or oral surgery is another vexing problem. There may be sensory loss in the tongue or lower lip and weakness of the masseter or pterygoid muscle.

Sometimes the onset of “atypical facial pain” (see below) can be dated to a dental procedure such as tooth extraction, and, as usually happens, neither the dentist nor the neurologist is able to find a source for the pain or any malfunction of the trigeminal nerve. Roberts and coworkers as well as Ratner and associates have pointed out that residual microabscesses and subacute bone infection account for some of these cases. They isolated the affected region by local anesthetic blocks, curedtted the bone, and administered antibiotics, following which the pain resolved. The removed bone fragments showed vascular and inflammatory changes and infection with oral bacterial flora.

**Facial Pain of Uncertain Origin (“Atypical” Facial Pain)**

There remains—after all the aforementioned pain syndromes and all the possible intracranial and local sources of pain from throat, mouth, sinuses, orbit, and carotid vessels have been excluded—a small number of patients with pain in the face, or deep in the temple. In these patients, and often young women who describe the pain as constant and unceasingly severe, deep in the face, or at the angle of a tooth, they have been unresponsive to all varieties of analgesic medication. Because of the failure to identify an organic basis for the pain, one is tempted to attribute it to psychological or emotional factors or to abnormal personality traits. Only a small proportion of the patients satisfy the diagnostic criteria for hysteria, but depression of varying severity is found in nearly half of them. Many such patients, with or without depression, respond to tricyclic antidepressants and monoamine oxidase inhibitors. Always to be differentiated from this is the condition of trigeminal neuropathy, described in Chap. 47. Facial pain of the “atypical type,” like other chronic pain of indeterminate cause, requires close observation of the patient, looking for lesions as nasopharyngeal carcinoma to declare themselves. The pain should be managed by the conservative methods outlined in the preceding chapter and not by destructive cerebral surgery.

**Other Rare Types of Facial Pain** These include ciliary, nasociliary, supraorbital, and Sluder neuralgia. These are vague entities at best, and some merely represent different descriptive terms given to pains localized around the eye and nose (see “Cluster Headache” above; also Table 10-2). The Tolosa-Hunt syndrome of pain behind the eye and granulomatous involvement of some combination of cranial nerves III, IV, VI, and ophthalmic V, responsive to steroids, are discussed in Chap. 47.

A kind of reflex sympathtic dystrophy of the face is postulated as another rare form of persistent facial pain that may follow dental surgery or penetrating injuries to the face. It is characterized by severe burning pain and hyperesthesia in response to all types of stimuli. Sedoromotor, vasomotor, and trophic changes are lacking, unlike causalgia that affects the limbs. Nevertheless, this form of facial pain responds to repeated blockade or resection of the stellate ganglion.

Under the title of neck-tongue syndrome, Lance and Anthony have described the occurrence of a sharp pain and tingling in the upper neck or occiput on sudden rotation of the neck, associated with numbness of the ipsilateral half of the tongue. They attribute the syndrome to stretching of the C2 cranial ramus, which contains proprioceptive fibers from the tongue; these fibers run from the lingual nerve to the hypoglossal nerve and thence to the second cervical root.

The vexing problem that has gone by the self-evident name burning mouth syndrome occurs mainly in middle-aged and older women. The oral mucosa is normal and no one treatment has been consistently effective but gabapentin combined with antidepressants may be tried. One of our patients with a limited form of this condition, which affected only the upper palate and gums, benefitted from dental nerve blocks with lidocaine.

**REFERENCES**

The diagnosis of pain in these parts of the body often requires the assistance of a neurologist. His task is to determine whether a disease of the spine has implicated the spinal cord or the spinal roots and nerves. To do this effectively, some knowledge of orthopedics and rheumatology is requisite. We include a chapter on this subject in recognition of the fact that back pain is among the most frequent of medical complaints. Up to 80 percent of adults have low-back pain at some time in their lives, and an even larger percentage of adults will be found at autopsy to have degenerative disc disease, according to Kelsey and White. Similar changes are disclosed by imaging studies of the lower spine. Our purpose in this chapter is to focus on the neurologic implications of back and neck pain and to assist the clinician in developing a systematic approach to patients with such complaints.

Since pains in the lower part of the spine and legs are caused by rather different types of disease than those in the neck, shoulder, and arms, they are considered separately.

PAIN IN THE LOWER BACK AND LIMBS

The lower parts of the spine and pelvis, with their massive muscular attachments, are relatively inaccessible to palpation and inspection. Although some physical signs and radiographs are helpful, diagnosis often depends on the patient's description of the pain and his or her behavior during the execution of certain maneuvers. Seasoned clinicians, for these reasons, have come to appreciate the need for a systematic inquiry and method of examination, the descriptions of which are preceded here by a brief consideration of the anatomy and physiology of the spine.

Anatomy and Physiology of the Lower Part of the Back

The bony spine is a complex structure, roughly divisible into an anterior and a posterior part. The former consists of a series of cylindric vertebral bodies, articulated by the intervertebral discs and held together by the anterior and posterior longitudinal ligaments. The posterior elements are more delicate and extend from the bodies as pedicles and laminae that form, with the posterior aspects of the bodies and ligaments, the vertebral canal. Stout transverse and spinous processes project laterally and posteriorly, respectively, and serve as the origins and insertions of the muscles that support and protect the spinal column. The bony processes are also held together by sturdy ligaments, the most important being the ligamentum flavum. The posterior parts of the vertebrae articulate with one another at the diarthrodial apophyseal (facet) joints, each of which is composed of the inferior facet of the vertebra above and the superior facet of the one below. These anatomic features are illustrated in Fig. 11-1 and Fig. 11-2. The facet and sacroiliac joints, covered by synovia, the compressible intervertebral discs, and the collagenous and elastic ligaments permit a limited degree of flexion, extension, rotation, and lateral motion of the spine.

Figure 11-1 The fifth lumbar vertebra viewed from above (A) and from the side (B)

Figure 11-2 The main ligamentous structures of the spine. A. Buckling of the yellow ligament (ligamentum flavum) may compress the nerve root or the spinal nerve at its origin in the intervertebral foramen, particularly if the foramen is narrowed by osteophytic overgrowth. B. Posterior aspect of the vertebral bodies. Fibers of the posterior longitudinal ligament merge with the posteromedial portion of the annulus fibrosus, leaving the posterolateral portion of the annulus relatively unsupported. (Reprinted by permission from Finneson.)

The stability of the spine depends on the integrity of the vertebral bodies and intervertebral discs and on two types of supporting structures, ligamentous (passive) and muscular (active). Although the ligamentous structures are quite strong, neither they nor the vertebral body-disc complexes have sufficient integral strength to resist...
the enormous forces that may act on the spinal column; the stability of the lower back is therefore largely dependent on the voluntary and reflex activity of the sacrospinals, gluteus maximus, and hamstring muscles.

The vertebral and paravertebral structures derive their innervation from the meningeal branches of the spinal nerves (also known as recurrent meningeal or sinuvertebral nerves). Each of the sinuvertebral nerves arises from the posterior root ganglion and ascends to supply the paravertebral structures. These meningeal branches enter through a patent foramen ovale located in the intervertebral foramina, providing innervation to the intervertebral disks, the ligaments, and the joint capsules.

The paravertebral structures include the muscles of the back, which are divided into superficial and deep layers. The superficial muscles include the trapezius, rhomboids, levator scapulae, and splenius; the deep muscles include the multifidus, longissimus, iliocostalis, and spinalis. These muscles provide stability and mobility to the spine.

The paravertebral muscles are innervated by the anterior primary rami of the spinal nerves and receive sympathetic nerve fibers from the intermediolateral column of the thoracic spinal cord. The paravertebral muscles are important in maintaining posture and providing the muscular pump for the thoracic cavity.

In patients with severe circumferential constriction of the cauda equina due to spondylolisthesis (lumbar stenosis), sensorimotor impairment and sometimes referred pain are elicited by standing and walking. The neurologic symptoms involve the calves and the back of the thighs, simulating the exercise-induced symptoms due to vascular insufficiency—hence the term spinal claudication (see page 218).

Of importance is the observation that referred pain from the lower back (sometimes called pseudoradiculitis) does not, as a rule, project below the knees and is not accompanied by neurologic changes other than a vague numbness without demonstrable sensory impairment. The subcutaneous tissues within the area of referred pain may be tender. Of course, local, referred, and radicular pain may occur together.

Pain resulting from muscular spasm usually occurs in relation to local pain. The spasm may be thought of as a nocifensive reflex for the protection of the diseased parts against injurious motion. Muscle spasm is associated with many disorders of the low back and can distort normal posture. Chronic muscular contraction may give rise to a dull, sometimes cramping ache. One can feel the tautness of the sacrospinals and gluteal muscles and demonstrate by palpation that the pain is localized to them. However, except for the most severe degrees of spasm, no actual injury of the back, the contribution of this component to back pain is relatively small.

Other pains, often of undetermined origin, are sometimes described by patients with chronic disease of the lower part of the back: drawing and pulling in the legs, cramping sensation (without involuntary muscle spasm), tearing, throbbing, or jabbing pains, and feelings of burning or coldness. These sensations, like paresthesias and numbness, should always suggest the possibility of nerve or root disease.
Abdominal, rectal, and pelvic examinations are essential elements in the study of the patient with low back symptoms that fail to be clarified by the aforementioned examination of ankylosing spondylitis. Tenderness over the interspinous ligaments is indicative of disc lesions. A "step-off" forward displacement of the spinous process and exaggerated lordosis are important clues to the presence of degenerative disc disease, straightening up from a flexed position is performed with difficulty and is aided to some extent by flexing the knees.

Lateral bending is usually less instructive than forward bending. In unilateral ligamentous or muscular strain, bending to the opposite side aggravates the pain by stretching the damaged tissues. With unilateral sciatica, the patient lists to one side and strongly resists bending to the opposite side, and his preferred posture in standing is with the leg slightly flexed at the hip and knee. When the herniated disc lies lateral to the nerve root and displaces it medially, tension on the root is reduced by bending the trunk to the side opposite the lesion; with herniation medial to the root, tension is reduced by inclining the trunk to the side of the lesion.

In the sitting position, flexion of the spine can be performed more easily, even to the point of bringing the knees in contact with the chest. The reason for this is that knee flexion relaxes tightened hamstring muscles and relieves the stretch on the sciatic nerve. Asking the seated patient to extend the leg so that the sole of the foot can be inspected is a way of checking for a feigned Lasègue sign (see below).

Examination in the reclining position yields much the same information as in the standing and sitting positions. With lumbosacral disc lesions and sciatica, passive lumbar flexion causes little pain and is not limited as long as the hamstrings are relaxed and there is no stretching of the sciatic nerve. Thus, with the knees flexed to 90 degrees, sitting up from the reclining position is unimpaired and not painful; with knees extended, there is pain and limited motion (Kraus-Weber test). With vertebral disease (e.g., arthritis), passive flexion of the hips is free, whereas flexion of the lumbar spine may be impeded and painful.

Passive straight-leg raising (possible up to 90 degrees in normal individuals), like forward bending in the standing posture with the legs straight, places the sciatic nerve and its roots under tension, thereby producing radicular radiating pain. It may also cause an anterior rotation of the pelvis around a transverse axis, increasing stress on the lumbosacral joint and causing pain if this joint is arthritic or otherwise diseased. Consequently, in diseases of the lumbosacral joints and roots, passive straight-leg raising evokes pain and is limited on the affected side, and to a lesser extent, on the opposite side (Lasègue sign). Straight raising of the opposite leg may also cause pain on the affected side and is believed by some to be an even more reliable sign of prolapsed disc than a Lasègue sign. It is important to remember that the evoked pain is always referred to the diseased side, no matter which leg is elevated. While in the supine position, leg length (anterosuperior iliac spine to medial malleolus) and the circumference of the thigh and calf should be measured.

Hyperextension may be performed with the patient standing or lying prone. If the condition causing back pain is acute, it may be difficult to extend the spine in the standing position. A patient with lumbosacral strain or disc disease (except in the acute phase or if the disc fragment has migrated laterally) can usually extend or hyperextend the spine with little or no aggravation of pain. If there is an active inflammatory process or fracture of the vertebral body or posterior elements, hyperextension may be markedly limited. In disease of the upper lumbar roots, hyperextension is the motion that is limited and reproduces pain; however, in some cases of lower lumbar disc disease with thickening of the ligamentum flavum, this movement is also painful. In patients with narrowing of the spinal canal (spondylosis, spondylolisthesis), upright stance and extension may produce neurologic symptoms (see further on).

Maneuvers in the lateral decubitus position yield less information as a rule. In cases of sacroiliac joint disease, abduction of the upside leg against resistance reproducibly causes pain in the sacroiliac region, with radiation to the pain of the buttck, posterior thigh, and symphysis pubis. Hyperextension of the upside leg with the downside leg flexed is another test for sacroiliac disease. Rotation and abduction of the leg evoke pain in a diseased hip joint and with trochanteric bursitis. Another helpful indicator of hip pain is the Patrick test: with the patient supine, the heel of the offending leg is placed on the opposite knee and pain is evoked by depressing the flexed leg and externally rotating the hip.

Gentle palpation and percussion of the spine are the last steps in the examination. It is preferable to first palpate the regions that are the least likely to evoke pain. At all times the examiner should know what structures are being palpated (see Fig. 11-3). Localized tenderness is seldom pronounced in disease of the spine because the involved structures are so deep. Nevertheless, tenderness over a spinous process or jarring by gentle percussion may indicate the presence of inflammation (as in disc space infection), pathologic fracture, a spinal metastasis, or a disc lesion at the site deep to it.

**Figure 11-3**

1. (1) Costovertebral angle. (2) Spinous process and interspinous ligament. (3) Region of articular facet (fifth lumbar to first sacral). (4) Dorsum of sacrum. (5) Region of iliac crest. (6) Lumbal angle. (7) Spinous processes of fifth lumbar and first sacral vertebrae (tenderness = faulty posture or occasionally spina bifida occulta). (8) Region between posterior superior and posterior inferior spines. Sacroiliac ligaments (tenderness = sacroiliac sprain, often tender with fifth lumbar or first sacral disc). (9) Sacrococcygeal junction (tenderness = sacrococcygeal injury, i.e., sprain or fracture). (10) Region of sacroiliac notch (tenderness = fourth or fifth lumbar disc rupture and sacroiliac sprain). (11) Sciatic nerve trunk (tenderness = ruptured lumbar disc or sciatic nerve lesion).

Tenderness over the costovertebral angle often indicates genitourinary disease, adrenal disease, or an injury to the transverse process of the first or second lumbar vertebra (Fig. 11-3, 11). Tenderness on palpation of the paraspinal muscles may signify a strain of muscle attachments or injury to the underlying transverse processes of the lumbar vertebrae. Focal pain in the same sagittal line along the thoracic spine points to inflammation of the costotransverse articulation between spinous and rib (costotransversalis).

In palpating the spinous processes, it is important to note any deviation in the lateral plane (this is indicative of fracture or arthritis) or in the anteroposterior plane. A "step-off" forward displacement of the spinous process and exaggerated lordosis are important clues to the presence of spondylolisthesis (see further on). Tenderness over the interspinous ligaments is indicative of disc lesions (Fig. 11-3, 21). Tenderness over the region of the articular facets between the fifth lumbar and first sacral vertebrae is consistent with lumbosacral disc disease (Fig. 11-3, 31). Tenderness in this region and in the sacroiliac joints is also a frequent manifestation of ankylosing spondylitis.

Abdominal, rectal, and pelvic examinations are essential elements in the study of the patient with low back symptoms that fail to be clarified by the aforementioned spinal maneuvers. Neoplastic, inflammatory, or degenerative disorders may produce symptoms referred to the lower part of the spine.
Upon completion of the examination of the back and legs, one turns to a search for motor, reflex, and sensory changes in the lower extremities (see *Protrusion of Lumbar Intervertebral Discs,* further on in this chapter).

**Ancillary Diagnostic Procedures**

Depending on the circumstances, these may include a blood count and erythrocyte sedimentation rate (especially helpful in screening for infection or myeloma); calcium, phosphorus, uric acid, alkaline phosphatase, acid phosphatase, and prostate-specific antigen (if one suspects metastatic carcinoma of the prostate); a serum protein electrophoresis (myeloma proteins); in special cases, a tuberculin test or serologic test for Brucella: a test for rheumatoid factor; and HLA typing (for ankylosing spondylitis). Radiographs of the lumbar spine (preferably with the patient standing) in the anteroposterior, lateral, and oblique planes are still useful in the routine evaluation of low back pain and sciatica. Readily demonstrable in plain films are narrowing of the intervertebral disc spaces, bony facetal or vertebral overgrowth, displacement of vertebral bodies (spondylolisthesis), and an unsuspected infiltration of bone by cancer. In cases of suspected disc herniation or tumor involvement of the spinal canal, one proceeds directly to MRI. Although these imaging procedures have largely replaced conventional myelography, the latter examination, when combined with computed tomography (CT), provides detailed information about the dural sleeves that surround the spinal roots, at times disclosing subtle truncations caused by laterally situated disc herniations and at times revealing surface abnormalities of the spinal cord, such as arteriovenous malformations. Administration of gadolinium at the time of MRI enhances regions of inflammation and tumor.

Injection of contrast medium directly into the intervertebral disc (discogram) is still practiced in a few institutions but is more difficult to interpret than CT-myelography and MRI and carries the risk of damage to nerve roots or the introduction of infection. Discography is indicated only in special circumstances and should be undertaken only by those who are specialized in its performance. Isotope bone scans are useful in demonstrating tumors and inflammatory processes such as osteomyelitis.

Nerve conduction studies and electromyography (EMG) are particularly helpful in suspected root and nerve diseases, as indicated further on in the discussion of protruded lumbar discs. However, as for all the aforementioned tests, they are useful only in the context of the history and clinical examination; otherwise they are subject to overuse and overinterpretation.

**Principal Conditions Giving Rise to Pain in the Lower Back**

**Congenital Anomalies of the Lumbar Spine** Anatomic variations of the spine are frequent, and though rarely of themselves the source of pain and functional derangement, they may predispose an individual to discogenic and spondylotic complications by virtue of altering the mechanics and alignment of the vertebral body or size of the spinal canal.

The commonest anomaly is a lack of fusion of the laminae of one or several of the lumbar vertebrae or of the sacrum (spina bifida). Occasionally, a subcutaneous mass, hypertrichosis, or hyperpigmentation in the sacral area betrays the condition, but in most patients it remains occult until it is disclosed radiologically. The anomaly may be accompanied by malformation of vertebral joints and usually induces pain only when aggravated by injury. The neurologic aspects of defective fusion of the spine (dysraphism) are discussed in Chap. 38.

Many other congenital anomalies affect the lower lumbar vertebrae: asymmetrical facetal joints, abnormalities of the transverse processes, “sacralization” of the fifth lumbar vertebra (in which L5 appears to be fixed to the sacrum), or “lumbarization” of the first sacral vertebra (in which S1 looks like a sixth lumbar vertebra) are seen occasionally in patients with low back symptoms, but apparently with no greater frequency than in asymptomatic individuals. The role of these anomalies in the genesis of low back derangement is unclear, but in the authors’ opinion they are rarely the cause of specific symptoms.

Spondylolisthesis consists of a bony defect in the pars interarticularis (the segment at the junction of pedicle and lamina) of the lower lumbar vertebrae. The defect is remarkably common; it affects approximately 5 percent of the North American population, is probably genetic, and predisposes to fracture at this location. Radiographically, the pars interarticularis defect is best visualized on oblique projections. In some persons it is unilateral and may cause unilateral aching back pain that is accentuated by hyperextension and twisting. It is not uncommon in athletes. In the usual bilateral form, small fractures at the pars interarticularis allow the vertebral body, pedicles, and superior articular facets to move anteriorly, leaving the posterior elements behind. This latter deformity, known as spondylolisthesis, is mainly a disease of children (peak incidence between 5 and 7 years of age). It may cause little difficulty at first but eventually becomes symptomatic. The patient complains of limitation of motion and pain in the low back, radiating into the thighs. Examination discloses tenderness near the segment that has “slipped” (most often L5, occasionally L4), a palpable “step” of the spinous process forward (peak incidence between 5 and 7 years of age), hamstring spasm, and, in severe cases (spondylolisthesis), shortening of the trunk and protrusion of the lower abdomen (both of which result from the abnormal forward shift of L5 on S1) as well as signs of involvement of spinal roots—paresthesias and sensory loss, muscle weakness, and reflex impairment. These neurologic symptoms and signs tend not to be severe.

Sometimes, the fourth lumbar vertebra may slip forward on the fifth, narrowing the spinal canal, without the presence of a defect in the pars interarticularis. This is termed intact arch spondylolisthesis and occurs most often in middle-aged or elderly women. This form of spondylolisthesis is probably due to degenerative disease of the inferior and superior facets. It causes severe low back pain, made worse by standing or walking and relieved by bed rest. Symptoms of root compression are common (Alexander et al).

Patients with progressive vertebral displacement and neurologic deficits require surgery, usually posterolateral fusion and excision of the posterior elements. Reduction of displaced vertebral bodies before fusion and direct repair of pars defects are possible in special cases.

**Traumatic Disorders of the Low Back** Traumatic disorders constitute the most frequent cause of low back pain. In severe acute injuries, the examiner must be careful to avoid further damage. All movements must be kept to a minimum until an approximate diagnosis has been made and adequate measures have been instituted for the proper care of the patient. If the patient complains of pain in the back and cannot move his legs, the spine may have been fractured and the cord or cauda equina compressed or crushed. The neck should not be manipulated, and the patient should not be allowed to sit up. (See Chap. 44 for further discussion of spinal cord injury.)

**Sprains and Strains** The terms lumbarosacral strain, sprain, and derangement are used loosely by most physicians, and it is probably not possible to differentiate them. What was formerly referred to as “sacroiliac strain” or “sprain” is now known to be due, in many instances, to disc disease. The authors prefer the term acute low back or myofascial strain for minor, self-limited injuries that are usually associated with lifting heavy loads in a mechanically disadvantaged position, a fall, stiffness that arises from prolonged uncomfortable postures such as air travel or car rides, or sudden unexpected motion, as may occur in an auto accident.

The discomfort of acute low-back strain is often severe, and the patient may assume unusual postures related to spasm of the lower lumbar and sacrospinous muscles. The pain is usually confined to the lower part of the back, in the midline or just to one side or other of the spine. The diagnosis of lumbarosacral strain depends upon the description of the injury or activity that precipitated the pain, the localization of the pain, the finding of localized tenderness, the augmentation of pain by postural changes, e.g., bending forward, twisting, or standing up from a sitting position, and the absence of signs of radicular involvement. In more than 80 percent of cases of acute low-back strain of this type, the pain resolves in a matter of several days or a week even without specific treatment.

Sacroliliac strain is the most likely diagnosis when there is tenderness over the sacroiliac joint and pain radiating to the buttock and posterior thigh, but this always needs to be distinguished from a ruptured intervertebral disc (see further on). Strain is characteristically worsened by abduction of the thigh against resistance and is also felt in the symphysis pubis or groin. It, too, responds within days or a week or two to conservative management.

**Treatment of Acute Low-Back Strains** The pain of muscular and ligamentous strains is self-limited, responding to simple measures in a relatively short period of time. The basic principle of therapy in both disorders is rest, in a recumbent position, for several days. Lying on the side with knees and hips flexed or supine with a pillow under the knees favors the position. With strains of the sacrospinous muscles and sacroliliac ligaments, the optimal position is hyperextension. This position is best maintained by having the patient lie with a small pillow or folded blanket under the lumbar portion of the spine or by lying face down. Physical measures—such as application of ice in the acute phase (30 min on, 60 min off) and heat after the third or fourth day, diathermy, and massage—can be tried but are of limited value. Nonsteroidal anti-inflammatory medication should be given liberally during the first few days. Muscle relaxants are of little use, serving mainly to make bed rest more tolerable. When weight bearing is resumed, discomfort may be diminished by a light lumbosacral support, but many orthopedists refrain from prescribing this aid. Thereafter, corrective exercises are prescribed, designed to stretch and strengthen trunk (especially abdominal) muscles, overcome faulty...
The signs of severe spinal root compression are impairment of sensation, loss or diminution of tendon reflexes, and muscle weakness. The hypotonia is evident on the affected side (Neri sign); the degree of limitation of forward bending approximates that of straight-leg raising. Sciatica may be provoked by forced flexion of the head and neck, coughing, or pressure on both jugular veins, all of which increase the intraspinal pressure (Naffziger sign). Marked inconsistencies in response to these pain-provoking signs. When sciatica is severe, straight-leg raising is restricted to 20 to 30 degrees of elevation; when the condition is less severe or with improvement, the range is limited primarily to the side opposite the affected side (Fajerstagn sign). The presence of a crossed straight-leg-raising sign is strongly indicative of a ruptured disc that find their way to a lateral and posterior position in the spinal canal may produce the opposite situation, one of being unable to extend the spine and lie supine. The pain of herniated intervertebral disc varies in severity from a mild discomfort to the most severe knife-like stabs that radiate the length of the leg and are intolerable. The patient is usually most comfortable lying on his back with legs flexed at the knees and hips (dorsal decubitus position) and with the shoulders raised on pillows to obliterate the lumbar lordosis. For some patients, a particular lateral decubitus position is more comfortable. As mentioned earlier, free fragments of disc nucleus pulposus, the posterior longitudinal ligaments, and the annulus fibrosus may have taken place silently or have been manifest by mild, recurrent lumbar ache. The cause of a herniated lumbar disc is usually a flexion injury, but a considerable proportion of patients do not recall a traumatic episode. Degeneration of the nucleus pulposus, the posterior longitudinal ligaments, and the annulus fibrosus may be taken place silently or have been manifest by mild, recurrent lumbar ache. A sneeze, lurch, or other trivial movement may then cause the nucleus pulposus to prolapse, pushing the frayed and weakened annulus posteriorly. Fragments of the nucleus pulposus protrude through rents in the annulus, usually to one side or the other (sometimes in the midline), where they impinge upon a root or roots. In more severe cases of disc disease, the nucleus may protrude through the annulus or be extruded and lie epidurally, as a free fragment. A large protrusion may compress the root(s) against the articular apophysis or lamina. The protruded material may be resorbed to some extent and become reduced in size, but often it does, causing chronic irritation of the root or a discarthrosis with posterior osteophyte formation.

**The Clinical Syndrome**

The fully developed syndrome of prolapsed intervertebral disc consists of: (1) pain in the sacroiliac region, radiating into the buttck, thigh, calf, and foot and broadly termed sciatica; (2) a stiff or unnatural spinal posture; and (3) some combination of paresthesias, weakness, and reflex impairment.

The use of spinal manipulation—practiced by chiropractors, osteopaths, and others—has always been a contentious matter in the United States, partly because of unrealistic therapeutic claims made in diseases other than low back derangements. By contrast, in certain parts of Europe, orthopedists often incorporate manipulative procedures in conventional care. The percentage of slow motion films on a joint examined by physiatrists is quite similar. It must be recognized that many patients seek chiropractic manipulation on their own, often before seeing a physician, and may not disclose this information to the physician. When the supporting elements of the spine (pedicles, facets, and ligaments) are not disrupted, chiropractic manipulation of the lumbar spine has provided relief to a considerable number of patients with low-back strain or facet pain. A randomized British trial has shown manipulation to be superior to analgesics and bed rest in improving the symptoms of chronic low back pain. (Hadler et al.) Some believe the results are due to placebo effects (Cherkin), others that the results are due to the manipulation itself (McKenzie). The results from other studies have been less consistent, and these are often not well controlled. Despite these questions, most patients report some improvement in their condition after treatment, and many patients continue to seek chiropractic care for their low back pain. The presence of a crossed straight-leg-raising sign is strongly indicative of a ruptured disc.
inspection and palpation of the buttock and calf, and the Achilles tendon is usually weakened or lost on the side of the lesion. The reflex change has a little relationship to the severity of the pain or sensory loss. Furthermore, compression of the fourth or fifth lumbar root may occur without any change in the tendon reflexes. Bilaterality of root compression at these two sites. Lesions of the fifth lumbar root produce pain in the region of the hip, posterolateral thigh, lateral calf (to the external malleolus), dorsal surface of the foot, and the first or second and third toes. Paresthesias may be felt in the entire territory or only in its distal parts. The tenderness is in the lateral gluteal region and near and head of the femur. Weakness, if present, involves the extensors of the big toe and of the foot. The ankle jerk may be diminished (more often it is normal), but the knee jerk is hardly ever altered. Walking on the heels may be more difficult and uncomfortable than walking on the toes because of weakness of dorsiflexion.

As indicated above, herniations of the intervertebral lumbar discs occur most often between the fifth lumbar and first sacral vertebrae (compressing the S1 root; see Fig. 11-4) and between the fourth and fifth lumbar vertebrae (compressing the L5 root). It is important, therefore, to recognize the clinical characteristics of root compression at these two sites. Lesions of the fifth lumbar root produce pain in the region of the hip, posterolateral thigh, lateral calf (to the external malleolus), dorsal surface of the foot, and the first or second and third toes. Paresthesias may be felt in the entire territory or only in its distal parts. The tenderness is in the lateral gluteal region and near and head of the femur. Weakness, if present, involves the extensors of the big toe and of the foot. The ankle jerk may be diminished (more often it is normal), but the knee jerk is hardly ever altered. Walking on the heels may be more difficult and uncomfortable than walking on the toes because of weakness of dorsiflexion.

With lesions of the first sacral root, the pain is felt in the midgluteal region, posterior part of the thigh, posterior region of the calf to the heel, outer plantar surface of the foot, and fourth and fifth toes. Tenderness is most pronounced over the midgluteal region (in the region of the sacroiliac joint), posterior thigh areas, and calf. Paresthesias and sensory loss are mainly in the lower part of the leg and outer toes, and weakness, if present, involves the flexor muscles of the foot and toes. The Achilles reflex is diminished or absent in the majority of cases. In fact, loss of the Achilles reflex is often the first and only objective sign. Walking on the toes is more difficult and uncomfortable than walking on the heels because of weakness of the plantar flexors.

The rarer lesions of the third and fourth lumbar roots give rise to pain in the anterior part of the thigh and knee and anteromedial part of the leg (fourth lumbar), with corresponding sensory impairment. The knee jerk is diminished or abolished. L3 motor root lesions may weaken the quadriceps, thigh adductor, and iliopsoas; L4 root lesions weaken the anterior tibial innervated muscles. L1 root pain is projected to the groin and L2 to the lateral hip. Motion of the spine and certain positions are most evocative of root pain; if the pain is constant in all positions, root irritation is seldom the cause.

Much has been made of a distinctive syndrome associated with extreme lateral disc protrusions, particularly those lying within the proximal portion of the intervertebral spinal foramina. Unremitting radicular pain without back pain and a tendency to worsen with extension of the back and torsion toward the side of the herniation are said to be characteristic. Similarly, in rare instances of lumbar intradural disc rupture, there may not be sciatic pain because the free fragment does not impinge on the roots of the cauda equina. Both of these configurations may confound radiologic diagnosis and make surgery more difficult.

Rarer still are protrusions of thoracic intervertebral discs (0.5 percent of all surgically verified disc protrusions, according to Love and Schom). The four lowermost thoracic intervertebral spaces are the most frequently involved. Trauma, particularly hard falls on the heels or buttocks, is an important causative factor. Deep boring spine pain, root pain circling the body or projected to the abdomen or thorax (sometimes simulating visceral disease), paresthesias below the level of the lesion, loss of sensation, both deep and superficial, and paraparesis or paraplegia are the usual clinical manifestations.

Frequently, a herniated disc at one interspace compresses more than one root (Fig. 11-4), and it follows that the symptoms will then reflect this involvement. Anomalies of the lumbosacral roots may lead to errors in localization (see descriptions by Postacchini et al). The combined rupture of two or more discs occurs occasionally and further complicates the clinical picture. When both the L5 and S1 roots are compressed by a large herniated disc, the signs of the S1 lesion usually predominate.

Low-back pain may also be caused by degeneration of the intervertebral disc, without frank extrusion of disc tissue, or by degenerative arthritic changes of the spine, described further on, under lumbar spondylitis. Or the herniation may occur into the adjacent vertebral body, giving rise to a so-called Schmorl node. In such cases there are no signs of nerve root involvement, although back pain may be present, sometimes recurrent and referred to the thigh. And not to be forgotten as a cause of low-back pain is the implication of a root or nerve by an intrinsic tumor.

**Diagnosis** When all components of the syndrome are present, diagnosis is easy; but most neurologists prefer to corroborate their clinical impression by CT, with or without contrast myelography, or by MRI of the L3-S1 spine. Most neurologists favor MRI, in part because of the advantages of the sagittal image; however, the differences are slight except when the extruded fragment is molded into the adjacent bone (as it is prone to be with laterally extruded fragments) and becomes inedient on CT (see Forristall et al). As indicated earlier, we turn to CT-myelography for refined definition of the root sleeves and use the EMG to corroborate subtle findings. Usually MRI will demonstrate the extruded disc at the suspected site and will also exclude herniations at other sites or an unsuspected tumor (Fig. 11-5). At the lumbosacral junction there is a wide gap between the posterior margins of the vertebrae and the dural sac, so that a lateral or central protrusion of the L5-S1 disc may fail to distort the dural margin as seen on myelography. In this situation (and in others where the disc is not evident), nerve conduction studies and electromyography are useful. We find, as do Leyshon and coworkers, that the needle study in particular is abnormal showing fibrillation potentials in denervated muscles after one or two weeks in over 90 percent of cases. Loss or marked asymmetry of the H reflex is a particularly useful sign of S1 radiculopathy. The finding of denervation potentials in the paraspinal muscles (indicating root rather than peripheral nerve lesions) and in other muscles in a root distribution is also helpful, provided that at least 2 or 3 weeks have elapsed from the onset of root pain.

**Figure 11-4** Mechanisms of compression of the fifth lumbar and first sacral roots. A lateral disc protrusion at the L4-5 level usually involves the fifth lumbar root and spares the fourth; a protrusion at L5-S1 involves the first sacral root and spares the fifth lumbar root. Note that a more medially placed disc protrusion at the L4-5 level (cross-hatched) may involve the fifth lumbar root as well as the first (or second and third) sacral root.

**Figure 11-5** Lumbar disc herniation on T-1 weighted MRI. A. Sagittal view of large L5-S1 herniated nucleus pulposis (arrow). The extruded material has the same signal characteristics as the normal adjacent disc. B. Axial view of same disc (arrow) showing the paracentral mass that obliterates the epidural fat signal and...
compresses the S1 root.

It is important to keep in mind that a number of disc abnormalities, frequently observed on MRI and loosely referred to as “herniation,” may be incidental findings, unrelated to the patient’s symptoms. Jensen and colleagues, in an MRI study of the lumbar spine in 98 asymptomatic adults, found that in more than half of them there was a symmetrical extension of a disc (or discs) beyond the margins of the interspace (bulging). In 27 percent, there was a focal or asymmetrical extension of the disc beyond the margins (protrusion), and in only 1 percent was there more extreme extension of the disc (extrusion). These findings emphasize the importance of using precise morphologic terms in describing the MRI abnormalities and always evaluating these abnormalities in the light of the patient’s symptoms.

**Management of Ruptured Lumbar Disc**

In the treatment of an acute or chronic rupture of a lumbar disc, complete bed rest is usually advised and appears to be helpful, although even this time-honored tenet has been questioned by the results of a randomized study (Vroomen et al). Nonetheless we adhere to this form of treatment and it results in marked improvement in over 80 percent of patients. Analgesic medication, either nonsteroidal anti-inflammatory agents or narcotics, may be necessary for a few days in some patients with severe sciatica, we have been impressed with the relief afforded by administration of oral dexamethasone for several days. We recognize, however, that this has not been systematically studied. The only indication for emergency surgery is an acute compression of the cauda equina by massive disc extrusion, causing bilateral sensorimotor loss and sphincteric paralysis or severe unilateral motor loss. Although not the recommended course for most patients, it should be pointed out that there are instances where even a dramatic syndrome of cauda equina compression has cleared up after several weeks of bed rest. Traction is of little value in lumbar disc disease, and it is best to permit the patient to find the most comfortable position. After 1 or 2 weeks at rest, the patient can be allowed to resume activities gradually, sometimes with the protection of a brace or light spinal support. The patient may suffer minor recurrence of the pain but should be able to continue his usual activities and eventually will recover.

If the pain and neurologic findings do not subside in response to this type of conservative management or the patient suffers frequent disabling acute episodes, surgical treatment must be considered. This should be preceded by CT-myelography or MRI to localize the lesion (and exclude intra- or extradural tumors). The surgical procedure most often indicated for lumbar disc disease is a hemilaminectomy, with excision of the disc involved. In cases with sciatic pain due to L4-5 or L5-S1 disc ruptures, 80 to 90 percent are relieved by operation. Recurrence occurs in approximately 5 percent (Shannon and Paul). Arthrosis (spinal fusion) of the involved segments is indicated only in cases where there is extraordinary instability, usually related to an anatomic abnormality (such as spondylolisthesis). The treatment of nerve root compression with repeated epidural injections of methylprednisolone enjoyed a period of popularity, but controlled studies of this procedure have failed to confirm its sustained efficacy (White et al; Chuckler et al) and the procedure is not without complications. Carette et al have found only short-term improvement with facet injections, but ultimate need for surgery was not altered (see further on). Nevertheless, many neurologists have not discarded this form of treatment in view of notable success in selected patients.

Chemonucleolysis has been used for the management of lumbar disc lesions; however, as with this procedure increased, so did the number of failures and adverse effects, and the procedure has been abandoned. The same is true for the intradural injection of methylprednisolone.

**Other Causes of Sciatica and Low-Back Pain**

An increasing experience with lumbar back pain, gluteal neuralgia, and sciatica has impressed the authors with the large number of such cases that are unsolvable. At one time all these cases were classified as sciatic neuritis or “sacroiliac strain.” After Mixter and Barr popularized the concept of prolapsed disc, all sciatica and lumbar pains were ascribed to this condition. Operations became widely practiced, not only for frank disc protrusion but also for “hard discs” (unruptured) and related pathologies of the spine. The surgical results became less and less satisfactory until recently, in large referral centers, as many patients were being seen with unrelieved postamputation pain as with unruptured ruptured discs. To explain these chronic pain cases, a number of new pathologic entities, some of uncertain status, have been described. Entrapment of lumbar roots appears to be the consequence not only of disc rupture but also of spondyloitic spurs with stenosis of the lateral recess, hypothyropy of apophyseal facets, compression of the nerve by the pyriformis muscle, and arachnoidii. Lateral recess stenosis in particular may be a cause of sciatica by disc surgery. Another surprising finding in the course of imaging the spinal canal is a cyst-like dilatation of the perineural sheath (Tarlov cysts). One or more sacral roots may be involved at points where they penetrate the dura and be associated with radicular symptoms. There are reports of relief from opening the cysts and freeing the roots. Sciatica that is temporally linked to the premenstrual period is not uncommon and is almost always due to endometriosis that involves the nerve at the sciatic notch. We have also observed cases of sciatica that occurred with each pregnancy.

These are but a few of the large number of spinal abnormalities disclosed by newer radiologic techniques. An atlas of these abnormalities—congenital and developmental stenoses, Paget disease, apophyseal joint abnormalities including synovial cysts arising from the joint, unilateral spondylothesis, trochanteric and ischiogluteal bursitis—are admirably presented in the symposium on CT of the lumbar spine (see References, under “Symposium”).

Compression of the cauda equina by epidural tumor, as described further on, most often begins with back pain or sciatica, most often as a result of deposits of prostatic or breast cancer or myeloma. The sciatic nerve or the plexus from which it originates may be implicated in tumor growths (lymphoma, neurofibrosarcoma). Some patients with this group of diseases of the cauda equina produce back pain and bilateral sciatica and may be mistaken for the more usual types of cauda equina compression—cytomegalovirus infection in AIDS patients. Lyme disease, herpetic infection, and neoplastic meningitis at times behave in this fashion. In all of these, the CSF shows an intense pleocytosis. The Guillain-Barré syndrome may also produce misleading back and radicular pain before weakness is apparent. The caudal roots in these diseases enhance with gadolinium on MRI.

Finally one must not overlook the possible occurrence of a lumbosacral plexus neuritis, a unilateral (occasionally bilateral) disorder akin to brachial neuritis, and acute or subacute sciatic or femoral neuropathy due to diabetes, herpes zoster, or a retroperitoneal mass, any of which may produce a syndrome similar to that of ruptured disc (see Chap. 45).

**Lumbar Stenosis and Spondylotic Caudal Radiculopathy**

In the lumbar region, osteoarthritic or spondylotic changes may lead to compression of one or more caudal roots. The problem is exaggerated if there is a congenitally narrow lumbar canal. The roots are caught between the posterior surface of the vertebral body and the ligamentum flavum posterolaterally. Lateral recess stenosis, alluded to above, may also contribute to root compression. Upon standing or walking (downhill walking is especially difficult), there is in many cases a gradual onset of numbness and weakness of the legs, which forces the patient to sit down. When this condition is more severe, the patient gains relief by squatting or lying down with the legs flexed at the hips and knees. Usually the numbness begins in one leg, spreads to the other, and ascends as standing or walking continues. Tendon reflexes may disappear, only to return on flexing the spine. Pain in the low back and gluteii is variable. Disturbances of micrunation and posture are rare. In patients with lumbar stenosis, neurologic symptoms persist without relation to body position. The clinical picture, with its intermittency, corresponds to the so-called intermittent claudication of the cauda equina described by van Gelderen in 1948. Soon thereafter, it was shown by Verbiest to be due not to ischemia but to encroachment on the cauda by hypertrophied apophyseal joints, thickened ligaments, and small protrusions of disc material engulfed upon the canal that is developed by a shallowly hollowed in the anteroposterior diameter. Sometimes a slight subluxation at L3-4 or L4-5 is also present. Later it became evident that the canal in these cases is also narrow from side to side (reduced interpedicular distance radiographically). Decompression of the spinal canal relieves the symptoms in a considerable proportion of the cases.

Spondylotic caudal radiculopathy is the lumbar equivalent of spondylotic cervical myelopathy and radiculopathy. Insofar as the former is a cauda equina syndrome, its differential diagnosis is also discussed in Chap. 44, “Diseases of the Spinal Cord.”

**Osteoarthritis or Osteoarthropathy**

This, the most frequent type of arthritic disease, usually occurs in later life and may involve all or any part of the spine. However, it is most prevalent in the cervical and lumbar regions, where it is sometimes confused with discogenic syndromes. The pain is centered in the affected part of the spine, is increased by movement, and is associated with stiffness and limitation of motion. There is a notable absence of systemic symptoms such as fatigue, malaise, and fever, and the pain can usually be relieved by rest. A slightly flexed posture is preferred. Sitting posture is usually comfortable, although stiffness and discomfort are accentuated when the erect posture is resumed. The pain often bears little relation to the radiologic findings; pain may be present despite minimal radiographic findings; conversely, marked osteophytic overgrowth with spur formation, bridging of vertebral, narrowing of disc spaces, subluxation of posterior joints on flexion, and air in the disc spaces can be seen in both symptomatic and asymptomatic persons.

**The Facet Syndrome**

This syndrome has been clarified in recent years, but its definition is still somewhat imprecise. It appears that two distinct painful states can be related to disease of the facet joint and adjacent lateral recess. In one type, facet hypertrophy gives rise to a lumbar monoradiculopathy, indistinguishable from that
due to a ruptured disc. Reynolds et al have documented 22 such cases. Of these patients, 16 had an L5 radiculopathy, 3 an S1 radiculopathy, and 3 an L4 radiculopathy; in 15 of the patients there was coexisting back pain. At operation, the spinal root was compressed against the floor of the intervertebral canal by overgrowth of an inferior or superior facet. Foraminotomy and facetectomy, after exploration of the root from the dural sac to the pedicle, relieved the pain in 12 of the 15 operated cases.

In a second type, facet hypertrophy gives rise to lumbar back pain, often parasagittal, sometimes in the midline, with variable tenderness over the joint but without signs of root compression; it is relieved for a variable period by injection of the joint with lidocaine or its derivatives. Often one is uncertain whether it was the anesthetic effect on the joint or the infiltration of the region around the nerve root that relieved the pain. Two controlled studies have provided evidence of the ineffectiveness of another popular treatment for this type of low-back pain, namely, corticosteroid injections into the facet joints (Carette et al; Lilis et al). Notwithstanding these studies, we have found the injection of anesthetics and steroids in and around the facet to be a useful temporizing measure in some patients. In any case, this group of patients does not require operation.

Lumbar Adhesive Arachnoiditis

This also is a somewhat vague entity, in which the arachnoid membrane is thickened and opaque in the vicinity of the cauda equina. The term is also applied to thickening of the arachnoidal sheaths around roots (roots have essentially no epineurium). It can be seen in lumbar myelograms in which the contrast material fails to outline the roots and flow freely in the subarachnoid space. According to a British review, lumbar arachnoiditis is rare, having been seen in only 82 of 7000 myelograms. Judging by American writings, it is much more frequent (see “Symposium,” in the References). The usual clinical features are intractable low-back and leg pain and paresthesias, all positional, in combination with neurologic abnormalities referable to lumbar spinal roots. In our patients, multiple myelograms, disc rupture, operative procedures, infections, and subarachnoid bleeding have been causally involved. Some cases have followed spinal anaesthesia and epidural anesthesia by a period of months or years. The presumption is that the dura has been breached and that there were clinical signs of an aseptic meningitis soon after the procedure. The MRI may show eccentrically thickened meninges in the spinal canal with arachnoid adhesions and collections of CSF that displace nerve roots (Fig. 11-6). Treatment is unsatisfactory. Lysis of adhesions and administration of intrathecal steroids have been of no value. Epidural injection of steroids is occasionally helpful, according to some orthopedists.

Figure 11-6: Severe lumbar arachnoiditis causing back pain, sciatica, and paresthesias years after spinal anaesthesia. Lumbar MRI performed with infusion of gadolinium showing thickened arachnoid and displacement of cauda equine roots by acquired arachnoid cysts.

Ankylosing Spondylitis

This disorder, referred to in the past as rheumatoid spondylitis and as von Bechterew or Marie-Strumpell arthritis, affects young adult males predominantly. Its prevalence in the general population has been estimated at 1 to 3 per 1000. Approximately 95 percent of patients with ankylosing spondylitis are marked by the histocompatibility antigen HLA-B27 (which is present in only 7 percent of nonaffected persons). Pain, usually centered in the low back, is the main complaint, at least in the initial stages of the disease. Often it relates to the back of the thighs and groin. At first the symptoms are vague (tired back, “catches” up and down the back, sore back), and the diagnosis may be overlooked for many years. Although the pain is recurrent, limitation of motion is constant and progressive; over time, it dominates the clinical picture. Early in the course, this is experienced as “morning stiffness” or an increase in stiffness after periods of inactivity; these findings may be present long before radiologic changes are manifest. Rarely, a cauda equina syndrome may complicate ankylosing spondylitis, the result apparently of an inflammatory reaction and later a proliferation of connective tissue in the caudal canal (Matthews). Limitation of chest expansion, tenderness over the sternum, decreased motion and tendency to progressive flexion of the hips, and the characteristic immobility and flexion deformity of the spine (“poker spine”) may be present early in the course of the disease. The radiologic hallmarks are, at first, destruction and subsequently obliteration of the sacroiliac joints, followed by bony bridging of the vertebral bodies to produce the characteristic “bamboo spine.” When this occurs, the pain usually subsides, but the patient has by then little motion of the back and neck. Ankylosing spondylitis may also be accompanied by the Reiter syndrome, psoriasis, and inflammatory diseases of the intestine (see also Chap. 44). The great risk in this disease is fracture dislocation of the spine from relatively minor trauma, particularly flexion-extension injuries.

Occasionally ankylosing spondylitis is complicated by destructive vertebral lesions. This complication should be suspected whenever the pain returns after a period of quiescence or becomes localized. The cause of these lesions is not known, but they may represent a response to nonunion of fractures, taking the form of an excessive production of fibrous inflammatory tissue. Ankylosing spondylitis, when severe, may involve both hips, greatly accentuating the back deformity and disability.

Rheumatoid arthritis, when it affects the spine, may be confined to the cervical region and is considered further on in this chapter.

Neoplastic and Infectious Diseases of the Spine

Metastatic carcinoma (breast, bronchus, prostate, thyroid, kidney, stomach, uterus), multiple myeloma, and lymphoma are the common malignant tumors that involve the spine. The primary lesion may be small and asymptomatic and the first manifestation of the tumor may be pain in the back due to metastatic deposits. The pain is described as constant and dull; it is often unrelieved by rest and may be worse at night. Radicular pain may be added, as described earlier in the chapter. At the time of onset of the back pain, there may be no radiographic changes; when such changes do appear, they usually take the form of destructive lesions in one or several vertebral bodies with little or no involvement of the disc space, even in the face of a compression fracture. Before such destructive changes become evident, a CT or radioactive isotope scan may be helpful in detecting areas of osteolytic activity due to neoplastic or inflammatory disease and characteristic changes are also evident on MRI.

Infection of the vertebral column, osteomyelitis, is usually caused by staphylococci and less often by coliform and tubercule bacilli. The patient complains of pain in the spine, or back or neck, or sciatica. The cause of these lesions is not known, but they may represent a response to nonunion of fractures, taking the form of an excessive production of fibrous inflammatory tissue. Ankylosing spondylitis, when severe, may involve both hips, greatly accentuating the back deformity and disability.

In a second type, facet hypertrophy gives rise to lumbar back pain, often parasagittal, sometimes in the midline, with variable tenderness over the joint but without signs of root compression; it is relieved for a variable period by injection of the joint with lidocaine or its derivatives. Often one is uncertain whether it was the anesthetic effect on the joint or the infiltration of the region around the nerve root that relieved the pain. Two controlled studies have provided evidence of the ineffectiveness of another popular treatment for this type of low-back pain, namely, corticosteroid injections into the facet joints (Carette et al; Lilis et al). Notwithstanding these studies, we have found the injection of anesthetics and steroids in and around the facet to be a useful temporizing measure in some patients. In any case, this group of patients does not require operation.

In a second type, facet hypertrophy gives rise to lumbar back pain, often parasagittal, sometimes in the midline, with variable tenderness over the joint but without signs of root compression; it is relieved for a variable period by injection of the joint with lidocaine or its derivatives. Often one is uncertain whether it was the anesthetic effect on the joint or the infiltration of the region around the nerve root that relieved the pain. Two controlled studies have provided evidence of the ineffectiveness of another popular treatment for this type of low-back pain, namely, corticosteroid injections into the facet joints (Carette et al; Lilis et al). Notwithstanding these studies, we have found the injection of anesthetics and steroids in and around the facet to be a useful temporizing measure in some patients. In any case, this group of patients does not require operation.

Intraspinal Hemorrhage

Sudden, excruciating midline back pain (le coup de poignard or “the strike of the dagger”)—often with rapidly evolving paraparesis, urinary retention, and numbness of the legs—may announce the occurrence of subarachnoid, subdural, or epidural bleeding. The commonest cause of such an event is a spinal arteriovenous malformation (AVM), as discussed on page 1318. Spinal arterial aneurysms are much less common. It should be mentioned that back pain of...
comparable intensity may mark the onset of acute myelitis, spinal cord infarction, compression fracture, and occasionally Guillain-Barré syndrome.

**Pain from Visceral Disease** Peculiar ulcer disease and carcinoma of the stomach most typically induce pain in the epigastrium. However, if the posterior stomach wall is involved, particularly if there is retroperitoneal extension, the pain may be felt in the thoracic spine, centrally or to one side, or in both locations. If intense, it may seem to encircle the body. The back pain tends to reflect the characteristics of the pain from the affected organ; e.g., if due to peptic ulceration, it appears about 2 h after a meal and is relieved by food and antacids.

Diseases of the pancreas are apt to cause pain in the back, being more to the right of the spine if the head of the pancreas is involved and to the left if the body and tail are involved. Pancreatic neoplasms—e.g., pancreatic head adenocarcinomas—may evoke pain in the thoracic or lumbar spine with a tendency to radiate to the lower part of the abdomen, groins, anterior thighs, or flank. A tumor in the iliospinal region often produces a unilateral lumbar ache with radiation toward the groin and labia or testicle; there may also be signs of involvement of the upper lumbar spinal roots. An aneurysm of the abdominal aorta may induce pain that is localized to an analogous region of the spine. The sudden appearance of lumbar pain in a patient receiving anticoagulants should arouse suspicion of retroperitoneal bleeding. This pain may also be referred to the groin.

Inflammatory diseases and neoplasms of the colon cause pain that may be felt in the lower abdomen, the midlumbar region, or both. As with intense pain higher in the spine, the pain is often distributed for the most part of the descending colon and left iliac flexure. The pain may be central or peripheral but is most often referred to the left side. In endometriosis, the pain begins premenstrually and often merges with menstrual pain, which may also be felt in the sacral region. Rarely, cystic engorgement of ectopic endometrial tissue may give rise to sciatica and other radicular pain. Malposition of the uterus (retroversion, uterus descensus, and prolapse) characteristically gives rise to sacral pain, especially after the patient has been standing for several hours. Changes in posture may also evoke pain here when a fibroma of the uterus pulls on the uterosacral ligaments. Low-back pain with radiation into one or both thighs is a common phenomenon during the last weeks of pregnancy.

Pain due to carcinomatous infiltration of pelvic nerve plexuses is continuous and becomes progressively more severe; it tends to be more intense at night and may have a burning quality. The primary lesion can be inconspicuous and may be overlooked on pelvic examination.

**Psychiatric Illness** Pain due to carcinomatous infiltration of pelvic nerve plexuses is continuous and becomes progressively more severe; it tends to be more intense at night and may have a burning quality. The primary lesion can be inconspicuous and may be overlooked on pelvic examination.

Coccydynia This is the name applied to pain that is localized to the "tail piece," the three or four small vestigial bones at the lowermost part of the sacrum. The trauma of childbirth, a fall on the buttocks, avascular necrosis, a glomus tumor, or one of a variety of other rare tumors and anul disorders can sometimes be established as the cause of pain in this region. Pain is more often, the source remains obscure. In the past, patients in this latter group were indiscriminately subjected to coccygectomy, but more recent studies have demonstrated that most cases respond favorably to injections of local anesthetic and methylprednisolone or to manipulation of the coccyx under anesthesia (Wray et al).

**Obscure Types of Low-Back Pain and the Question of Psychiatric Disease** It is a safe clinical rule that all patients who complain of low-back pain have some type of primary or secondary disease of the spine and its supporting structures or of the abdominal or pelvic visceral. However, even after careful examination, there remains a sizable group of patients in whom no pathologic basis can be found for the back pain. Two categories can be recognized: one with postural back pain and another with aggravating psychiatric illness, but there are always cases where the diagnosis remains obscure.

**Postural Back Pain** Many slender, asthenic individuals and some fat, middle-aged ones have chronic discomfort in the back, and the pain interferes with effective work. The physical examination is unrevealing except for slack musculature and poor posture. The pain is diffuse in the middle or lower region of the back; characteristically, it is relieved by bed rest and induced by the maintenance of a particular posture over a period of time. Spinal manipulation is said to have helped a number of these patients. Pain in the neck and between the shoulder blades is a common complaint among thin, tense, active women and seems to be related to taut trapezius muscles.

Adolescent girls and boys are subject to an obscure form of epiphyseal disease of the spinal vertebrae (Scheuermann disease), which, over a period of 2 to 3 years, may cause low-back pain upon exercise.

**Psychiatric Illness** Low-back pain may be a major symptom in patients with hysteria, malingering, anxiety neurosis, depression, and hypochondriasis as well as in many nervous persons whose symptoms do not conform to any of these psychiatric illnesses. Again, it is good practice to assume that pain in the back in such patients may signify disease of the spine or adjacent structures, and this should always be carefully sought. However, even when some organic factors are found, the pain may be exaggerated, prolonged, or woven into a pattern of invalidism because of coexistant primary or secondary psychologic factors. This is especially true when there is the possibility of secondary gain (notably workers' compensation or settlement of personal injury claims). Patients seeking compensation for protracted low-back pain without obvious structural disease tend, after a time, to become suspicious, uncooperative, and hostile toward their physicians or anyone who may question the authenticity of their illness. One notes in them a tendency to describe their pain vaguely and a preference to discuss the degree of their disability and their mistreatment at the hands of the medical profession. The description of the pain may vary considerably from one examination to another. Often also, the response to treatment and to radiation is nonuniform and radiation fails to respond to reduction in activity. These features and a negative examination of the back should lead one to suspect a psychologic factor. A few patients, usually frank malingerers, adopt the most bizarre gait and attitudes, such as walking with the trunk flexed at almost a right angle (camptocormia), and are unable to straighten up. Or the patient may be unable to bend forward even a few degrees, despite the absence of muscle spasm, and may wince at the slightest pressure, even over the sacrum, which is seldom a site of tenderness unless there is pelvic disease.

The depressed and anxious patient with back pain represents a troublesome problem. A common error is to minimize the importance of anxiety and depression or to ascribe them to worry over the illness and its social effects. In these circumstances, common and minor back ailments, e.g., those due to osteoarthrosis and postural ache, etc., are enhanced and rendered intolerable. Such patients are often subjected to unnecessary surgical procedures. The disability seems excessive for the degree of spinal malfunction, and misery, irritability, and despair are the prevailing features of the syndrome. One of the most reliable diagnostic features is the response to drugs or other measures that alleviate the depression (see Chap. 57).

**Failed Back Syndrome** Surely the most difficult patients to manage are those with chronic low-back pain who have already had one or more laminectomies and sometimes a fusion without substantial relief. In one large series of patients operated on for proven disc prolapse, 25 percent were left with troublesome symptoms and 10 percent required further surgery (Weir and Jacobs). In such patients our practice has been to repeat the MRI and CT-myelography. In a small number of the patients, it will be found that the disc has reherniated, or that there is a lateral recess stenosis, or that a disc has ruptured at another level. It may happen that the surgeon did not remove all the disc tissue, in which case another operation to remove the remainder will be successful. Electromyography and nerve conduction studies, searching for evidence of a radiculopathy, are helpful. If there is evidence of a radiculopathy but no disc material, or only scar tissue is seen, one does not know whether the pain is due to injury from the initial rupture or was the aftermath of surgery. Various explanations are then invoked—radiculitis, lateral recess syndrome, facet syndrome, unstable spine, and lumbar arachnoiditis described earlier in the chapter (see reviews by Quiles et al and by Long as well as the “Symposium” listed in the References).

One would suppose that these chronic pain cases could be subdivided into a group with continued radicular pain and another with referred pain from disease of the spine. However, once the pain becomes chronic, the separation is not easy. Pressure over the spine, buttock, or thigh may cause pain to be projected into the leg. Lidocaine blocks of nerve roots have yielded inconsistent results. Occupational injuries, in which workers' compensation or litigation is a factor, make the patient's response very difficult. The patient's history will reveal symptoms most consistent with most cases, and the procedure of most patients, intrathecal or epidural steroid injections have seldom helped for long in our experience. At present the best that can be offered the patient is weight reduction (if he is obese), stretching and progressive exercise to strengthen abdominal and back muscles, as well as nonsteroidal anti-inflammatory and antidepressant drugs. A trial of massage therapy or a limited course of spinal manipulation is reasonable.
Cervical spondylosis

Fig. 11-7

Paresthesias and sensory loss are most evident in the second and third fingers or may be experienced in the tips of all the fingers. Weakness involves the extensors pronounced over the medial aspect of the shoulder blade opposite the third to fourth thoracic spinous processes and in the supraclavicular area and triceps region. Blade, pectoral region and medial axilla, posterolateral upper arm, elbow and dorsal forearm, index and middle fingers, or all the fingers. Tenderness is most evident in the supraclavicular region, or in the axilla and around the shoulder. It is induced by certain maneuvers and motions of the arm, and is sometimes associated with tenderness of structures above the clavicle. There may be a palpable abnormality above the clavicle (aneurysm of the subclavian artery, tumor, cervical rib). The combination of circulatory abnormalities and signs referable to the medial cord of the brachial plexus is characteristic of the thoracic outlet syndrome, which is described further on.

Osteoarthrosis and osteophyte spur formation of the cervical spine may cause pain that radiates into the back of the head, shoulders, and arm on one or both sides. Coincident compression of nerve roots is manifest by paresthesias, sensory loss, weakness and atrophy, and tendon reflex changes in the arms and hands. Should bony ridges form in the spinal canal, as described in detail in Chap. 44, the spinal cord may be compressed, with resulting spastic weakness, ataxia, and loss of vibratory and position sense in the legs (cervical spondylosis). The bony changes are evident on plain films but are better seen by CT. There may be difficulty in distinguishing cervical spondylosis from spinal cord compression from a primary neurologic disease (syringomyelia, amyotrophic lateral sclerosis, or tumor) with an unrelated cervical osteophyte, particularly at the C5-6 and C6-7 levels. Here the CT-myelogram and MRI are of particular diagnostic importance in revealing compression of the spinal cord, generally with narrowing of the spinal canal to less than 10 to 11 mm in the anteroposterior diameter (see also pages 1322–1326).

A combination of osteoarthrotic and osteophyte spur formation of the cervical spine with injury to ligaments and muscles when the neck has been forcibly extended and flexed (e.g., the acceleration or "whiplash injury" in rear-end automobile collisions) can create a number of difficult clinical problems. The injury ranges from a minor sprain of muscles and ligaments to severe tearing of these structures, to avulsion of muscle and tendon from vertebral body, and even to vertebral and intervertebral disc damage. The latter lesions can be seen with MRI and, if severe, may result in root or spinal cord compression or, occasionally, in cartilagenous embolization of the spinal cord (see page 1321). Milder degrees of whiplash injury are often complicated by psychologic and compensation factors (see LaRocca for a review of this subject).

Spinal rheumatoid arthritis may be restricted to the cervical apophyseal (facet) joints and the atlantodensial articulation. The usual manifestations are pain, stiffness, and limitation of motion in the neck and pain in the back of the head. In contrast to ankylosing spondylitis, rheumatoid arthritis is rarely confined to the spine. Because of major affection of other joints, the diagnosis is relatively easy to make, but significant involvement of the cervical spine may be overlooked in patients with diffuse disease. In the advanced stages of the disease, one or several of the vertebrae may become displaced anteriorly, or a synovitis of the atlantoaxial joint may damage the transverse ligament of the atlas, resulting in forward displacement of the atlas on the axis, i.e., atlantoaxial subluxation. Pain in the neck may project into and cause numbness or burning of one half the tongue (the "neck-tongue syndrome"; see page 201). In either instance, serious and even life-threatening compression of the spinal cord may occur gradually or suddenly. Carefully performed lateral radiographs in flexion and extension are useful in visualizing atlantodensial dislocation or subluxation of the lower segments. Occipital headache and neck pain related to degenerative changes in the upper cervical facets is discussed with other cranial lesions on page 199 (so-called third occipital nerve pain).

Cervical Disc Protrusion

A common cause of neck, shoulder, and arm pain is disc herniation in the lower cervical region (Fig. 11-7A and Fig. 11-7B). It may develop after trauma, which may be major or minor (from sudden hyperextension of the neck, falls, diving accidents, forceful chiropractic manipulations, etc.). The roots most commonly involved in cervical disc protrusion are the seventh (in 70 percent of cases) and the sixth (20 percent); fifth- and eighth-root involvement make up the remaining 10 percent (Yoss et al).

When the protruded disc lies between the sixth and seventh vertebrae, there is involvement of the seventh cervical root. The pain is in the region of the shoulder blade, pectoral region and medial axilla, posterolateral upper arm, elbow and dorsal forearm, index and middle fingers, or all the fingers. Tenderness is most pronounced over the medial aspect of the shoulder blade opposite the third to fourth thoracic spinous processes and in the suprascapular area and triceps region. Paresthesias and sensory loss are most evident in the second and third fingers or may be experienced in the tips of all the fingers. Weakness involves the extensors.
of the forearm and sometimes of the wrist; occasionally the hand grip is weak as well; the triceps reflex is diminished or absent; and the biceps and supinator reflexes are preserved.

With a laterally situated disc protrusion between the fifth and sixth cervical vertebrae, the symptoms and signs are referred to the sixth cervical root. The full syndrome is characterized by pain at the trapezius ridge and tip of the shoulder, with radiation into the anterior-upper part of the arm, radial forearm, often the thumb, and sometimes the lateral aspect of the index finger as well; paresthesias and sensory impairment in the same regions; tenderness in the area above the spine of the scapula and in the supraclavicular and biceps regions; weakness in flexion of the forearm; and diminished to absent biceps and supinator reflexes (triceps reflex retained or exaggerated).

The fifth cervical root syndrome, produced by disc herniation between the fourth and fifth vertebral bodies, is characterized by pain in the shoulder and trapezius region and by supra- and infraclavicular weakness, manifest by an inability to abduct the arm and rotate it externally with the shoulder adducted.

Compression of the eighth cervical root at C7-T1 may mimic an ulnar palsy. The pain is along the medial side of the forearm and the sensory loss is in the distribution of the median cutaneous nerve of the forearm and of the ulnar nerve in the hand. The weakness involves the muscles supplied by the ulnar nerve (page 1434).

These syndromes are usually incomplete in that only one or several of the typical findings are present. Particularly noteworthy is the occurrence, in laterally placed cervical disc rupture, of isolated weakness without pain, especially with discs at the fifth and sixth levels. Frits and coworkers have described the distribution of pain in 250 cases of herniated disc or spondylotic nerve root compression in the cervical region. Virtually every patient, irrespective of the particular root(s) involved, showed a limitation in the range of motion of the neck and aggravation of pain with movement (particularly hyperextension). Coughing, sneezing, and downward pressure on the head in the hyperextended position usually exacerbated the pain, and traction (even manual) tended to relieve it. Nerve conduction studies, F responses, and EMG are extremely helpful in confirming the level of root compression and distinguishing pain of radicular origin from that originating in the brachial plexus (see page 1357).

In many of the cervical radicular syndromes, the onset is acute and no traumatic incident can be documented. It is difficult to relate the syndrome to osseous changes that must have been present for years. Even more difficult to explain is the tendency to recovery within a few weeks when movement of the neck is limited by traction or a collar. Conservative measures should always be tried before turning to laminectomy and foraminotomy unless there are additional signs of a myelopathy, such as weakness, gait ataxia, or sphincteric dysfunction.

Unlike herniated lumbar discs, cervical ones, if large and centrally situated, may result in compression of the spinal cord (central disc, all of the cord; paracentral disc, asymmetrical but bilateral parts of the cord; Fig. 11-7B). The centrally situated disc may be painless, and the cord syndrome may simulate a degenerative disease (amyotrophic lateral sclerosis, combined system disease). Failure to think of a protruded cervical disc in patients with obscure symptoms in the legs, including stiffness and falling, is a common error. A vague sensory change can often be detected several dermatomes below the level of compression. The diagnosis and the level of disc protrusion should be confirmed by CT myelography or by MRI (Fig. 11-7B).

Management of Herniated Cervical Disc In some cases of herniated cervical disc, a sustained period of inactivity and immobilization of the head and neck by use of a close-fitting soft cervical collar may be all that is necessary for treatment. In the case of a ruptured cervical disc, in distinction to lumbar disc, traction with a halter may be of considerable benefit. Traction can be administered with the patient recumbent, or it can be performed intermittently in the sitting position, using special equipment. The simplest of which applies 2 to 10 lb of upward traction while the patient is seated with his back to a door and the weight attached to a rope over the top of the door. This should be performed two or three times daily. After 1 or 2 weeks of rest and traction, the patient can be allowed to resume activities gradually, usually with the protection of a soft collar. The patient may suffer minor recurrence but should be able to continue his usual activities and eventually will recover.

If the pain and neurologic findings do not subside in response to this type of conservative management or the patient suffers frequent disabling acute episodes, surgical treatment must be considered. This should always be preceded by a CT-myelogram or MRI to localize the lesion (and to exclude intra- or extradural tumors). The surgical procedure most often indicated is a hemilaminectomy, with excision of the disc involved. Arthrodesis ( spinal fusion) of the involved segments is indicated only in cases where there is extraordinary instability, usually related to an extensive laminectomy that has rendered the spine unstable. Large, centrally placed cervical disc protrusions may require an anterior approach, which is accomplished by displacing the trachea and esophagus and drilling through the disc from its ventral aspect.

Cervical Spondylosis

This is basically a chronic degenerative disease of the lower cervical spine that narrows the spinal canal and intervertebral foramina, causing compressive injury of the spinal cord. Since the main effects of cervical spondylosis are on the cord, it is discussed in detail in Chap. 44. Cervical spondylosis is also a common cause of neck and arm pain as described earlier, symptoms that are helped by bed rest and traction; if signs of spinal cord and root involvement are present, a collar to limit movement of the head and neck may halt the progression and even lead to improvement. Decompressive laminectomy or anterior excision of single spondylotic spurs and fusion is reserved for instances of the disease with advancing neurologic symptoms or intractable pain (see Chap. 44).

Thoracic Outlet Syndromes

A number of anatomic anomalies occur in the lateral cervical region; these may, under certain circumstances, compress the brachial plexus, the subclavian artery, and the subclavian vein, causing muscle weakness and wasting, pain, and vascular abnormalities in the hand and arm. The most frequent of these abnormalities are an incomplete cervical rib, with a sharp fascial band passing from its tip to the first rib; a taut fibrous band passing from an elongated, down-curving transverse process of C7 to the first rib; less often, a complete cervical rib, which articulates with the first rib; and anomalies of the position and insertion of the anterior and medial scalene muscles. Thus, the sites of potential neurovascular compression extend all the way from the intervertebral foramina and superior medianius to the axilla. Depending on the postulated abnormality and mechanism of symptom production, the terms cervical rib, anterior scalene, costoclavicular, and neurovascular compression have been applied to this syndrome. The international anatomic term is superior thoracic aperture syndrome.

Variations in regional anatomy could theoretically explain these several postulated mechanisms, but to this day there is not full agreement about the anterior scalene and costoclavicular syndromes. An anomalous cervical rib, which arises from the seventh cervical vertebra and extends laterally between the anterior and medial scalene muscles and then under the brachial plexus and subclavian artery to attach to the first rib, obviously disturbs the anatomic relationships of these structures and may compress them (Fig. 11-8). However, since an estimated 1.0 percent of the population has cervical ribs, usually on both sides, and only about 10 percent of these persons have neurologic or vascular symptoms (almost always one-sided), other factors must be operative in most instances. A majority of the patients are women in the late teens or early adult life (female-to-male ratio 5:1) in whom sagging of the shoulders, large breasts, and poor muscular tone may be of importance. Clavicular abnormalities, both congenital and traumatic, and certain occupational activities may also play a part.

Figure 11-8 Course of the brachial plexus and subclavian artery between the anterior scalene and middle scalene muscles. Distalation of the subclavian artery just distal to the anterior scalene muscle is illustrated. Immediately distal to the anterior and middle scalene muscles is another potential area of constriction, between the clavicle and the first rib. With extension of the neck and turning of the chin to the affected side (Addison maneuver), the tension on the anterior scalene muscle is increased and the subclavian artery compressed, resulting in a supraclavicular bruit and obliteration of the radial pulse.
The anterior and middle scalene muscles, which flex and rotate the neck, are both inserted into the first rib; the subclavian artery and vein and the brachial plexus must pass beneath it. Hence the abnormalities of these muscles were once thought to be causes of the syndrome. However, section of these muscles (scalenection) so rarely altered the symptoms that this mechanism is no longer given credence.

Three neurovascular syndromes have been associated with a rudimentary cervical rib (rarely with a complete cervical rib) and related abnormalities at the thoracic outlet. These syndromes sometimes coexist, but more often each occurs independently.

1. Compression of the subclavian vein, causing a dusky discoloration, venous distention, and edema of the arm. The vein may become thrombosed after prolonged exercise, the so-called effort-thrombotic syndrome of Paget and Schroetter.

2. Compression of the subclavian artery, which results in ischemia, which may be complicated by digital gangrene and retrograde embolization. A unilateral Raynaud phenomenon, brittle nails, and ulceration of the fingertips are important diagnostic findings. A supraclavicular bruit is suggestive but not in itself diagnostic of subclavian artery compression. The conventional tests for vascular compression—diminution or obliteration of the pulse when the patient, seated and with the arm dependent, takes and holds a full breath, tilts the head back, and turns it to the affected side (Adson test)—or abduction and externally rotates the arm and braces the shoulders (Wright maneuver)—are not entirely reliable. Sometimes these maneuvers fail to obliterate the radial pulse in cases of proved compression; contrariwise, these tests may be positive in normal persons. Nevertheless, a positive test on the symptomatic side (with reproduction of the patient's symptoms) but not on the other side should always suggest a local lesion. The addition of plethysmographic recording of the radial pulse and ultrasound of the vessel adds greatly to the accuracy of these positional tests.

3. A primarily neurologic syndrome, characterized by slight wasting and weakness of the hypothenar, interosseous, adductor pollicis, and deep flexors muscles of the fourth and fifth fingers (i.e., the muscles innervated by the lower trunk of the brachial plexus and ulnar nerve). Weakness of the flexor muscles of the forearm may be present in advanced cases. Tendon reflexes are usually preserved. In addition, most patients with this form of the syndrome complain of an intermittent aching of the arm, particularly of the ulnar side, and about half of them complain also of numbness and tingling along the ulnar border of the forearm and hand. A loss of superficial sensation in these areas is a variable finding. It may be possible to reproduce the sensory symptoms by firm pressure just above the clavicle or by simple traction on the arm. Vascular features are often absent or minimal in patients with the neurologic form of the syndrome.

In all three forms of the syndrome, shoulder and arm pain is a prominent complaint. The discomfort is of the aching type and is felt in the posterior hemithorax, pectoral region, and upper arm.

Diagnostic measures should include the Adson test or preferably the Wright maneuver, described earlier, with digital plethysmography to quantitate the degree of positional vascular compromise; also films of the cervical spine should be obtained, looking for a cervical rib or an elongated C7 transverse process (the fibrous bands are not visualized). Typically, nerve conduction studies disclose a reduced amplitude of the ulnar sensory potentials. There may be a decreased amplitude of the median or ulnar evoked potentials, a mild but uniform slowing of the median motor conduction velocity, and a prolongation of the F-wave latency. Concentric needle examination of affected hand muscles reveals large-amplitude motor units, suggesting collateral reinnervation. The application of somatosensory evoked potentials may prove to be a useful adjunct to the conventional nerve conduction and EMG studies (Yiannikas and Walsh). Brachial artery angiography is usually reserved for patients with a suspected arterial occlusion, an aneurysm, or an obvious cervical rib. The place of venography in the diagnostic workup is uncertain, for a number of otherwise normal individuals can occlude the subclavian vein by fully abducting the arm.

In the authors' experience, unambiguous instances of thoracic outlet syndrome are not common. This has also been the experience of Wilbourn, whose review of this subject is recommended. Neck and arm pain in slender, neurotic women presents particularly difficult problems in diagnosis; often the physician assumes the presence of a thoracic outlet syndrome, only to discover that operation affords little or no lasting relief. One should be skeptical of the diagnosis unless the rigid clinical and EMG criteria enumerated above have been met. Common mistakes are to confuse the thoracic outlet syndrome with carpal tunnel syndrome, ulnar neuropathy or entrapment at the elbow, or cervical radiculopathy due to arthritis or disc disease. Imaging studies and careful nerve conduction and EMG studies may be necessary to exclude latter disorders.

Treatment of the Thoracic Outlet Syndrome In the management of this syndrome, a conservative approach is advisable. If the main symptoms are pain and paresthesias, Leffert advises the use of local heat, analgesics, muscle relaxants, and an assiduous program of special exercises to strengthen the shoulder muscles.

Twice a day, holding a 1- or 2-lb weight in each hand, the patient intermittently shrugs and raises the shoulders forward upward, then backward upward, and then upward, each performed 10 times. In a second exercise, with the weights held at the side, the extended arms are lifted over the head until the backs of the hands meet; again this done 10 times. In a third exercise, the patient faces a corner of a room and places one hand on each wall; with elbows bent, he leans into the wall and at the same time inhales, then exhales as he pushes away. A full range of neck motions is then practiced. On such a regimen some patients experience a relief of symptoms after 2 to 3 weeks.

If pain is severe and persistent and is clearly associated with the vascular and/or neurogenic features of the syndrome, surgery is indicated. The usual approach is through the supraclavicular space, with cutting of fibrous bands and excision of the rudimentary rib. In cases of venous or minor arterial forms of the syndrome, some thoracic surgeons favor the excision of a segment of the first rib through the axilla. Pain is often dramatically relieved but the sensorimotor defects improve only slightly. Atherosclerosis with thrombosis and embolism of the subclavian artery and thrombosis of the vein require decompression and arterioplasty and venous thrombectomy, respectively. Brachial sympatheticctomy may be necessary in exceptional patients with a persistent Raynaud phenomenon.

As mentioned earlier, vasomotor, sudomotor, and trophic changes in the skin, with atrophy of the soft tissues and decalcification of bone, may follow the prolonged immobilization and disuse of an arm or leg for whatever reason. The patient may be reluctant to move the limb because of pain or a lack of motivation to get well or for reasons of monetary gain. Surgery in this group of patients is ill advised, and the physician's efforts should be directed to mobilization of the affected part through an intensive physical therapy program and settlement of litigation if this is a factor.

Other Painful Conditions Originating in the Neck, Brachial Plexus, and Shoulder

The brachial plexus is an important source of shoulder and arm pain. The main disorders are brachial neuritis and metastatic infiltration and radiation damage to the plexus. These disorders are discussed in detail in Chap. 46.

Metastases to the cervical region of the spine are less common than to other parts of the vertebral column. They are frequently painful and may cause root compression. Posterior extension of the tumor from the vertebral bodies or compression fractures may lead to the rapid development of quadriplegia.

Metastases to the cervical region of the spine are less common than to other parts of the vertebral column. They are frequently painful and may cause root compression. Posterior extension of the tumor from the vertebral bodies or compression fractures may lead to the rapid development of quadriplegia.

The Pancoast tumor, usually a squamous cell carcinoma in the superior sulcus of the lung, may implicate the lower cervical and upper thoracic (T1 and T2) spinal nerves as they exit from the spine. In these cases, a Horner syndrome, numbness of the inner side of the arm and hand, and weakness of all muscles of the hand and of the triceps muscles are combined with pain beneath the upper scapula and in the arm. The neurologic abnormalities may occur long before the tumor becomes visible radiographically.

Shoulder injuries (rotator cuff), subacromial or subdeltoid bursitis, periartthritis or capsulitis ("frozen shoulder"), tendinitis, and arthritis may develop in patients who are otherwise well, but these conditions also occur occasionally as complications of hemiplegia. The pain tends to be severe and extends toward the neck and down the arm into the hand. The dorsum of the hand may tingle without other signs of nerve involvement. Immobility of an arm following myocardial infarction may be associated with pain in the shoulder and arm and with vasomotor changes and secondary arthropathy of the hand joints (shoulder-hand syndrome); after a time, osteoporosis and atrophy of cutaneous and subcutaneous structures occur (Sudeck atrophy or Sudeck-Leriche syndrome). Similar changes may occur in the foot and leg or all articular structures on the side of a hemiplegia or in association with the painful lesions described in the first part of this chapter. These conditions fall within the province of the orthopedist and are not discussed in detail. The neurologist, however, should know that they can be prevented by proper exercises and relieved by cooling of the affected limb, exercises, and physiotherapy (see further on).

Medial and lateral epicondyritis (tennis elbow) are readily diagnosed by demonstrating tenderness over the affected parts and an aggravation of pain on certain movements of the wrist. We have observed entrapment of the ulnar nerve in some cases of medial epicondyritis.

The pain of the carpal tunnel syndrome (page 1433) often extends into the forearm and sometimes higher and may be mistaken for disease of the shoulder or neck.
Similarly, involvement of the ulnar, radial, or median nerves may be mistaken for brachial plexus or root lesions. Electromyography and nerve conduction studies are helpful in these circumstances.

**PAIN CONFINED TO THE EXTREMITIES**

**Arthritis of the Extremities** The principal symptom of osteoarthritis is pain that is brought on by activity and relieved by rest. Stiffness after sitting and immediately upon arising in the morning is common but seldom persists for more than a few minutes. The more common locations are the terminal phalanges, carpal-metacarpal joint of the thumb, knees, hips, and spine. Rheumatoid arthritis most commonly involves the proximal interphalangeal and metacarpophalangeal joints, toes, wrists, ankle, knee, elbow, hip, and shoulder.

**Polymyalgia Rheumatica** This syndrome is observed in middle-aged and elderly persons and is characterized by severe pain, aching, and stiffness in the proximal muscles of the limbs and a markedly elevated erythrocyte sedimentation rate. Constitutional symptoms (loss of weight, fever, and anemia) and articular swelling are less consistent manifestations. Activity of the disease correlates with elevation of the sedimentation rate, unlike the case in polymyalitis, with which it is confused by the unilatertal, creatine kinase levels are normal. In many patients, polymyalgia rheumatica is associated with giant-cell (temporal, or cranial) arteritis, which may be the only symptomatic expression of the disease (pages 193, 263 and 907). The arteritis may affect one or both optic nerve heads, and blindness is the main risk of the disease. This disorder is self-limited, lasting 6 months to 2 years, and responds dramatically to corticosteroid therapy, although the latter may need to be continued in low dosage for several months or a year or longer, using the sedation rate or C-reactive protein and hip and shoulder pain as guides.

**Arteriosclerosis Obliterans** Athereosclerosis of large and medium-sized arteries, the most common vascular disease of humans, often leads to symptoms that are induced by exercise (intermittent claudication) but may also occur at rest (ischemic rest pain). The diabetic patient is especially susceptible. The muscle pain that is brought on by exercise and promptly relieved by rest most frequently involves the calf and thigh muscles. If the athero sclerotic narrowing or occlusion implicates the aorta and iliac arteries, it may also cause hip and buttock claudication and impotence in the male (Leriche syndrome). Ischemic rest pain—and sometimes attendant ulceration and gangrene, usually localized to the foot and toes—is the consequence of multiple sites of vascular occlusion. Pain at rest is characterized worse at night and totally or partially relieved by dependency.

The examination of such patients will reveal a loss of one or more peripheral pulses, trophic changes in the skin and nails (in advanced cases), and the presence of bruits over or distal to sites of narrowing. The ankle reflexes are often diminished.

**Raynaud Phenomenon** Painful blanching of the fingers with emotional stress or exposure to cold is the main feature. In many cases, no cause can be discerned. Other so-called secondary cases are due to partial obstruction of the brachial circulation, as occurs with some of the forms of the thoracic outlet syndrome, with repeated trauma to the hands, as in sculling or with use of a jackhammer, or with cryoglobulinemia, athereosclerotic myeloma, and autoimmune diseases. The Raynaud phenomenon is discussed further on page 569.

**Reflex Sympathetic Dystrophy and Causalgia** This is an excessive or abnormal response to injury of the shoulder, arm, or leg, particularly if an incomplete nerve injury is associated. It consists of protracted pain, characterized distinctly as "burning," together with cyanosis or pallor, swelling, coldness, pain on passive motion, osteoporosis, and marked sensitivity of the affected part to tactile stimulation. The condition is variously described under such terms as Sudeck atrophy, posttraumatic osteoporosis (in which the bone scan may show increased local uptake of radioactive nuclides), and the related shoulder-hand syndrome. The unique pain syndrome is referred to as causalgia. Pharmacologic or surgical sympathetics may appear to relieve the symptoms in some patients. In others, with a hyperesthesia of both C-fiber receptors and postganglionic sympathetic fibers, it is not helpful (Lindblom and Ochoa). This subject is discussed further on pages 148 and 1438.

**Neurona Formation after Nerve Injury** Persistent and often incapacitating pain and dysesthesias may follow any type of injury that leads to partial or complete interruption of a nerve with subsequent neura formation or intraneural scarring—fracture, contusion of the limbs, compression from lying on the arm in a drunken stuper, searing of sensory nerves in the course of surgical operations or biopsy of nerve, or incomplete regeneration after nerve suture. It is stated that the nerves in these cases contain a preponderance of unmyelinated C fibers and a reduced number of A-d fibers; this imbalance is presumably related to the genesis of painful dysesthesias. These cases are best managed by complete excision of the neura with end-to-end suture of healthy nerve, but not all cases lend themselves to this procedure.

Another special type of neura is the one that forms at the end of a nerve severed at amputation (stump neura). Pain from this source is occasionally abolished by relatively simple procedures such as resection of the distal neura, proximal neuraotomy, or resection of the regional sympathetic ganglia. Anterolateral cordotomy with attainment of complete analgesia may abolish pain from a stump neura (as well as pain from a phantom limb), but it is of limited value since there is usually a return of sensation and of pain after several months (6 months in the case of the lower extremities and earlier in the arms).

**Erythromelalgia** This rare disorder of the microvasculature produces a burning pain and bright red color change, usually in the toes and forefoot and sometimes in the hands, usually in association with changes in ambient temperature. Since it was first described by Weir Mitchell in 1878, many articles have been written about it, but the cause of the primary form is still obscure. Each patient has a temperature threshold above which symptoms appear and the feet become bright red and warm. The affected patient rarely wears stockings or regular shoes, since these tend to bring out the symptoms. The pain is relieved by walking on a cold surface or soaking the feet in ice water and by rest and elevation of the legs. The peripheral pulses are intact, and there are no motor, sensory, or reflex changes. There are rare secondary forms of the disease associated with myeloproliferative disorders, particularly polycythemia vera, thrombocythemia, and occlusive vascular diseases; in some instances it is a manifestation of a painful neuropathy (Chap. 46). The ergol-based dopamine agonists that are used in the treatment of Parkinson disease sometimes cause this syndrome. Aspirin and methysersynergide have been recommended in the treatment of this disease but we have not had the opportunity of confirming their efficacy.

**Myofascial Pain Syndrome (Filibraymolgia)** A confusing problem in the differential diagnosis of neck and limb pain is posed by the patient with pains that are clearly musculoskeletal in origin but are not attributable to any of the aforementioned diseases of the spine, articular structures, or nerves. The pain is localized to certain points in skeletal muscles, particularly the large muscles of the neck and shoulder girdle, arms, and thighs. Ill-defined, tender nodules or cords can be felt in the musculoskeletal in origin but are not attributable to any of the aforementioned diseases of the spine, articular structures, or nerves. The pain is localized to certain points in skeletal muscles, particularly the large muscles of the neck and shoulder girdle, arms, and thighs. Ill-defined, tender nodules or cords can be felt in the muscle tissue (page 1572). Excision of such nodules reveals no sign of inflammation or other disease process. The currently fashionable terms fibromyalgia and fibrositis are applied to this syndrome, but the results in any given individual are unpredictable.

**CHAPTER REFERENCES**

The sensations of smell (olfaction) and taste (gustation) are suitably considered together. Physiologically, these modalities share the singular attribute of responding primarily to chemical stimuli; i.e., the end organs that mediate olfaction and gustation are chemoreceptors. Also, taste and smell are interdependent clinically; appreciation of the flavor of food and drink depends to a large extent on their aroma, and an abnormality of one of these senses is frequently misinterpreted as an abnormality of the other. In comparison to sight and hearing, taste and smell play a relatively unimportant role in the life of the individual. However, the role of chemical stimuli in communication between humans has not been fully explored. Pheromones (pheroin, “to carry”; hormon, “exciting”), that is, odors emitted from the body and perfumes, play a part in sexual attraction (Agosta); noxious body odors repel. In certain vertebrates the olfactory system is remarkably well developed, rivaling the sensitivity of the visual system, but it has been stated that even humans, in whom the sense of smell is relatively weak, have the capacity to discriminate between as many as 10,000 different odors (Reed).

Clinically, disorders of taste and smell can be persistently unpleasant, but only rarely is the loss of either of these modalities a serious handicap. Nevertheless, since all foods and inhalants pass through the mouth and nose, these two senses serve to detect noxious odors (e.g., smoke) and to avoid tainted food and potential poisons; loss of these senses could then have serious consequences. Also, a loss of taste and smell may signify a number of intracranial and systemic disorders, and assume clinical importance from this point of view.

OLFACTORY SENSE

Anatomic and Physiologic Considerations

Nerve fibers subserving the sense of smell have their cells of origin in the mucous membrane of the upper and posterior parts of the nasal cavity (superior turbinates and nasal septum). The entire olfactory mucosa covers an area of about 2.5 cm² and contains three cell types—the olfactory or receptor cells (which number between 6 and 10 million in each nasal cavity); sustentacular or supporting cells; which maintain the electrolyte (particularly K) levels in the extracellular milieu; and basal cells, which are stem cells and the source of both the olfactory and sustentacular cells during regeneration. The olfactory cells are actually bipolar neurons. Each of these cells has a peripheral process (the olfactory rod), from which project 10 to 30 fine hairs, or cilia. These hair-like processes, which lack motility, are the sites of olfactory receptors. The central processes of these cells, or olfactory fila, are very fine (0.2 mm in diameter), unmyelinated fibers that converge to form small fascicles enwrapped by Schwann cells that pass through openings in the cribiform plate of the ethmoid bone into the olfactory bulb (Fig. 12-1). Collectively, the central processes of the olfactory receptor cells constitute the first cranial, or olfactory, nerve. Notably, this is the only site in the organism where neurons are in direct contact with the external environment. The epithelial surface is covered by a layer of mucus, which is secreted by tubuloalveolar cells (Bowman’s glands) and within which there are immunoglobulins A and M, lactoferrin, and lysozyme as well as odorant-binding proteins. These molecules are thought to prevent the intracranial entry of pathogens via the olfactory pathway (Kimmelman).

In the olfactory bulb, the receptor-cell axons synapse with granule cells and mitral cells (triangular, like a bishop’s mitre), the dendrites of which form brush-like terminals or olfactory glomeruli (Fig. 12-1). Smaller, so-called tufted cells in the olfactory bulb also contribute dendrites to the glomerulus. Approximately fifteen thousand olfactory-cell axons converge on a single glomerulus. This high degree of convergence is thought to account for an integration of afferent information. The mitral and tufted cells are excitatory; the granule cells—along with centrifugal fibers from the olfactory nuclei, locus ceruleus, and periforn cortex—subserve mitral cell activity. Presumably, interaction between these excitatory and inhibitory neurons provides the basis for the special physiologic aspects of olfaction.

The axons of the mitral and tufted cells form the olfactory tract, which courses along the olfactory groove of the cribiform plate to the cerebrum. Lying caudal to the olfactory bulbs are groups of cells that constitute the anterior olfactory nucleus (Fig. 12-1). Dendrites of these cells synapse with fibers of the olfactory tract, while their axons project to the olfactory nucleus and bulb of the opposite side; these neurons are thought to function as a reinforcing mechanism for olfactory impulses.

Posteriorly, the olfactory tract divides into medial and lateral olfactory striae. The medial stria contains fibers from the anterior olfactory nucleus, which pass to the opposite side via the anterior commissure. Fibers in the lateral stria originate in the olfactory bulb, give off collaterals to the anterior perforated substance, and terminate in the medial and cortical nuclei of the amygdaloid complex and the prepiriform area (also referred to as the lateral olfactory gyrus). The latter represents the primary olfactory cortex, which in humans occupies a restricted area on the anterior end of the parahippocampal gyrus and uncus (area 34 of Brodmann; see Fig. 22-3). This olfactory cortex is unique among sensory systems. From the prepiriform cortex, fibers project to the neighboring entorhinal cortex (area 28 of Brodmann) and the medial dorsal nucleus of the thalamus; the amygdaloid nuclei connect with the hypothalamus and septal nuclei. The role of these latter structures in olfaction is not well understood, but presumably they subserve reflexes related to eating and sexual function. As with all sensory systems, feedback regulation occurs at every point in the afferent olfactory pathway.

In quiet breathing, little of the air entering the nostril reaches the olfactory mucosa; sniffing carries the air into the olfactory crypt. To be perceived as an odor, an inhaled substance must be volatile—i.e., spread in the air as very small particles—and soluble in water. Molecules provoking the same odor seem to be related more broadly to chemical stimuli by their chemical quality than by their chemical quantal. Thus, a jet of scented vapor is directed to the sensory epithelium, as by sniffing, a slow negative potential shift called the electro-olfactogram (EOG) can be recorded from an electrode placed on the mucosa. The conductance changes that underlie the receptor potential are induced by molecules of odorous material dissolved in the mucus overlying the receptor. The transduction of odorant stimuli to electrical signals appears to be mediated in part by a GTP-dependent adenyl cyclase (“G protein”); like other cyclic AMP pathways, it utilizes an intracellular second messenger, but in the case of olfaction, the responsible molecule has not been definitely identified. There follow conformational changes in transmembrane receptor proteins and a series of intracellular processes of the olfactory receptor cells constitute the first cranial, or olfactory, nerve. Notably, this is the only site in the organism where neurons are in direct contact with the external environment. The epithelial surface is covered by a layer of mucus, which is secreted by tubuloalveolar cells (Bowman’s glands) and within which there are immunoglobulins A and M, lactoferrin, and lysozyme as well as odorant-binding proteins. These molecules are thought to prevent the intracranial entry of pathogens via the olfactory pathway (Kimmelman).

Figure 12-1 Diagram illustrating the relationships between the olfactory receptors in the nasal mucosa and neurons in the olfactory bulb and tract. Cells of the anterior olfactory nucleus are found in scattered groups caudal to the olfactory bulb. Cells of the anterior olfactory nucleus make immediate connections with the olfactory tract. They project centrally via the medial olfactory stria and to contralateral olfactory structures via the anterior commissure. Insert: diagram of the olfactory structures on the inferior surface of the brain (see text for details).
biochemical events that generate axon potentials. Intensity of olfactory sensation is determined by the frequency of firing of afferent neurons. The quality of the odor is thought to be provided by “cross-fiber” activation, since the individual receptor cells are responsive to a wide variety of odors and exhibit different types of responses to stimuli—excitatory, inhibitory, and on-off responses have been obtained. The olfactory potential can be eliminated by destroying the olfactory receptor surface or the olfactory filaments. The loss of EOG occurs 6 to 16 days after severance of the nerve; the receptor cells disappear, but the sustentacular cells are not altered. Most significant is the fact that, as a result of division of the basal cells of the olfactory epithelium, the olfactory receptor cells are constantly dying and being replaced by new ones. In this respect the chemoreceptors, both for smell and for taste, are unique, constituting the only examples of neuronal regeneration in humans.

The trigeminal system also participates in chemesthesia through undifferentiated receptors in the nasal mucosa. These receptors have little discriminatory ability but a great sensitivity to all irritant stimuli. The trigeminal afferents also release neuropeptides that result in hypersecretion of mucus, local edema, and sneezing. Finally, it should be noted that stimulation of the olfactory pathway at sites other than the receptor cells may also induce olfactory experiences.

The olfactory system adapts quickly to the sensory stimulus, and for sensation to be sustained, there must be repeated stimulation. The olfactory sense differs from other senses in yet another way. It is common experience that an aroma can restore long-forgotten memories of complex experiences. That olfactory and emotional stimuli are strongly linked is not surprising in view of their common roots in the limbic system. Yet the ability to recall an odor is negligible in comparison with the ability to recall sounds and sights. As Vladimir Nabokov has remarked: “Memory can restore to life everything except smells.”

Clinical Manifestations

Disturbances of olfaction may be subdivided into four groups, as follows:

1. Quantitative abnormalities: loss or reduction of the sense of smell (anosmia, hyposmia) or, rarely, increased olfactory acuity (hyperosmia)
2. Qualitative abnormalities: distortions or illusions of smell (dysosmia or parosmia)
3. Olfactory hallucinations and delusions caused by temporal lobe disorders or psychiatric disease
4. Higher-order loss of olfactory discrimination (olfactory agnosia)

Anosmia (Loss of Sense of Smell) This is the most frequent clinical abnormality, and, if unilateral, will usually not be recognized by the patient. Unilateral anosmia can sometimes be demonstrated in the hyperalert patient on the side of anesthesia, blindness, or deafness. Bilateral anosmia, on the other hand, is not a uncommon complaint, and the patient is usually convinced that the sense of taste has been lost as well (ageusia). This calls attention to the fact that taste depends largely on the volatile particles in foods and beverages, which reach the olfactory receptors through the nasopharynx, and that the perception of flavor is a combination of smell, taste, and texture. The loss of the ability to distinguish the primary taste sensations (sweet, sour, bitter, and salty). The olfactory defect can be verified readily enough by presenting a series of nonirritating olfactory stimuli (vanilla, peanut butter, coffee, tobacco, etc.,) first in one nostril, then in the other, and asking the patient to sniff and identify them. If the odors can be detected and described, even if they cannot be named, it may be assumed that the olfactory nerves are relatively intact (humans can distinguish many more odors than they can identify by name). Ammonia and similar pungent substances are unsuitable stimuli because they do not test the sense of smell but have a primary irritating effect upon the free nerve endings of the trigeminal nerves.

A more elaborate scratch and sniff test has been developed and standardized by Doty and colleagues (University of Pennsylvania Smell Identification Test). In this test the patient attempts to identify 40 microencapsulated odorants and his olfactory performance is compared with that of age- and sex-matched normal individuals. Unique features of this test is a means for detecting malingering and amenability to self-administration. Air-dilution olfactory detection is a more refined way of determining thresholds of sensation and of demonstrating normal olfactory perception in the absence of identification. Olfactory evoked potentials are being used in some electrophysiology laboratories, but their reliability is uncertain. These refined techniques are essentially research tools and are not used in neurologic practice.

The loss of smell usually falls into one of three categories: nasal (in which odorants do not reach the olfactory receptors), olfactory neuroepithelial (due to destruction of receptors or their axon filaments), and central (olfactory pathway lesions). In an analysis of 4000 cases of anosmia from specialized clinics, Hendricks found that three categories of pathology—nasal or paranasal sinus disease, viral infection of the upper respiratory tracts (the largest group), and head injury—accounted for most cases. Regardless of the nasal diseases responsible for bilateral hyposmia or anosmia, the most frequent are those in which hypertrophy and hyperplasia of the nasal mucosa prevent olfactory stimuli from reaching the receptor cells. Heavy smoking is said to be the most frequent cause of hyposmia. Chronic atrophic rhinitis; sinusitis of allergic, vasomotor, or infective types; nasal polyposis; and overuse of topical vasoconstrictors are other common causes. Biopsies of the olfactory mucosa in cases of allergic rhinitis have shown that the sensory epithelial cells are still present, but their cilia are deformed and shortened and are buried under other mucosal cells. Influenza, herpes simplex, and hepatitis virus infections may be followed by hyposmia or anosmia due to destruction of receptor cells, and, if the nasal basal cells are also destroyed, they may persist. These cases may also be affected as a result of atrophic rhinitis and local radiation therapy or by a very rare type of tumor (esthesioneuroblastoma) that originates in the olfactory epithelium. There is also a group of rare diseases in which the primary receptor neurons are congenitally absent or hypoplastic and lack cilia. One of these is the Kallmann syndrome of congenital anosmia and hypogonadotropic hypogonadism. A similar disorder occurs in the Turner syndrome and in albinos, because of the absence of “olfactory pigment” or some other congenital structural defect.

Anosmia that follows head injury is most often due to tearing of the delicate filaments of the receptor cells as they pass through the cribiform plate, especially if the injury is severe enough to cause fracture. The damage may be unilateral or bilateral. With closed head injury, anosmia is relatively infrequent (6 percent of Sumner's series of 584 cases). Some recovery of olfaction occurs in about one-third of all head trauma cases over a period of several days to months. Beyond 6 to 12 months, recovery is negligible. Cranial surgery, subarachnoid hemorrhage, and chronic meningeval inflammation may have a similar effect. Strangely, in some of the cases of traumatic anosmia the loss is also a loss of taste (ageusia). Ferrier, who first described traumatic ageusia in 1876, noted that there was always anosmia as well—an observation subsequently corroborated by Sumner. Often the ageusia clears within a few weeks. A bilateral lesion near the frontal operculum and paralimbic region, where olfactory and gustatory receptive zones are in close proximity, would best explain this concurrence. Obviously the interruption of olfactory filaments alone would not explain ageusia.

In women, olfactory acuity varies throughout the menstrual cycle and may be disordered during pregnancy. Nutritional and metabolic diseases such as thiamine deficiency, vitamin A deficiency, adrenal and perhaps thyroid insufficiency, cirrhosis, and chronic renal failure may give rise to transient anosmia, all as a result of sensorineural dysfunction. A large number of toxic agents—the more common ones being organic solvents (benzene), metals, dusts, cocaine, corticosteroids, methotrexate, aminoallylglycoside antibiotics, tetracyclines, opiates, and ¬dopa—can damage the olfactory epithelium (Doty et al). It has been reported that a large proportion of patients with degenerative disease of the brain show anosmia or hyposmia, for reasons that are quite unclear. Included in this group are Alzheimer, Parkinson, Huntington, and Pick disease and the Parkinson-dementia syndrome of Guam. The studies relating to this subject have been reviewed in detail by Doty. A number of theories have been proposed to explain these findings, but they are conjectural. It has been known for some time that alcoholics with Korsakoff psychosis have a defect in odor discrimination (Mair et al). In the latter disorder, anosmia is presumably due to degeneration of neurons in the hippocampus in cases of Alzheimer disease, but we know of no studies of the central olfactory connections in this or any other degenerative disorder. Anosmia has been found in some patients with temporal lobe epilepsy and in some such patients who had been subjected to anterior temporal lobectomy. In these conditions, Andy and coworkers have found an impairment in discriminating the quality of odors and in matching odors with test objects seen or felt.

As with other sensory modalities, olfaction (and taste) are diminished with aging. The receptor cell population is depleted, and if the loss is regional, neuroepithelium is slowly replaced with respiratory epithelium (which is normally present in the nasal cavity and serves to filter, humidify, and warm incoming air). Neurons of the olfactory bulb may also be reduced as part of the aging process. Bilateral anosmia is an increasingly common manifestation of malingering, now that it has been recognized as a compensable disability by insurance companies. The fact that true anosmics will complain inordinately of a loss of taste (but show normal taste sensation) may help to separate them from malingers. Testing of olfactory evoked potentials, if perfected, would be of use here.

The nasal epithelium or the olfactory nerves themselves may be affected in Wegener granulomatosis and by craniopharyngioma. A meningioma of the olfactory groove may implicate the olfactory bulb and tract and may extend posteriorly to involve the optic nerve, sometimes with optic atrophy; these abnormalities, if combined with optic atrophy on the opposite side, are known as The Foster Kennedy syndrome (page 260). A large aneurysm of the anterior cerebral or anterior communicating artery may produce a similar syndrome. With tumors confined to one side, the anosmia may be strictly unilateral, in which case it will not be reported by the patient but will be found on examination. Children with anterior meningealveolephalones are usually anosmic and, in addition, may exhibit cerebrospinal fluid (CSF) rhinorhea.
when the head is held in certain positions. Injury of the cribiform plate and hydrocephalus are other causes of CSF rhinorrhea. These defects in the sense of smell are attributable to lesions of either the receptor cells and their axons or the olfactory bulbs, and current test methods do not distinguish between lesions in these two localities. It is not known whether olfactory symptoms may be produced by lesions of the anterior perforated space or of the medial and lateral olfactory striae. In some cases of increased intracranial pressure, olfactory sense has been impaired without evidence of lesions in the olfactory bulbs.

The term specific anosmia has been applied to an unusual olfactory phenomenon, in which a person with normal olfactory acuity for most substances encounters a particular compound or class of compounds that is odorless to him, although obvious to others. In a sense, this is a condition of "smell blindness," analogous to color blindness. The basis of this disorder is unclear, although there is evidence that specific anosmia for musky and urinous odors is inherited as an autosomal recessive trait (see Amoore).

Whether a true hyperosmia exists is a matter of conjecture. Neurotic individuals may complain of being unduly sensitive to odors, but there is no proof of an actual change in their threshold of perception of odors. During migraine attacks and in some cases of aseptic meningitis, the patient may be unusually sensitive not only to light and sound but sometimes to odors as well.

Dysosmia or Parosmia These terms refer to distortions of odor perception, where an odor is present. Parosmia may occur with local nasopharyngeal conditions such as enpyema of the maxillary sinuses and nasal polyps. In some instances the abnormal tissue itself may be the source of unpleasant odors; in others, where partial injuries of the olfactory bulbs have occurred, parosmia is in the nature of an olfactory illusion. Parosmia may also be a troublesome symptom in middle-aged and elderly persons with a depressive illness, who may report that every article of food has an extremely unpleasant odor (cacosmia). Sensations of disagreeable taste are often associated (cacoguesia). Nothing is known of the basis of this state; there is usually no loss of discriminative sensation.

The treatment of parosmia is difficult. The use of antipsychotic drugs has given unpredictable results. Claims for the efficacy of zinc and vitamins have not been verified. Some reports indicate that repeated anesthetization of the nasal mucosa reduces or abolishes the parosmic disturbance. In many cases the disorder subsides spontaneously. Minor degrees of parosmia are not necessarily abnormal, for unpleasant odors have a way of lingering for several hours and of being reawakened by other olfactory stimuli (phantosmia), as every pathologist knows.

Olfactory Hallucinations These are always of central origin. The patient claims to smell an odor that no one else can detect (phantosmia). Most often this is due to lesions in the olfactory staves ("uncinate fits"), in which circumstances the olfactory hallucinations are brief and accompanied by an alteration of consciousness and other manifestations of epilepsy (page 339). If the patient is convinced of the presence of a hallucination and also gives it personal reference, the symptom assumes the status of a delusion. The combination of olfactory hallucinations and delusions of this type signifies a psychiatric illness. Zilozoff has written informatively on this subject. There is often a complaint of a large array of odors, most of them foul. In most cases, the smells seem to emanate from the patient (intrinsic hallucinations); in others, they seem to come from an external source (extrinsic hallucinations). Both types vary in intensity and are remarkable with respect to their persistence. They may be combined with gustatory hallucinations. According to Prins-Phillips, who took note of the psychiatric illness in a series of 137 patients with olfactory hallucinations, most were associated with endogenous depression and schizophrenia. In schizophrenia, the olfactory stimulus is usually interpreted as arising externally and as being induced by someone for the purpose of upsetting the patient. In depression, the stimulus is usually intrinsic and is more overwhelming. The patient uses all manner of ways to get rid of the perceived stench, the usual ones being excessive washing and use of deodorants; the condition may lead to social withdrawal. There is some reason to believe that the amygdaloid group of nuclei is the source of the hallucinations, since stereotactic lesions here have reportedly abolished both the olfactory hallucinations and the psychiatric disorder (Chitanondh).

Olfactory hallucinations and delusions may occur in conjunction with senile dementia, but when this happens one should also consider the possibility of an associated late-life depression. Occasionally olfactory hallucinations are part of an alcohol withdrawal syndrome. Peculiar reactions to smell characterize certain sexual psychopathies. Usually the smell appear to be extrinsic, but in this regard it should be noted that odors imagined by normal individuals are also perceived as coming from outside the person through inspired air, and unpleasant ones are more clearly represented than pleasant ones.

In lower vertebrates, these functions and similar ones (modulation of menstrual and reproductive behavior) have been attributed to the activities of a subset of olfactory receptors in the rostral end of the nasal mucosa. The axons of these cells penetrate the cribiform plate and synapse with secondary neurons in a discrete portion of the olfactory bulb (accessory olfactory bulb). This functionally and anatomically distinct olfactory tissue is referred to as the vomeronasal system or organ of Jacobson (see review of Wyciscek and Meredith).

Loss of Olfactory Discrimination (Olfactory Agnosia) Finally, one must consider a disorder in which the primary perceptual aspects of olfaction (detection of odors, adaptation to odors, and recognition of different intensities of the same odor) are intact but the capacity to distinguish between odors and their recognition by quality is impaired or lost. In the writings on this subject, this deficit is usually referred to as a disorder of olfactory discrimination. In dealing with other sense modalities, however, the inability to identify and name a perceived sensation would be called an agnosia. To recognize this deficit requires special testing, such as matching to sample, the identification and naming of a variety of scents, and determining whether two odors are identical or different. Such an alteration of olfactory function has been shown to characterize patients with the alcoholic form of Korsakoff psychosis; this impairment is not attributable to impaired olfactory acuity or to failure of learning and memory (Mair et al). As indicated above, the olfactory disorder in the alcoholic Korsakoff patient is most likely due to lesions in the medial dorsal nucleus of the thalamus; several observations in animals indicate that this nucleus and its connections with the orbitofrontal cortex give rise to deficits in odor discrimination (Mair et al, Slotnick and Kaneko). Eichenbaum and associates demonstrated a similar impairment of olfactory capacities in a patient who had undergone extensive bilateral medial temporal lobe resections. The operation was believed to have eliminated a substantial portion of the olfactory afferents to the frontal cortex and thalamus, though there was no anatomic verification of this. In patients with stereotactic or surgical amygdalotomies, Andy and coworkers noted a similar reduction in odor discrimination. Thus it appears that both portions of the higher olfactory pathways (medial temporal lobes and medial dorsal nuclei) are necessary for the discrimination and identification of odors.

GUSTATORY SENSE

Anatomic and Physiologic Considerations The sensory receptors for taste (taste buds) are distributed over the surface of the tongue and, in smaller numbers, over the soft palate, pharynx, larynx, and esophagus. Mainly they are located in the epithelium along the lateral surfaces of the circumvallate papillae and foliate papillae and to a lesser extent on the surface of the fungiform papillae (Fig. 12-2). The taste buds are round or oval structures, each composed of up to two hundred vertically oriented receptor cells arranged like the staves of a barrel. The superficial portion of the bud is marked by a small opening, the taste pore or pit, which opens onto the mucosal surface. The tips of the sensory cells project through the pore as a number of filiform microvilli ("taste hairs"). Fine, unmyelinated sensory fibers penetrate the base of the taste bud and synapse directly with the sensory taste cells, which have no axons.
The taste receptors are activated by chemical substances in solution and transmit their activity along the sensory nerves to the brainstem. As stated earlier, there are four primary and readily tested taste sensations—salty, sweet, bitter, and sour; the full range of taste sensations is much broader, consisting of combinations of these elementary gustatory sensations. Any one taste bud is capable of responding to a number of sapid substances, but always it is preferentially sensitive to one type of stimulus (Fig. 12-2). In other words, the receptors are only relatively specific. The sensitivity of these receptors is remarkable: as little as 0.05 mg/dL of quinine sulfate will arouse a bitter taste when applied to the base of the tongue.

If the gustatory impairment is unilateral, taste is tested by withdrawing the tongue with a gauze sponge and using a moistened applicator to place a few crystals of salt or sugar on discrete parts of the tongue; the tongue is then wiped clean and the subject is asked to report what he had sensed. A useful stimulus for sour sensation is a low-voltage direct current, the electrodes of which can be accurately placed on the tongue surface. If the taste loss is bilateral, mouthwashes with a dilute solution of sucrose, sodium chloride, citric acid, and caffeine may be used. After swishing, the fluid is spat out and the mouth rinsed with water. The patient indicates whether he has tasted the substance and is asked to identify it. Special types of apparatus (electrogustometers) have been devised for the measurement of taste intensity and for determining the detection and recognition thresholds of taste and olfactory stimuli (Kranup; Henkin et al.), but there are beyond the scope of the usual clinical examination.

The receptor cells of the taste buds have a brief life cycle (about 10 days), being replaced constantly by mitotic division of adjacent basal epithelial cells. The number of taste buds, not large to begin with, is gradually reduced with age; also, changes occur in the taste cell membranes, with impaired function of ion channels and receptors (Mistretta). Both gustatory (and olfactory) acuity diminish (everything begins to taste and smell the same). According to Schiffman, taste thresholds for salt, sweeteners, and amino acids are 2 to 2½ times higher in the elderly than in the young. The reduction in the acuity of taste and smell with aging may lead to a distortion of food habits (e.g., excessive use of salt and other condiments) and contribute to the anorexia and weight loss of elderly persons.

Sensory impulses for taste arise from several sites in the oropharynx and are transmitted to the medulla via several cranial nerves (V, VII, IX, and X). The main pathway arises on the anterior two-thirds of the tongue; the taste fibers first run in the lingual nerve (a major branch of the mandibular- trigeminal nerve). After coursing within the lingual nerve for a short distance, the taste fibers diverge to enter the chorda tympani (a branch of the seventh nerve); thence they pass through the pars intermedia and ganglion of the seventh nerve to the rostral part of the nucleus of the tractus solitarius in the medulla, where all taste afferents converge (see below). Fibers from the palatal taste buds pass through the pterygopalatine ganglion and greater superficial petrosal nerve, join the facial nerve at the level of the stylomastoid foramen, and are transmitted to the gustatory area of the brainstem. Possibly, taste fibers from the tongue also contribute to the transmission of the main trigeminal division of the trigeminal nerve. The presence of this alternative pathway probably accounts for reported instances of unilateral taste loss that have followed section of the root of the trigeminal nerve in instances in which no loss of taste has occurred with section of the chorda tympani. From the posterior third of the tongue, soft palate, and palatal arches, the sensory taste fibers are conveyed via the glossopharyngeal nerve and ganglion nodosum to the nucleus of the tractus solitarius. Taste fibers from the extreme dorsal part of the tongue and the few that arise from taste buds on the pharynx and larynx run in the vagus nerve. Rostral and lateral parts of the nucleus tractus solitarius, which receive the special afferent (taste) fibers from the facial and glossopharyngeal nerves, constitute the gustatory nucleus. Probably both sides of the tongue are represented in this nucleus.

The second sensory neuron for taste has been difficult to track. Neurons of the nucleus solitarius project to adjacent nuclei (e.g., dorsal motor nucleus of the vagus, ambiguous, salivatorius superior and inferior, trigeminal, and facial nerves), which serve viscerovisceral and visceralosomatic reflex functions, but those concerned with the conscious recognition of taste are believed to form an ascending pathway to a pontine parabrachial nucleus. From the latter, two ascending pathways have been traced (in animals). One is the solitariothalamic lemniscus to the ventroposteromedial nucleus. A second passes to the ventral parts of the forebrain, to parts of the hypothalamus (which probably influences autonomic function), and to other basal forebrain limbic areas in or near the uncus of the temporal lobe. Other ascending fibers lie near the medial lemniscus and are both crossed and uncrossed. Experiments in animals indicate that taste impulses from the thalamus project to the gustatory area of the brainstem. This is the probable point of origin of gustatory projections in humans as well, insofar as gustatory hallucinations have been produced by electrical stimulation of the parietal and/or insular opercula (Hausser-Hawu and Bancaud). Penfield and Faulk evoked distinct taste sensations by stimulating the anterior insula.

Richter has explored the biologic role of taste in normal nutrition. Animals made deficient in sodium, calcium, certain vitamins, proteins, etc., will automatically select the correct foods, on the basis of their taste, to compensate for their deficiency.

Clinical Manifestations

Apart from the loss of taste sensation that accompanies normal aging (see above), heavy smoking, particularly pipe smoking, is probably the commonest cause of impairment of taste sensation. Extreme drying of the tongue from any cause may lead to temporary loss or reduction of the sense of taste (ageusia or hypogeusia), since saliva is essential for normal taste function. Saliva acts as a solvent for chemical substances in food and for conveying them to taste receptors. Dryness of the mouth (xerostomia) from inadequate saliva, as occurs in the Sjogren syndrome; hyperviscosity of saliva, as in cystic fibrosis; irradiation of head and neck; and pancytopenia all interfere with taste. Also, in familial dysautonomia (Riley-Day syndrome), the number of circumvallate and fungiform papillae are reduced, accounting for a diminished ability to taste sweet and salty foods. If unilateral, ageusia is seldom the source of complaint. Taste is frequently lost over one-half of the tongue (except posteriorly) in cases of Bell's palsy (as indicated on page 1452).

A permanent decrease in acuity of taste and smell (hypogeusia and hyposmia), sometimes associated with perversions of these sensory functions (dysgeusia and dysosmia), may follow influenza-like illnesses. These abnormalities have been associated with pathologic changes in the taste buds as well as in the nasal mucous membranes (Agranoff et al.). The patient whose dysgeusia is related to the chemotherapy (Henkin; Shenk et al.) has developed his symptoms in association with scleroderma, acute hepatitis, viral encephalitis, myxedema, adrenal insufficiency, malignancy, deficiency of vitamins B and A, and the administration of a wide variety of drugs (see further on).

Distortions of taste and loss of taste are sources of complaint in patients with a variety of malignant tumors. Oropharyngeal tumors may, of course, abolish taste by invading the chorda tympani or lingual nerves. Malnutrition due to neoplasia or radiation therapy may also cause ageusia, as pointed out by Settle and colleagues. Some patients with certain carcinomas remark on an increase in their threshold for bitter foods, and some who have been radiated for breast cancer or sublingual or oropharyngeal tumors find sour foods intolerable. The loss of taste from radiation of the oropharynx is usually recovered within a few weeks or months; the reduced turnover of taste buds caused by radiation therapy is only temporary.

Persistent misinterpretations and distortions of taste (and smell) have been reported with a wide variety of drugs. According to Schiffman, more than 250 drugs have been implicated in the alteration of taste sensation. Lipid lowering drugs, antihistamines, antimicrobials, antineoplastic, bronchodilators, antidepressants, and anticonvulsants are the main offenders. Little is known about the mechanisms by which drugs induce these effects.

An interesting syndrome, called idiopathic hypogeusia, in which a decreased taste acuity is associated with dysgeusia, hypoposmia, and dysosmia has been described by Henkin and coworkers. Food has an unpleasant taste and aroma, to the point of being revolting (cacogenusia and cacosmia); the persistence of these symptoms may lead to a loss of weight, anxiety, and depression. Patients with this disorder were said to have a decreased concentration of zinc in their parotid saliva and to respond to small oral doses of zinc sulfate. The authors have had no opportunity to confirm these observations.

Another poorly defined disorder is the so-called burning mouth syndrome, which occurs mainly in postmenopausal women and is characterized by persistent, severe intra-oral pain (particularly of the tongue). We have seen what we believe to be fragmentary forms of the syndrome in which pain and burning are isolated to the alveolar ridge or gingival mucosa. The oral mucosa appears normal and some patients may report a diminution of taste sensation. A small number of such patients prove to have diabetes or vitamin B_12 deficiency, but in most no systemic illness or local abnorality can be found. The few such cases that we have encountered appeared to have a depressive illness and responded variably to administration of tricyclic antidepressants.

Unilateral lesions of the medulla oblongata have not been reported to cause ageusia, perhaps because the nucleus of the tractus solitarius is usually outside the zone of infarction. Unilateral thalamic and parietal lobe lesions have both been associated with contralateral impairment of taste sensation. As indicated above, ageusia may lead to a loss of weight, anxiety, and depression. Patients with this disorder were said to have a decreased concentration of zinc in their parotid saliva and to respond to small oral doses of zinc sulfate. The authors have had no opportunity to confirm these observations.
in the amygdala, in close association with olfactory fibers. Gustatory hallucinations are much less frequent than olfactory ones. Nevertheless, the former were found in 30 of 718 cases of intractable epilepsy (Hausser-Hauw and Bancaud). During surgery, these investigators produced an aura of disagreeable taste by electrical stimulation of the parietal and frontal opercula and also by stimulation of the hippocampus and amygdala (uncinate seizures). In their view, the low-threshold seizure focus for taste in the temporal lobe is secondary to functional disorganization of the opercular gustatory cortex by the seizure. Gustatory hallucinations were more frequent with right-hemisphere lesions, and in half of the cases, the gustatory aura was followed by a convulsion.

CHAPTER REFERENCES

The four chapters in this section are concerned with the clinical aspects of the highly specialized functions of taste and smell, vision, hearing, and the sense of balance. These special senses and the cranial nerves that subserve them represent the most finely developed parts of the sensory nervous system. The sensory dysfunctions of the eye and ear are, of course, the domain of the ophthalmologist and otologist, but they are of interest to the neurologist as well. Some of them reflect the presence of serious systemic disease, and others represent the initial or leading manifestation of neurologic disease. It is from both these points of view that they are considered here. In keeping with the general scheme of this text, the disorders of the special senses (and of ocular movement) are considered in a particular sequence: first, the presentation of certain facts of anatomic and physiologic importance, followed by their cardinal clinical manifestations and then by a consideration of the syndromes of which these manifestations are a part. Because of their specialized nature, some of the diseases that produce these syndromes are discussed here rather than in later chapters of the book.
The faculty of vision is our most important source of information about the world. Attesting to the importance of visual function is the magnitude of its representation in the central nervous system. The largest part of the cerebrum is involved in vision: the visual control of movement as well as the perception of printed words and the form and color of objects. The optic nerve, which is a central nervous system (CNS) structure, contains over a million fibers (compared to 50,000 in the auditory nerve). The visual system has special significance in several other respects, and study of this system has greatly advanced our knowledge of the nervous system. Indeed, we know more about vision than about any other sensory system. Because of its diverse composition of epithelial, vascular, collagenous, neural, and pigmented tissues, the eye is virtually a medical microcosm, susceptible to many diseases. Moreover, the eye's transparent media permit direct inspection of these tissues and afford an opportunity to observe, during life, many lesions of neurologic and systemic medical disease.

Since the eye is the sole organ of vision, impairment of visual function (defect in acuity and visual fields) obviously stands as the most frequent and important symptom of eye disease. A number of terms are commonly used to describe visual loss. Amotaxis refers to blindness, especially blindness that is not due to an error of refraction or to intrinsic disease of the eye itself. Amblyopia has much the same meaning—dimness of vision from any cause, ocular or nonocular. Nystagmus is the term for poor twilight or night vision and is associated with vitamin A deficiency, retinitis pigmentosa, and, often, color blindness. There are also positive symptoms (phosphene, visual illusions, and hallucinations), but they are less significant than symptoms of visual loss. Irritation, redness, photophobia, pain, diplopia and strabismus, changes in pupillary size, and drooping or closure of the eyelids are the other major symptoms and signs. The impairment of vision may be unilateral or bilateral, sudden or gradual, episodic or enduring. The common causes of failing eyesight vary with age. In infancy, congenital defects, severe myopia, hypoplasia of the optic nerve, optic pits, and coloboma are the main causes. In later childhood and adolescence, nearsightedness, or myopia, is the usual cause, though a pigmented retinopathy or a retinal optic nerve, or suprasellar tumor must not be overlooked. In middle age, beginning usually in the fifth decade, farsightedness (presbyopia) is almost invariable. Still later in life, cataracts, glaucoma, retinal hemorrhages and detachments, macular degeneration, and tumor, unilateral or bilateral, are the most frequent causes of visual impairment.

As a rule, episodic visual loss in early adult life, often hemispheric, is due to migraine. One or more attacks of retrobulbar neuritis, often a harbinger of multiple sclerosis, is the other important cause of transient (weeks) monocular visual loss in this age period. Later in life, transient monocular blindness, or amaurosis fugax, is more common; it is related to stenosis of the ipsilateral carotid artery or less often to embolism of retinal arterioles. Rarely, amaurosis occurs in the child or young adult, in which case systemic lupus erythematosus or the antiphospholipid syndrome may be responsible. Or there may be no discernible cause. Cerebrovascular disease deranges vision with increasing frequency in later life.

**APPROACH TO THE PROBLEM OF VISUAL LOSS**

In the investigation of a disturbance of vision, one must always inquire as to what the patient means when he claims not to see properly, for the disturbance in question may vary from near- or farsightedness to excessive tearing, diplopia, partial syncope, or even giddiness or dizziness. Fortunately the patient's statement can be checked by the measurement of visual acuity, which is the single most important part of the ocular examination. Inspection of the refractive media and the optic fundi—especially the macular region, the testing of pupillary reflexes, and the plotting of visual fields completes the examination.

In the measurement of visual acuity the Snellen Chart, which contains rows of letters of diminishing size, is utilized. The letter at the top of the chart subtends 5 min of an arc at a distance of 200 ft (or roughly 60 m). The patient follows rows of letters that can normally be read at lesser distances. Thus, if the patient can read only the top letter at 20 rather than 200 ft, the acuity is expressed as 20/200 (V+20/200), or 6/60 if distances are measured in meters rather than feet). If the patient's eyesight is normal, the visual acuity will equal 20/20, or 6/6 using the metric scale. Many persons, especially during youth, can read at 20 ft the line that can normally be read at 15 ft from the chart (V+20/15). Patients with a corrected refractive error should wear their glasses for the test. For bedside testing, a ‘near card’ or newspaper held 14 in. from the eyes can be used. In young children, acuity can be estimated by having them mimic the examiner's finger movements at varying distances or recognize and pick up objects of different sizes from varying distances.

If the visual acuity (with glasses) is less than 20/20, either the refractive error has not been properly corrected or there is some other reason for the diminished acuity. The possibility of a refractive error can be ruled out if the patient can read the 20/20 line at a distance (not on a near card) through a pinhole in a cardboard held in front of the eye; the pinhole permits a narrow shaft of light to fall on the macular fovea (the area of greatest visual acuity) without distortion by the curvature of the lens. Minor degrees of visual impairment may be disclosed by alternately stimulating each eye with a bright white or colored object, enabling the patient to compare.

Light entering the eye is focused by the biconvex lens onto the outer layer of the retina. Consequently the cornea, the fluid of the anterior chamber, the lens, the vitreous, and the retina itself must be transparent. The clarity of these media can be determined ophthalmoscopically, and a complete examination requires that the pupil be dilated to at least 6 mm in diameter. This is best accomplished by instilling two drops of 2.5 to 10% phenylephrine (Neosynephrine) or 0.5 to 1.0% pilocarpine into each eye. The mydriatic action of phenylephrine lasts for 3 to 6 h. Very rarely, an attack of angle-closure glaucoma (manifesting itself by diminished vision, ocular pain, nausea, and vomiting) may be precipitated by pupillary dilation; this requires the immediate attention of an ophthalmologist.

By looking through a high-plus lens of the ophthalmoscope from a distance of 6 to 12 in., the examiner can visualize opacities in the refractive media; by adjusting the lenses from a high-plus to a zero or minus setting, it is possible to “depth-focus” from the cornea to the retina. Depending upon the refractive error of the examiner, lenticular opacities are best seen within the +20 to +12 range. The retina comes into focus with +1 to –1 lenses. The pupil appears as a red circular structure (red reflex), the color being provided by blood in the capillaries of the choroid layer. If all the refractive media are clear, reduced vision that is uncorrectable by glasses is due to a defect in the macula, the optic nerve, or parts of the brain with which they are connected.

**NONNEUROLOGIC CAUSES OF REDUCED VISION**

It is hardly possible, within the confines of this chapter, to describe all the causes of opacification of the refractive media. Those with the most important medical or neurologic implications are briefly commented upon. Although changes in the refractive media do not involve neural tissue primarily, certain ones are often associated with neurologic disease and provide clues to its presence.

In the cornea, the most common abnormality is scarring due to trauma and infection. Ulceration and subsequent fibrosis may occur with recurrent herpes simplex, herpes zoster, and trachomatous infections or with certain mucocutaneous-ocular syndromes (Stevens-Johnson, Reiter). Hypercalcemia secondary to sarcoid, hyperparathyroidism, and vitamin D intoxication or milk-alkali syndrome may give rise to precipitates of calcium phosphate and carbonate beneath the corneal epithelium, primarily in a plane corresponding to the interpapillary fissure—so-called band keratopathy. Polysaccharides are deposited in the corneas in some of the...
mucopolysaccharidoses (page 1015), and copper in hepatolenticular degeneration (Kayser-Fleischer ring, page 1026). Crystal deposits may be observed in multiple myeloma and cryoglobulinemia. The corneas are also diffusely clouded in certain lysosomal storage diseases (Chap. 37). Arcus senilis occurring at an early age (due to hypercholesterolemia), sometimes combined with yellow lipid deposits in the eyelids and periorbital skin (xanthelasma), serve as markers of atheromatous vascular disease.

In relation to the anterior chamber of the eye, the common problem is one of impediment to the outflow of aqueous fluid, leading to excavation of the optic disc and visual loss, i.e., glaucoma. In more than 90 percent of cases (of the open-angle type), the cause of this syndrome is unknown; a genetic factor is suspected. The drainage channels in this type appear normal. In about 5 percent, the angle between pupil and lateral cornea is narrow and blocked when the pupil is dilated (appositional glaucoma). In the remaining cases, the condition is secondary to some disease process that blocks outflow channels—inflammatory debris of uveitis, red blood cells from hemorrhage in the anterior chamber (hyphema), or new formation of vessels and connective tissue on the surface of the iris (rubeosis iridis), a rare complication of ocular ischemia secondary to diabetes mellitus or carotid artery occlusion. The visual loss is gradual in open-angle glaucoma and the eye looks normal, unlike the red, painful eye of angle-closure glaucoma. However, some cases of open-angle glaucoma may progress to rapid loss of vision. Intraocular pressures that are persistently above 20 mmHg may damage the optic nerve. This may be manifest first as an arcuate defect in the upper or lower nasal field or as an enlargement of the blind spot (Bjerrum field defect), which, if untreated, may go on to blindness. Other characteristic field patterns are winged extensions from the blind spot (Scheie scotoma) and a narrowing of the superior nasal quadrant that may progress to a horizontal edge, corresponding to the horizontal raphe of the retina (nasal step). The damage is at the optic nerve head with the ophthalmoscope, the optic disc appears excavated and any pallor that is present extends only to the rim of the disc and not beyond, thus distinguishing it from optic neuropathy.

In the lens, cataract formation is the common abnormality. The cause of the common type in the elderly is unknown. The “sugar cataract” of diabetes mellitus is the result of sustained high levels of blood glucose, which is changed in the lens to sorbitol, the accumulation of which leads to a high osmotic gradient with swelling and disruption of the lens fibers. Galactosemia is a much rarer cause, but the mechanism of cataract formation is similar, i.e., the accumulation of dulcitol in the lens. In hypoparathyroidism, lowering of the concentration of calcium in the aqueous humor is in some way responsible for the opacification of newly forming superficial lens fibers. Prolonged high doses of chlorpromazine and corticosteroids as well as radiation therapy are believed to induce lenticular opacities as well. Down syndrome and oculooculocerebrorenal syndrome (Chap. 38), spinoocerebellar ataxia with oligophrenia (Chap. 39), and certain dermatologic syndromes (atopic dermatitis, congenital ichthyosis, incontinentia pigmenti) are also accompanied by lenticular opacities. Myotonic dystrophy (Chap. 48) and, rarely, Wilson disease (Chap. 37) are associated with special types of cataract. Subluxation of the lens, the result of weakening of its zonular ligaments, occurs in syphilis, Marfan syndrome, and homocystinuria.

In the vitreous humor, hemorrhage may occur from rupture of a ciliary or retinal vessel. On ophthalmoscopic examination, the hemorrhage appears as a diffuse haziness of part or all of the vitreous or, if the blood is between the retina and the vitreous and displaces the latter rather than mixing with it, takes the form of a sharply defined mass. The common causes are orbital or cranial trauma, rupture of an intracranial aneurysm or arteriovenous malformation with high intracranial pressure, rupture of newly formed vessels of proliferative retinopathy in patients with diabetes mellitus, and retinal tears, in which the hemorrhage breaks through the internal limiting membrane of the retina. The commonest vitreous opacities are the benign “floaters” or “spots before the eyes,” which appear as gray flecks or threads with changes in the position of the eyes; they may be annoying or even alarming until the person stops looking for them. A sudden burst of flashing lights associated with an increase in floaters may mark the onset of retinal detachment. Another common occurrence, with advancing age, is shrinkage of the vitreous humor and retraction from the retina, causing persistent streaks of light (phosphenes), usually in the periphery of the visual field. The phosphenes, known as “Moore’s lightning streaks,” are quite benign. They are most prominent on movement of the globe, on closure of the eyelids, at the moment of accommodation, with saccadic eye movements, and with sudden exposure to dark. The vitreous may be infiltrated by lymphoma that originates in the brain; biopsy by planar vitrectomy has been used to establish the diagnosis.

The term uveitis refers to an infective or noninfective inflammatory disease that affects any of the uveal structures (iris, ciliary body, and choroid.). According to Bienfang and colleagues, uveitis accounts for 10 percent of all cases of legal blindness in the United States. Infective causes are toxoplasma and cytomegalic inclusion disease. Noninfective autoimmune types are more frequent in the adult. The inflammation may be in the anterior part of the eye or in the posterior part, behind the iris and extending to the retina and choroid. Anterior uveitis is sometimes linked to ankylosing spondylitis, and the posterior forms are associated with sarcoidosis, Behçet disease, multiple sclerosis, and lymphoma.

**NEUROLOGIC CAUSES OF REDUCED VISION**

Certain anatomic and physiologic facts are requisite for an interpretation of the neurologic lesions that affect vision. Visual stimuli entering the eye traverse the inner layers of the retina, the retina pigmented epithelium, the photoreceptor cells—the flask-shaped cones and the slender rods. The photoreceptors rest on a single layer of pigmented epithelial cells, which form the outermost surface of the retina. The rods and cones and pigmented epithelium receive their blood supply from the capillaries of the choroid, not from the retinal arterioles. The rod cells contain rhodopsin, a conjugated protein in which the chromophore is a retinal ester. The rods function in the perception of visual stimuli in subdued light (twilight or scotopic vision), and the cones are responsible for color discrimination and the perception of stimuli in bright light (photopic vision). Most of the cones are concentrated in the macular region, particularly in its central part, the fovea, and are responsible for the highest level of visual acuity. Specialized pigments in the rods and cones absorb light energy and transform it into electrical signals, which are transmitted to the bipolar cells of the retina and then, in turn, to the superficially (anteriorly) placed neurons, or ganglion cells (Fig. 13-1). There are no ganglion cells in the fovea.

![Figure 13-1 Diagram of the cellular elements of the retina. Light entering the eye passes through the full thickness of the retina to reach the rods and cones (first system of retinal neurons). Impulses arising in these cells are transmitted by the bipolar cells (second system of retinal neurons) to the ganglion cell layer. The third system of visual neurons consists of the ganglion cells and their axons, which run uninterruptedly through the optic nerve, chiasm, and optic tracts, synapsing with cells in the lateral geniculate body. (Courtesy of Dr. E. M. Chester.)](image-url)

Three types of retinal ganglion cells, referred to as X, Y, and W, have been identified in nonhuman primates on the basis of their retinal topography and terminations. The X cells are centered in the maculae and project to the striate cortex. The Y cells are distributed throughout the retina and project to both the striate cortex and the superior colliculi. The W cells terminate only in the superior colliculi. Presumably the same neuronal types exist in humans, but in different proportions.

The axons of the retinal ganglion cells, as they stream across the inner surface of the retina, pursue an arculate course. Being unmyelinated, they are not visible, although fluorescein retinography shows a trace of their outlines and an experienced examiner, using a bright light and deep green filter, can visualize the fibers through direct ophthalmoscopy. The ganglion cell axons are collected in the optic discs and then run uninterruptedly through the optic nerves, optic chiasm, and optic tracts to the lateral geniculate body. (Fig. 13-3 and Fig. 13-4). The fibers derived from macular cells form a discrete bundle that first occupies the temporal side of the disc and optic nerve and then assumes a more central position within the nerve (papillomacular bundle). These fibers are of smaller caliber than the peripheral optic nerve fibers. It is important to keep in mind the retinal ganglion cells and their axonic extensions are, properly speaking, an exenterized part of the brain and that the pathologic reactions in this part reflect their CNS origin.
In the optic chiasm, the fibers derived from the nasal half of each retina decussate and continue in the optic tract with uncrossed temporal fibers of the other eye (Fig. 13-2 and Fig. 13-3). Thus, interruption of the left optic tract causes a right homonymous hemianopic defect in each eye, i.e., a homonymous (left nasal and right temporal) field defect (Fig. 13-3D). In partial tract lesions, the visual defects in the two eyes are not exactly congruent, since the tract fibers are not evenly admixed. A variable bundle of fibers from the inferior-nasal part of the optic nerve turns anteriorly into the opposite optic nerve as it crosses in the chiasm (Wilbrand's knee). Lesions at this "functional" point of the optic nerve and the chiasm are therefore able to cause a contralateral quadrantic defect in addition to the central scotoma that is due to the ipsilateral optic nerve lesion, as shown in Fig. 13-2B. The optic chiasm lies just above the pituitary body and also forms part of the anterior wall of the third ventricle; hence the crossing fibers may be compressed from below by a pituitary tumor, a meningioma of the tuberculum sellae, or an aneurysm, and from above by a dilated third ventricle or craniopharyngioma. The resulting field defect is bitemporal (Fig. 13-2C); if one optic nerve is also implicated, there will be a loss of full-field vision in that eye. Optic tract lesions, in comparison with chiasmatic and nerve lesions, are relatively rare. Surprisingly, in albinism, there is an abnormality of chiasmatic decussation, in which a majority of the fibers, including many that would not normally cross to the other side, decussate. How this relates to the defect in the pigment epithelium is not known.

In children with congenital cataracts, the eye becomes abnormally large and usurps the monocular dominance columns of the blind eye (Hubel and Wiesel). The classic studies of Hubel and Wiesel have elucidated much of this visual cortical physiology. The deep neurons of area 17 project to the secondary and tertiary visual areas of the occipitotemporal cortex of the same and opposite cerebral hemispheres and also to other multisensory parietal and temporal cortices. Several of these extrastriate connections are just now being identified. Separate visual systems are utilized in the perception of motion, color, stereopsis, contour, and depth. The classic studies of Hubel and Wiesel have elucidated much of this visual cortical physiology. The deep neurons of area 17 project to the secondary and tertiary visual areas of the occipitotemporal cortex of the same and opposite cerebral hemispheres and also to other multisensory parietal and temporal cortices. Several of these extrastriate connections are just now being identified. Separate visual systems are utilized in the perception of motion, color, stereopsis, contour, and depth. The normal development of the connections described above requires that the visual system be activated at each of several critical periods of development. The early deprivation of vision in one eye causes a failure of development of the geniculate and cortical receptive fields of that eye. Moreover, the cortical receptive fields of the seeing eye become abnormally large and usurp the monocular dominance columns of the blind eye (Hubel and Wiesel). In children with congenital cataracts, the eye
will remain amblyopic if the opacity is removed later, after this critical period of development. A severe strabismus in early life, especially an esotropia, will have the same effect.

In regard to the vascular supply of the eye, the ophthalmic branch of the internal carotid artery supplies the retina, posterior coats of the eye, and optic nerve head. This artery gives origin to the posterior ciliary arteries; the latter form a rich capillary network of vessels (Fig. 13-1A) that penetrate deeply to the lamina cribrosa. This arterial circle supplies the optic disc and adjacent part of the optic nerve, the choroid, and the ciliary body; it anastomoses with the pial arterial plexus that surrounds the optic nerve. The other major branch of the ophthalmic artery is the central retinal artery. It supplies the inner retinal layers and issues from the optic disc, where it divides into four branches, each of which supplies a quadrant of the retina; it is these vessels and their branches that are visible by ophthalmoscopy. A short distance from the disc, these vessels lose their internal elastic lamina and the media (muscularis) becomes thin; they are properly classed as arterioles. The inner layers of the retina, including the ganglion and bipolar cells, receive their blood supply from these arterioles and their capillaries, whereas the deeper photoreceptor elements and the fovea are nourished by the underlying choroidal vascular bed, by diffusion through the retinal pigmented cells and the semipermeable Bruch's membrane upon which they rest.

Abnormalities of the Retina

As indicated above, this thin (100- to 350-µm) sheet of transparent tissue, and the optic nerve head, into which all visual information flows are an exteriorized part of the CNS and the only part of the nervous system that can be inspected directly by ophthalmoscopic examination. Common mistakes in funduscopic examination are a failure to carefully inspect the macula (which is located to 3 to 4 mm lateral to the optic disc and provides for 95 percent of visual acuity) and to search the periphery of the retina through a dilated pupil. There are variations in the appearance of the normal macula and optic disc, and these may prove troublesome. A normal macula will be called abnormal because of a slight aberration of the retinal pigment epithelium or a few drusen (see further on). With experience, the unnyelinated nerve fiber layer of the retina can be visualized by using bright-green (red-free) illumination. This is most often helpful in detecting demyelinative lesions of the optic nerve, which produce a loss of discrete bundles of the radially arranged and arching retinal fibers as they converge onto the disc.

The normal optic disc varies in color, being paler in infants and in blond individuals; and the prominence of the lamina cribrosa (a sieve-like structure in the central and nasal part of the disc through which run the fascicles of unmyelinated axons of the retinal ganglion cells) differs from one individual to another. The absence of receptive elements in the optic disc, or papilla, accounts for the normal blind spot. The ganglion-cell axons normally acquire their myelin sheaths after penetration of the lamina cribrosa, but they sometimes do so in their intraretinal course, as they approach the disc. The myelinated fibers adjacent to the disc appear as white patches with fine-feathered edges and are a normal variant, not to be confused with exudates.

In evaluating changes in the retinal vessels, one must remember that these are arterioles and not arteries. Since the walls of retinal arterioles are transparent, what is seen with the ophthalmoscope is the column of blood within them. The method of light refraction of many normal arterioles is thought to represent the reflection of light from the ophthalmoscope as it strikes the interface of the column of blood and the concave vascular wall. In arteriosclerosis (usually coexistent with hypertension), the lumina of the vessels are segmentally narrowed because of fibrous tissue replacement of the media and thickening of the basement membrane. Straightening of the arterioles and arteriolar-venular compression are other signs of hypertension arteriolar sclerosis. It is generally believed that the vein is compressed by the thickened arteriole within the adventitial envelope shared by both vessels at the site of crossing; this compression may lead to occlusion of branches of the retinal veins. Progressive arteriolar disease, to the point of occlusion of the lumen, results in a narrow, white (“silver-wire”) vessel with no visible blood column. This change is associated most often with severe hypertension but may follow other types of occlusion of the central retinal artery or its branches (see descriptions and retinal illustrations further on). Sheathing of the vessels, probably representing focal leakage of cells from the vessels, is observed in approximately 25 percent of patients with multiple sclerosis. Similar alterations are also seen in leukemia, malignant hypertension, sarcoid, Behçet disease, and other forms of vasculitis.

In malignant hypertension there are, in addition to the retinal arteriolar changes noted above, a number of extravascular lesions: the so-called soft exudates or cotton-wool patches, sharply marginated and glistening “hard” exudates, retinal hemorrhages, and edema of the disc. In many patients who show these retinal changes, analogous lesions are to be found in the brain (necrotizing arteriolitis and microinfarcts). These are the changes that underlie hypertensive encephalopathy.

The ophthalmoscopic appearance of retinal hemorrhages is determined by the structural arrangements of the particular tissue in which they occur. In the superficial layer of the retina, they are linear or flame-shaped (“splitter” hemorrhages) because of their confinement by the horizontally coursing nerve fibers in that layer. These hemorrhages usually overlie and obscure the retinal vessels. Round or oval (“dot-and-blot”) hemorrhages lie behind the vessels, in the outer plexiform layer of the retina (synaptic layer between bipolar cells and nuclei of rods and cones—Fig. 13-1B). In this layer, blood accumulates in the form of a cylinder between vertically oriented nerve fibers and appears round or oval when viewed end-on with the ophthalmoscope. Rupture of arterioles on the inner surface of the retina— as occurs with ruptured intracranial saccular aneurysms, arteriogenous malformations, and other conditions causing sudden severe elevation of intracranial pressure—permits the accumulation of a sharply outlined lake of blood between the internal limiting membrane of the retina and the coalescing vitreous or hyaloid membrane (the condensed gel at the periphery of the vitreous body); this is the subhyaloid or preretinal hemorrhage. Either the small superficial or deep retinal hemorrhage may show a central or eccentric pale (Roth) spot, which is caused by an accumulation of white blood cells, fibrin, histiocytes, or amorphous material between the vessel and the hemorrhage. This lesion is said to be characteristic of bacterial endocarditis, but is also seen in leukemia and in embolic retinopathy due to carotid disease.

Cotton-wool patches or soft exudates, like splitter hemorrhages, overlie and tend to obscure the retinal blood vessels. These patches, even large ones, rarely cause serious disturbances of vision unless they involve the macula. Soft exudates are in reality infarcts of the nerve fiber layer, due to occlusion of arterioles and capillaries; they are composed of clusters of void structures called cytid bodies, representing the terminal swellings of interrupted axons. Hard exudates appear as punctate white or yellow bodies; they lie in the outer plexiform layer, behind the retinal vessels, like the punctate hemorrhages. If present in the macular region, they are arranged in lines radiating toward the fovea (macular star). Hard exudates consist of fibrin strands, neutral fat, and fatty acids; their pathogenesis is not understood. They are observed most often in cases of diabetes mellitus and accelerated hypertension. Drusen (colloid bodies) appear ophthalmoscopically as pale yellow spots and are difficult to distinguish from hard exudates except when they occur alone: as a rule, hard exudates are accompanied by other funduscopic abnormalities. The source of retinal drusen is uncertain; probably they represent benign accumulations of lipoid and other cellular debris derived from the retinal pigment epithelium (Fig. 13-1C). Hyaline bodies, located on or near the optic disc, are also referred to as drusen but must be distinguished from those occurring peripherally. Drusen of the optic discs are probably mineralized residues of dead axons and can be seen on computed tomography (CT) in some cases. Their main significance for neurologists is that they are often associated with anomalous elevation of the disc and can be mistaken for papiledema (Table 13-1).

Table 13-1 Main causes of swelling of the optic disc

Anemysms of retinal vessels appear as small, discrete red dots and are located in largest number in the paramacular region. They are most often a sign of diabetes mellitus, sometimes appearing before the usual clinical manifestations of that disease have become obvious. The use of the red-free (green) light on the ophthalmoscope helps to pick out microaneurysms from the background. Microscopically, the aneurysms take the form of small (20- to 90-mm) saccular outpouchings from the walls of capillaries, venules, or arterioles. The vessels of origin of the aneurysms are invariably abnormal, being either acellular branches of occluded vessels or themselves occluded by fat or fibrin.

Finally, the periphery of the retina may harbor a hemangioblastoma, which may appear during adolescence, before the more characteristic cerebellar lesion. A large retinal artery may be seen leading to it and a large vein draining it. Occasionally, retinal examination discloses the presence of a vascular malformation that may be
Ischemic Lesions of the Retina

Occlusion of the internal carotid artery may cause no disturbance of vision whatsoever provided that there are adequate anastomotic branches from the external carotid artery in the orbit. Rarely, carotid occlusion with inadequate collateralization is associated with a chronic ischemic oculopathy, which may predominantly affect the anterior or posterior segment or both. Insufficient circulation to the anterior segment is manifest by episcleral vascular congestion, cloudiness of the cornea, anterior chamber flare, ruberosis and iris atrophy (ruberosis iridis) and an abnormally low or high intraocular pressure. Ischemia of the posterior segment is manifest by circulatory changes in the retina and optic nerve and venous stasis. Other neurologic signs of carotid disease may be present (pages 829–834).

More often, ischemia of the retina can be traced to the central retinal artery or its branches, which may be occluded by thrombi or emboli. Occlusion of the main artery is attended by sudden blindness. The retina becomes opaque and has a gray-yellow appearance; the arterioles are narrowed, with segmentation of columns of blood and a cherry-red appearance of the fovea (Fig. 13-5). With branch occlusions by emboli, one may be able to see the occluding material. Most frequently observed are so-called Hollenhorst plaques—glistening, white-yellow atheromatous particles (Fig. 13-6) seen in 40 of 70 cases of retinal embolism in the series of Arruga and Sanders. The remainder are white calcium particles, from calcified aortic or mitral valves or atheroma of the great vessels, and red or white fibrin-platelet emboli. The latter may be asymptomatic or associated with transient blindness and may be difficult to see without fluorescein retinography; these emboli soon disappear. Transient ischemic attacks of visual loss, involving all or part of the field of vision of one eye, are referred to as amaurosis fugax or transient monocular blindness (TMB) and are common manifestations of arteriosclerotic carotid stenosis or ulceration. Inspection of the retina during an attack shows stagnation of arterial blood flow, which returns within seconds or minutes as vision is restored (Fisher). One or a hundred attacks may precede infarction of a cerebral hemisphere in the territory of the anterior or middle cerebral artery. In one series of 80 such patients followed by Marshall and Meadows for 4 years, 16 percent developed permanent unilateral blindness, a completed hemispherical stroke, or both. If one eye is affected in this way, there is one chance in four that the other will be involved, usually within the first year (Sawle et al). This subject is discussed further in Chap. 34, on cerebrovascular diseases.

Figure 13-5 Appearance of the fundus in central retinal artery occlusion. In addition to the paucity of blood flow in retinal vessels, the retina has a creamy gray appearance and there is a “cherry red spot” at the fovea.

Figure 13-6 Glistening “Hollenhorst plaque” occlusion of a superior retinal artery branch (arrow). These occlusions represent atheromatous particles or platelet-fibrin emboli. Some are asymptomatic and others are associated with segmental visual loss or are seen after central retinal artery occlusion.

Since the central retinal artery and vein share a common adventitial sheath, atheromatous plaques in the artery are said to be associated in some instances with thrombosis of the retinal vein. There is then a spectacular display of retinal lesions that differs from the picture of central retinal artery occlusion. The veins are engorged and tortuous, and there are diffuse “dot-and-blot” and streaky linear retinal hemorrhages (Fig. 13-7). This lesion is observed most frequently with diabetes mellitus, hypertension, and leukemia; less frequently with sickle cell disease; and rarely with multiple myeloma and macroglobulinemia, in relation to the hyperviscosity they cause. Sometimes no associated systemic disease can be identified, in which case the possibility of an orbital mass (e.g., optic nerve glioma) should always be considered. In retinal vein thrombosis, visual loss is variable and there may be recovery of useful vision.

Figure 13-7 Occlusion of the central retinal vein with suffusion of the veins, swelling of the disc, and florid retinal hemorrhages.

A transitory retinal ischemia is observed occasionally as a manifestation of migraine; it has also been observed in polydymthemia, hyperglobulinemia, and sickle cell anemia. Massive blood loss or intraoperative hypotension, particularly in association with the use of a heart bypass pump, may also produce visual loss and ischemic infarction of the retina and optic nerve. In younger persons, transient monocular blindness is relatively uncommon and the cause is often not immediately apparent, although ischemia related to the antiphospholipid antibody or migraine is presumed to be responsible for many cases.

More common than retinal ischemia as a cause of sudden monocular blindness, especially in elderly persons, is ischemic optic neuropathy. It is due to infarction of the optic disc and sometimes of the retrobulbar portion of the optic nerve, for which reason it is considered further on with diseases of the optic nerve.

In summary, sudden painless monocular loss of vision should always raise the question of ischemia of the retina, due either to occlusive disease of the central retinal
Dryja et al

Fig. 13-9

Fig. 13-8

A nerve, but it can occur at an early stage of increased intracranial pressure. As the papilledema becomes chronic, elevation of the disc margin becomes less prominent. More pronounced degrees of papilledema appear as a "mushrooming" of the entire disc and surrounding retina, with edema and obscuration of vessels at the disc. Since many normal individuals, especially those with hypermetropia, have ill-defined disc margins, this early stage may have a characteristic. Detection of the retina and the pigment epithelium of the choroid produces punched-out lesions, exposing the whitish sciera and deposits of black pigment in various forms. The choroid may be the site of viral and noninfective inflammatory reactions, often in association with recurrent iridocyclitis and lacrimal inflammation.

Degenerations of the retina are an important cause of chronic visual loss. They assume several forms and may be associated with other neurologic abnormalities. The most frequent in youth and middle age is retinitis pigmentosa, a hereditary disorder of the outer photoreceptor layer and subjacent pigment epithelium. The retina is thin, and there are fine deposits of black pigment in the shape of bone corpuscles, more in the periphery; later the optic discs become pale. Clinically this disorder is marked by constriction of the fields with relative sparing of central vision ("gnarled" vision); metamorphopsia (distorted vision); delayed recovery from glare; and nystagmus (reduced twilight vision). It may be associated with the Laurence-Moon-Biedl syndrome, with certain mitochondrial diseases (Kearns-Sayre syndrome), and with certain degenerative and metabolic diseases (e.g., Refsum disease) of the nervous system. In one form of retinitis pigmentosa, which follows an autosomal dominant pattern of inheritance and is linked to chromosome 3, the gene for rhodopsin (a combination of vitamin A and the rod-cell protein opsin) produces a defective opsin. This results in a diminution of rhodopsin in rod cells, a diminished response to light, and eventual degeneration of the rod cells (Dryja et al.).

Another early-life hereditary retinal degeneration, characterized by massive central retinal lesions, is the autosomal recessive Stargardt form of juvenile tapetoretinal degeneration. Like retinitis pigmentosa, Stargardt disease may be accompanied by progressive atrophic paraparesis or ataxia. Nonpigmentary retinal degeneration is a familial occurrence of a number of other retinal diseases, such as neuronal ceroid lipofuscinosis (pages 1014 and 1024), Bassen-Kornzweig disease (pages 1021 and 1421), Refsum disease (page 1421), Batten-Mayou disease (page 1014), and others (see Chap. 37).

Macular degeneration is the most important cause of visual loss in the elderly. Examination discloses central scotomata and an alteration of the retina around the maculae. Central vision gradually diminishes, preventing reading, but these patients can still get about because of retained peripheral vision. Phenothiazine derivatives may conjugate with the melanin of the pigment layer, resulting in degeneration of the outer layers of the retina and a characteristic "bull's eye sign." Phenothiazine angiography. These drugs should be administered in their lowest effective dosage and the patient tested frequently for defects in visual fields and color vision.

Retinal degeneration may also occur in patients with an oat cell carcinoma of the lung. Antiretilal ganglion cell antibodies, presumably produced by the tumor cells, have been demonstrated in the serum of such patients by several authors (Brunwald et al.).

Certain lysosomal diseases of infancy and early childhood are characterized by an abnormal accumulation of undegraded proteins, polyaccharides, and lipids in cerebral neurons as well as in the maculae and other parts of the retina (hence the term storage diseases and cerebromacular degenerations). Corneal opacities, cherry-red spot and graying of the retina, and later optic atrophy are the observed oculomacular abnormalities. These diseases are discussed in Chap. 37.

In some of these retinal diseases, minimal changes in the pigment epithelium or other layers of the retina, enough to reduce visual acuity, may not be readily detected by ophthalmoscopy. In these circumstances, it is helpful to estimate the time required for recovery of visual acuity following light stimulation (macular photostress test). This test consists of shining a strong light through the pupil of an affected eye for 10 s and measuring the time necessary for the acuity to return to the pretest level (normally 50 s or less). With macular lesions, recovery time is prolonged, but with lesions of the optic nerve, it is not affected. Retinal diseases reduce or abolish the electrical activity generated by the outer layers of the retina, and this can be measured in the electroretinogram. Fluorescein angiography may also be helpful.

Papilledema and Raised Intracranial Pressure

Of the various abnormalities of the optic disc, papilledema, or optic disc swelling, has the greatest neurologic implication, for it signifies the presence of increased intracranial pressure. It must be made clear, however, that an ophthalmoscopic appearance identical to that of papilledema can be produced by infarction of the optic nerve head (anterior ischemic optic neuropathy) and by inflammatory changes in the intraorbital portion of the optic nerve (papillitis, or optic neuritis). Certain additional clinical and funduscopic findings, listed in Table 13-1 and described below, assist in distinguishing these processes, although all share the basic feature of conspicuous disc swelling.

In its mildest form, the papilledema may take the form of only slight elevation of the disc and blurring of the disc margins, especially of the superior and inferior aspects and a mild fullness of the veins of the disc. Since many normal individuals, especially those with hypermetropia, have ill-defined disc margins, this early stage of papilledema may be difficult to detect (Fig. 13-8). Pulses of the retinal veins, best seen where the veins turn to enter the disc, will have disappeared by the time intracranial pressure is raised, but this criterion is not absolute, since venous pulsations cannot be seen in 10 to 15 percent of normal individuals. On the other hand, the presence of spontaneous venous pulsations is a reliable indicator of an intracranial pressure below 180 to 190 mmHg and thus usually excludes the presence of early papilledema. Fluorescein angiography, red-free fundus photos (which highlight the retinal nerve fibers), and stereoscopic fundus photography may be helpful in detecting early edema of the optic discs.

Figure 13-8 Mild papilledema with hyperemia of the disc and slight blurring of the disc margins.

More pronounced degrees of papilledema appear as a "mushrooming" of the entire disc and surrounding retina, with edema and obscuration of vessels at the disc margins and in some instances, peripapillary hemorrhages (Fig. 13-9). When advanced, papilledema is almost always bilateral, although it may be more pronounced on the side of an intracranial tumor. A purely unilateral edema of the optic disc is usually associated with periorbital meningiomata or other tumor involving the optic nerve, but it can occur at an early stage of increased intracranial pressure. As the papilledema becomes chronic, elevation of the disc margin becomes less prominent and pallor of the optic nerve head more evident (Fig. 13-10). Varying degrees of secondary optic atrophy follow, leaving the disc pale and shrunken. Unlike the case...
The main causes of visual loss from optic neuropathy are listed in Table 13-1. In primary optic atrophy, the disc margins are irregular, often with peripapillary pigment deposits.

Figure 13-9 Fully developed papilledema. The main characteristics are marked swelling and enlargement of the disc, vascular engorgement, obscuration of small vessels at the disc margin as a result of nerve fiber edema, and white "cotton-wool spots" that represent superficial infarcts of the nerve fiber layer.

Figure 13-10 Chronic papilledema with beginning optic atrophy, in which the disc stands out like a champagne cork. The hemorrhages and exudates have been absorbed, leaving a glistening residue around the disc.

It is important to emphasize that acute papilledema from raised intracranial pressure does not affect visual acuity except transiently during spontaneous waves of greatly increased pressure. Therefore optic disc swelling in a patient with severely reduced vision is usually due not to papilledema but to intraorbital optic neuritis (papillitis) or to infarction of the nerve head (ischemic optic neuropathy), both of which are described further on. The examiner is aided by the fact that papilledema is generally bilateral, although the degree of disc swelling tends not to be symmetrical; in contrast, papillitis and infarction of the nerve head usually affect one eye, but there are exceptions to both of these statements. Also, the papillary reaction to light is muted only with the latter disorders, not with papilledema. The occurrence of papilledema on one side and optic atrophy on the other is referred to as the Foster Kennedy syndrome and is attributable to a frontal lobe tumor or an olfactory meningioma on the side of the optic atrophy.

Papilledema due to increased intracranial pressure must be distinguished from combined edema of the optic nerve and retina, which typifies both malignant hypertension and posterior uveitis with retinitis as well as infarction of the disc, described further on. Papilledema due to infarction of the nerve head is characterized by extension of the swelling beyond the nerve head, as described below, whereas the papilledema of increased pressure is associated with peripapillary hemorrhages. Often this distinction cannot be made on the basis of the funduscopic appearance alone, in which case the most reliable distinguishing feature is the presence or absence of visual loss (Table 13-1).

The essential element in the pathogenesis of papilledema is an increase in pressure in the sheaths of the optic nerve, which communicate directly with the subarachnoid space of the brain. This was demonstrated convincingly by Hayreh (1964), who produced bilateral chronic papilledema in monkeys by inflating balloons in the temporal subarachnoid space and then opening the sheath of one optic nerve; the papilledema promptly subsided on the operated side but not on the opposite side. Many years ago, Paton and Holmes hypothesized that the increased pressure in the perioptic subarachnoid spaces blocks the central retinal vein, leading to congestion in the capillary circulation of the optic nerve head. However, the picture of central retinal vein obstruction—consisting of rapidly evolving retinal edema, marked venous dilatation, and florid retinal hemorrhages—is quite different from that of papilledema. Furthermore, the capillaries that become congested in papilledema are derived not from the central retinal vein but from the short ciliary arteries (Hayreh). More recently, the pathogenesis of papilledema has been restudied in terms of axoplasmic flow in the optic nerve fibers (Minderer et al; Tso and Hayreh). These investigators found that compression of the optic nerve fibers by the elevated cerebrospinal fluid (CSF) pressure resulted in swelling of axons behind the optic nerve head and leakage of their contents into the extracellular spaces of the disc; these changes were thought to be responsible for the swelling of the optic disc and blurring of the disc margins. The vascular changes (hyperemia of the disc, capillary dilatation, and hemorrhages) appeared later and were considered to be secondary to edema of the optic disc. In our opinion, the block in axonic flow alone could not account for the marked congestion of vessels and hemorrhages.

The essential element in the pathogenesis of papilledema is an increase in pressure in the sheaths of the optic nerve, which communicate directly with the subarachnoid space of the brain. This was demonstrated convincingly by Hayreh (1964), who produced bilateral chronic papilledema in monkeys by inflating balloons in the temporal subarachnoid space and then opening the sheath of one optic nerve; the papilledema promptly subsided on the operated side but not on the opposite side. Many years ago, Paton and Holmes hypothesized that the increased pressure in the perioptic subarachnoid spaces blocks the central retinal vein, leading to congestion in the capillary circulation of the optic nerve head. However, the picture of central retinal vein obstruction—consisting of rapidly evolving retinal edema, marked venous dilatation, and florid retinal hemorrhages—is quite different from that of papilledema. Furthermore, the capillaries that become congested in papilledema are derived not from the central retinal vein but from the short ciliary arteries (Hayreh). More recently, the pathogenesis of papilledema has been restudied in terms of axoplasmic flow in the optic nerve fibers (Minderer et al; Tso and Hayreh). These investigators found that compression of the optic nerve fibers by the elevated cerebrospinal fluid (CSF) pressure resulted in swelling of axons behind the optic nerve head and leakage of their contents into the extracellular spaces of the disc; these changes were thought to be responsible for the swelling of the optic disc and blurring of the disc margins. The vascular changes (hyperemia of the disc, capillary dilatation, and hemorrhages) appeared later and were considered to be secondary to edema of the optic disc. In our opinion, the block in axonic flow alone could not account for the marked congestion of vessels and hemorrhages.

Abnormalities of the Optic Nerves

These structures, which constitute the axonic projections of the retinal ganglion cells to the lateral geniculate bodies and superior colliculi (the third visual neurons), can be inspected only in the optic nerve head. Observable changes in the optic disc are, therefore, of particular importance. They may reflect the presence of raised intracranial pressure (papilledema or "choked disc"), as already described, optic neuritis ("papillitis"), infarction of the optic nerve head, congenital defects of the optic nerves (optic pits and colobomas), hypoplasia and atrophy of the optic nerves, and glaucoma. Illustrations of these and other abnormalities of the disc and ocular fundus can be found in the atlas by E. M. Chester and in the text by Glaser, listed in the References.

Abnormalities of the Optic Nerves

These structures, which constitute the axonic projections of the retinal ganglion cells to the lateral geniculate bodies and superior colliculi (the third visual neurons), can be inspected only in the optic nerve head. Observable changes in the optic disc are, therefore, of particular importance. They may reflect the presence of raised intracranial pressure (papilledema or "choked disc"), as already described, optic neuritis ("papillitis"), infarction of the optic nerve head, congenital defects of the optic nerves (optic pits and colobomas), hypoplasia and atrophy of the optic nerves, and glaucoma. Illustrations of these and other abnormalities of the disc and ocular fundus can be found in the atlas by E. M. Chester and in the text by Glaser, listed in the References.

The main causes of visual loss from optic neuropathy are listed in Table 13-2 and are discussed in subsequent portions of this chapter.
In a large proportion of such patients, at least initially, no cause of the retrobulbar neuropathy can be found. After several weeks there is spontaneous recovery; vision returns to normal in more than two-thirds of instances. Regression of symptoms may occur spontaneously or may be hastened by the intravenous administration of high doses of corticosteroids, but the oral administration of the same drugs appears to increase the frequency of a relapse of optic neuritis (page 973). Occasionally, diminution of brightness, dyschromatopsia, or a scotoma is left; much more rarely, the patient is left blind. The optic disc later becomes slightly pale, especially on the temporal side, and the pallor extends beyond the margins of the disc into the peripapillary retinal nerve fiber layer. The CSF may be normal or may contain from 10 to 100 lymphocytes, an elevated total protein and gamma globulin, and oligoclonal bands.

As time progresses, approximately half of such patients will develop other symptoms and signs of multiple sclerosis within 5 years, and probably even more so when they are observed for longer periods. Conversely, in approximately 15 percent of patients with multiple sclerosis, the history discloses that retrobulbar neuritis was the first symptom. Multiple sclerosis is the most common cause of a unilateral retrobulbar neuritis, but post-infectious demyelinating disease is a probable cause of the minority that do not progress to multiple sclerosis. Less is known about children with retrobulbar neuropathy, in whom the disorder is more often bilateral and frequently related to a preceding viral infection (“neuroretinitis,” see below). Their prognosis is better than that of adults. Formerly, the syndrome was often blamed on sinus disease, but this rarely affects vision and should be considered only in the face of other evidence of infection, such as fever, purulent nasal discharge, leukocytosis, etc. Treatment of optic neuritis is discussed in the context of multiple sclerosis on page 973. Occasionally, a sphenoidal or ethmoidal mucocele can compress the optic nerve. Leber hereditary optic atrophy may simulate retrobulbar neuropathy even in causing a relatively abrupt onset of visual loss and some degree of recovery (page 1164).

In a condition that is related to optic neuritis known as neuroretinitis, papillitis is accompanied by macular edema and exudates, a “macular star” appearance. This is a rare parainfectious process seen mostly in children and young adults.

Anterior Ischemic Optic Neuropathy (ION; Anterior ION) In persons over 50 years of age, ischemic infarction of the optic nerve head is the most common cause of a persistent monocular loss of vision (Fig. 13-12). The onset is abrupt and painless, and the visual loss may be progressive for several days. The field defect is often altitudinal and involves the area of central fixation, accounting for the severe loss of acuity. Swelling of the optic disc, extending for a short distance beyond the disc margin and associated small, flamed-shaped hemorrhages, is typical, or the disc may appear entirely normal. As the disc edema subsides, optic atrophy becomes evident. The second eye is similarly affected at a later date in approximately one-third of patients, particularly those with hypertension and diabetes mellitus. Usually there are no premonitory symptoms or episodes of transient visual loss.

As to the pathogenesis of ION, the usual (anterior) form has been attributed by Hayreh to ischemia in the posterior ciliary artery circulation and more specifically to occlusion of the branches of the peripapillary choroidal arterial system. Infarction of the more posterior portions of the optic nerve(s) is uncommon. Most cases occur on a background of hypertensive vascular disease and diabetes, but not necessarily in relation to carotid artery stenosis, which in our experience has accounted for very few cases. The retina is not affected, as it is in cases of embolic occlusion of the central retinal artery. ION may also complicate intraocular surgery or follow an episode of severe blood loss or other causes of ischemia and hypotension.

Cranial, or giant-cell, arteritis (pages 193 and 907) is the other important cause of ION. In some of the arteritic cases, fleeting premonitory symptoms of visual loss (amaurosis fugax) may precede infarction of the nerve. Unlike the common atherosclerotic type of ION, infarction due to cranial arteritis may affect both optic nerves in close succession and, less often, ocular motor function as well. Also, the arteritis may present with the picture of central retinal artery occlusion. Systemic lupus erythematosus, diabetes, Lyme disease, neurosyphilis, and AIDS rarely give rise to the syndrome of retrobulbar neuropathy but should be considered only after optic neuritis or papillitis have been excluded.
nervous system has been excluded.

Optic Neuropathy due to Acute Cavernous and Paranasal Sinus Disease A number of disease processes adjacent to the orbit and optic nerve can cause blindness, usually with signs of compression or infarction of the optic and ocular motor nerves. They are seen far less frequently than ischemic optic neuropathy and optic neuritis. Severe cavernous sinus thrombosis (see page 750) may be accompanied by blindness of one eye, usually in succession and asymptomatically. In our experience, the visual loss has appeared days after the chemosis and ocular motor palsies. The mechanism of visual loss in this setting, sometimes without swelling of the optic nerve head, is unclear but most likely relates to a retrobulbar ischemia of the nerve. Similarly, optic and ocular motor disorders may complicate ethmoid or sphenoid sinus infections. Severe diabetes with mucormycosis or other invasive fungal or bacterial infection is the usual setting for these complications. Although the former is not considered a complicated sinus disease a common cause of optic neuropathy that no longer tenable, there are still a few instances in which such an association occurs and the nature of the visual loss is unclear. Slavin and Glaser described loss of vision from a sphenoethmoid sinusitis with cellulitis at the orbital apex. Visual symptoms in these circumstances can occur prior to overt signs of local inflammation.

Toxic and Nutritional Optic Neuropathies Simultaneous impairment of vision in the two eyes, with central or centrocecal scotomas, is usually caused not by a demyelinating process but by a toxic or nutritional one. The latter condition is observed most often in the chronically alcoholic patient. Impairment of visual acuity evolves over several days or a week or two, and examination discloses bilateral, roughly symmetrical central or centrocecal scotomas, the peripheral fields being intact (nystagmus, photophobia, and bilateral V S V vision) if treatment is immediate. If treatment is delayed, patients are left with varying degrees of permanent defect in central vision and pallor of the temporal portions of the optic discs. This disorder has commonly been referred to as “tobacco-alcohol amblyopia,” the implication being that it is due to the toxic effects of tobacco or alcohol, or both. In fact, the disorder is one of nutritional deficiency and is more properly designated as deficiency amblyopia or nutritional optic neuropathy (Chap. 41). The same disorder may be seen under conditions of severe dietary deprivation and in patients with vitamin B 12 deficiency. Another cause is Leber hereditary optic atrophy, which is discussed in Chap. 37.

A subacute optic neuropathy has been described in Jamaican natives. It is characterized by a bilaterally symmetrical central visual loss and is occasionally accompanied by nerve deafness, ataxia, and spasticity. A similar condition has been described in other Caribbean countries, most recently in Cuba, where an optic neuropathy of epidemic proportions was associated with a sensorineuropathy. A toxic etiology, rather than an increased risk from tobacco use (especially cigars in the Cuban epidemic), is likely but has not been proved conclusively (see Sadun et al and The Cuba Neuropathy Field Investigation report).

Impairment of vision due to methyl alcohol intoxication is abrupt in onset and characterized by large symmetrical central scotomas as well as by symptoms of systemic disease and acidosis. Treatment is directed mainly to correction of the acidosis. The subacute development of central field defects has also been attributed to several other toxins and the chronic administration of certain therapeutic agents: halogenated hydroxyquinolines (cloquinol), chloramphenicol, ethambutol, isoniazid, streptomycin, chlorpropamide (Diabinese), and various ergot preparations. Grant has catalogued the many drugs reported to have a toxic effect on the optic nerves.

Developmental Abnormalities Congenital cavitary defects due to defective closure of the optic fissure may be a cause of impaired vision because of failure of development of the papillomacular bundle. Usually the optic pit or a larger coloboma is unilateral and unassociated with development abnormalities of the brain (optic disc dysplasia and dysplastic coloboma). A hereditary form is known (Brown and Tasman). Vision may be impaired as a result of developmental anomalies of the optic nerves; the discs are of small diameter (hypoplasia of the optic disc or micropit).

Other Optic Neuropathies

Optic nerve and chiasmal involvement by gliomas, meningiomas, craniopharyngiomas, and metastatic tumors (most often from lung or breast) may cause scotomas and optic atrophy (Chap. 31). Pituitary tumors characteristically cause bitemporal hemianopia, but very large adenomas, as in pituitary apoplexy, can cause blindness in one or both eyes (see page 717). Infarction of an optic nerve may occur in sarcoidosis, Wegener granulomatosis, and with certain neoplasms, notably leukemia and lymphoma. Of particular importance is the optic nerve gloma that occurs in 15 percent of patients with type I von Recklinghausen neurofibromatosis. Usually it develops in children, often before the fourth year, causing a mass within the orbit and progressive loss of vision. If the eye is blind, the recommended therapy is surgical removal, to prevent extension into the optic chiasm and hypothalamus. If vision is retained, radiation and chemotheraphy are the recommended forms of treatment.

Thyroid ophthalmopathy with orbital edema, exophthalmos, and usually a swelling of extracocular muscles is an occasional cause of optic nerve compression.

Radiation-induced damage of the optic nerves and chiasm has been well documented. In a series of 219 patients at the M. D. Anderson Cancer Center who received radiotherapy for carcinoma of the nasopharynx, optic neuropathy occurred in 7. Optic neuropathy with blindness in 8, and chiastic damage with bilateral visual impairment in 1. These complications followed the use of more than 50 Gy (5000 rad) of radiation (Jiang et al).

Finally, it should be mentioned again that long-standing papilledema from any cause may eventually lead to optic atrophy and blindness. In the case of pseudotumor cerebri, the visual loss may be unexpectedly abrupt, appearing in a day or less and even sequentially in both eyes. This seems to happen most often in patients with constitutionally small optic nerves, no optic cup of the nerve head, and, presumably, a small aperture of the lamina cribosa.

NEUROLOGY OF THE CENTRAL VISUAL PATHWAYS

From the retina there is a point-to-point projection to the lateral geniculate ganglion and from the latter to the calcarine cortex of the occipital lobe. Thus the visual cortex receives a spatial pattern of stimulation that corresponds with the retinal image of the visual field. Visual impairments due to lesions of the central pathways usually only involve a part of the visual fields, and a plotting of the later provides information as to the site of the lesion.

For purposes of description of the visual fields, each retina and macula are divided into a temporal and nasal half by a vertical line passing through the fovea centralis. A horizontal line represented by the junction of the superior and inferior retinal vascular arcades also passes through the fovea and divides each half of the retina and macula into upper and lower quadrants. Visual field defects are always described in terms of the field defect from the patient’s view rather than the retinal defect. The retinal image of an object in the visual field is inverted and reversed from right to left, like the image on the film of a camera. Thus the left visual field of each eye is represented in the opposite half of each retina, with the upper part of the field represented in the lower part of the retina (see Fig. 13-2). The retinal projections to the geniculate nuclei and occipital cortex are illustrated in Fig. 13-4.

Testing for Abnormalities of the Visual Fields

Visual field defects caused by lesions of the retina, optic nerve and tract, lateral geniculate body, geniculocalcarine pathway, and striate cortex of the occipital lobe are illustrated in Fig. 13-3. In the alert, cooperative patient, the visual fields can be plotted accurately at the bedside. With one of the patient’s eyes covered and the other aligned with the corresponding eye of the examiner (patient’s right eye with examiner’s left), a target—such as a moving finger, a cotton pledget, or a white disc mounted on a stick—is brought from the periphery toward the center of the visual field (confrontational testing). With the target at an equal distance between the eye of the examiner and the patient, the fields of the patient and examiner can be compared. Similarly, the patient’s blind spot can be aligned with the examiner’s blind spot and its size determined by moving the target outward from the blind spot until it is seen. Central and paracentral defects in this field can be outlined the same way. For reasons not known, red-green test objects are more sensitive than white ones in detecting defects of the visual pathways.

It should be emphasized that movement of the visual target provides the coarsest stimulus to the retina, so that a perception of its motion may be preserved while a stationary target of the same size may not be seen. In other words, moving targets are less useful than static ones in confrontation testing of visual fields. Rapid finger counting and comparison of color intensity of a red object or the examiner’s hand from quadrant to quadrant are simple confrontation tests that will disclose any defect found or suspected by confrontation testing, the fields should be charted and scotomas outlined on a tangent screen or perimeter. Highly accurate computer-assisted perimetry is now
available in most ophthalmology clinics.

The method of testing by double simultaneous stimulation may elicit defects in the central processing of vision that are undetected by conventional perimetry. Movement of one finger in all parts of each temporal field may disclose no abnormality, but if movement is simultaneous in analogous parts of both temporal fields, the patient ignores the one in the remote right half of the field, having the other in the near right-hand hemifield. In young children or uncooperative patients, the integrity of the fields may be roughly estimated by observing whether the patient is attracted to objects in the peripheral field or blinks in response to sudden threatening gestures in half of the visual field.

A common abnormality disclosed by visual field examination is concentric constriction. This may be due to papilledema, in which case it is usually accompanied by an enlargement of the blind spot. A progressive constriction of the visual fields, at first unilateral and later bilateral, associated with pallor of the optic discs (optic atrophy), should suggest a chronic meningeval process involving the optic nerves (syphilitis, cryptococcosis, sarcoid, lymphoma). Long-standing, untreated glaucoma and retinitis pigmentosa are other causes of concentric constriction. Marked constriction of the visual fields of unvarying degree, regardless of the distance of the visual stimulus from the eye, ("gun-barrel" or "funnel" vision), is a sign of hypersuggestibility or hysteria. With organic disease, the constricted visual field naturally enlarges as the distance between the patient and the test object increases.

Prechiasmal Lesions

Lesions of the macula, retina, or optic nerve cause either a scotoma (an island of impaired vision surrounded by normal vision) or a defect that extends to the periphery of one visual field. Scotomas are named according to their position (central, cecocentral) or their shape (ring, arcuate). A small scotoma in the macular part of the field is usually due to an organic lesion in the retina or, less often, to retinal arterial or venous occlusion. Larger, more irregular scotomas in the macular field, with sharply defined margins, represent involvement of the macula, e.g., by macular degeneration, serousdetachments, or by toxic or infective agents such as syphilis, the congenital toxoplasmosis syndrome, or the hereditary retinopathies. When the scotoma is bilateral, it is due to bilateral macular involvement (e.g., ophthalmia purulenta or concurrent syphilis). Lesions of the macula that result in a waxy pallor of the discs and degeneration of the optic nerve represent involvement of the optic disc, retina, and optic nerve fibers with secondary involvement of the macula.

In certain instances of homonymous hemianopia, the patient is capable of some visual perception in the hemianopic fields, a circumstance that permits the study of the effects of lesions on the visual field. In such instances, the visual function that extends beyond the conventional limits of the hemianopia is called "blindsight" by Weiskrantz and colleagues. Blythe and coworkers found that 20 percent of their patients with a parietal lobe lesion also manifestly on the right, may see objects in the right half of the primary visual field. In young children or uncooperative patients, the integrity of the fields may be roughly estimated by observing whether the patient is attracted to objects in the peripheral field or blinks in response to sudden threatening gestures in half of the visual field.

Homonymous hemianopia (a loss of vision in corresponding halves of the visual fields) signifies a lesion of the visual pathway behind the chiasm and, if complete, gives no more information than that. Incomplete homonymous hemianopia has more localizing value. As a general rule, if the field defects in the two eyes are identical (congruous), the lesion is likely to be in the calcarine cortex or subcortical white matter of the occipital lobe; if they are incongruous, the visual fibers in the optic tract or in the parietal or temporal lobes are more likely to be implicated. Lesions of the optic tract give the most incongruous defects; only when the lesion is complete is the defect congruous. Actually, absolute congruity of field defects is rare, even with occipital lesions.

The lower fibers of the geniculocalcarine pathway (from the inferior retinas) enter in a wide arc over the temporal horn of the lateral ventricle and then proceed posteriorly to join the upper fibers of the pathway on their way to the calcarine cortex (Fig. 13-3). This arc of fibers is known variously as the Flechsig, Meyer, or Archambault loop, and a lesion that interrupts these fibers will produce a superior homonymous quadrantanopia (contralateral upper temporal and ipsilateral upper nasal quadrants; Fig. 13-26). This clinical effect was first described by Harvey Cushing, so his name has also been applied to the loop of temporal visual fibers. Parietal lobe lesions are said to affect the inferior fibers of the visual fields more than the superior ones, but this is difficult to document; with a lesion of the right parietal lobe, the patient ignores the left half of space; with a left parietal lesion, the patient is often aphasic. As to the localizing value of "quadranoptic" defects, the report of Jacobson is of interest; he found, in reviewing the imaging studies of 41 patients with inferior quadrantanopia and 30 with superior quadrantanopia, that in 76 percent of the former and 83 percent of the latter the lesions were confined to the occipital lobe.

If the entire optic tract or calcarine cortex on one side is destroyed, the homonymous hemianopia is complete. But often that part of the field subserved by the macula is spared, i.e., there is a 5- to 10-degree island of vision around the fixation point on the side of the hemianopia (sparing of fixation or macular sparing). With infarction of the occipital lobe due to occlusion of the posterior cerebral artery, the macular region, represented in the most posterior portion of the striate cortex, may be spared by virtue of collateral circulation from the middle cerebral artery. Incomplete lesions of the optic tract and radiation usually spare central (macular) vision. We have never observed a lesion of the tip of one occipital lobe that produced central homonymous hemianopic scotoma, bisecting the maculae. Lesions of both occipital poles (as in embolization of the posterior cerebral arteries) result in bilateral central scotomas; if all the calcarine cortex or all the subcortical geniculocalcarine fibers on both sides are completely destroyed, there is cerebral, or "cortical," blindness.

An altitudinal defect is one that is confined to the upper or lower half of the visual field but crosses the vertical meridian. Homonymous altitudinal hemianopia is usually due to lesions of both occipital lobes below or above the calcarine sulcus and rarely to a lesion of the occipital or temporal lobes. The most common cause of a homonymous altitudinal hemianopia is infarction due to occlusion of the posterior cerebral arteries. However, the most common cause of a concomitant homonymous hemianopia is ischemic optic neuropathy.

In certain instances of homonymous hemianopia, the patient is capable of some visual perception in the hemianopic fields, a circumstance that permits the study of the vulnerability of different visual functions. Colored targets may be detected in the hemianopic fields, whereas achromatic ones cannot. But even in seemingly complete hemianopic defects, in which the patient admits to being blind, it has been shown that he may still react to visual stimuli when forced-choice techniques are used. This type of residual visual function has been called "blindlight" by Weiskrantz and colleagues. Blythe and coworkers found that 20 percent of their patients with the visual field may seriously impair visual acuity. Demyelinative disease (retrobulbar neuritis), toxoplasmosis, vitamin deficiency (thiamine, riboflavin, pyridoxine, and choline), and demyelinating disease (multiple sclerosis) may produce persistent, albeit subtle, field defects. These field defects, often associated with an optic atrophy, are generally attributed to the preserved function of retinocollicular or geniculoprestriate cortical connections, but they may as likely be due to sparing of small islands of
calcineurin neurons.

In yet other instances of an occipital lesion and a dense homonymous hemianopia, the patient may be little disabled by his visual field loss (Benton et al; Meienberg). This is due to preservation of vision in a monocular part of the visual field known as the "temporal crescent." The latter is a peripheral unpaired portion of the visual field, between 60 and 100 degrees from the fixation point, and is represented in the most anterior part of the visual striate cortex. In particular, the temporal crescent is sensitive to moving stimuli, allowing the patient to avoid collisions with people and objects.

**Blindness in the Hysterical or Malingering Patient**

Hysterical blindness is described on page 1596, but a few comments are in order here. Feigned or visual hysterical visual loss is usually detected by attending to the patient's activities when he thinks he is unobserved and can be confirmed by a number of simple tests. Complete feigned blindness is exposed directly by observing the normal ocular jerk movements in response to a rotating optokinetic drum or strip by noting that the patient's eyes follow their own image in a moving mirror. The simplest way to establish the hysterical nature of monocular blindness is to note the presence of a normal pupillary response to light. An optokinetic response in the nonseeing eye (with the good eye covered) is an even more convincing test; also, the visual evoked potential from the allegedly blind eye is normal. Hysterical homonymous hemianopia is exceedingly rare and is only displayed by practiced malingerers and psychopaths. Lateral hemianopias of every variety are common (Keane). The uniformly constricted, tubular field defect of hysteria has already been mentioned.

**Visual Agnosia**

In distinction to blindness, there is another, far less common category of visual impairment in which the patient cannot understand the meaning of what he sees, i.e., visual agnosia. Primary visual perception is more or less intact, and the patient may describe accurately the shape, color, and size of objects and draw copies of them. Despite this, he cannot identify the objects unless he hears, smells, tastes, or palpates them. The failure of visual recognition of words alone is called visual verbal agnosia, or alexia. The ability to recognize visually presented objects and words depends upon the integrity not only of the visual pathways and processes posterior to the occipital cortex but also of the superior temporal lobe (Wernicke's area) and the angular gyrus (areas 39 and 40). Visual agnosia, homonymous hemianopia, or both of these abnormalities arise from lesions of the dominant occipital lobe and adjacent temporal and parietal (angular gyrus) cortex or from a lesion of the left calcarine cortex combined with one that interrupts the fibers crossing from the right occipital lobe (see Fig. 22-7). Failure to understand the meaning of an entire picture even though some of its parts are recognized is referred to as simultanagnosia, and a failure to recognize familiar faces is called prosopagnosia. These and other variants of visual agnosia (including visual neglect) and their pathologic bases are dealt with more fully in Chap. 22.

**Other Cerebral Disturbances of Vision**

These include various types of distortion in which images seem to recede into the distance (teleopsia), appear too small (micropsia), or, less frequently, seem too large (macropsia). If such distortions are perceived with only one eye, a local retinal lesion should be suspected. If perceived with both eyes, they usually signify disease of the temporal lobes, in which case the visual disturbances tend to occur in attacks and are accompanied by other manifestations of temporal lobe seizures (focal or generalized). Focal seizures may appear to be asseverate or even turned upside down. More often lesions of the vestibular nucleus or its immediate connections produce the illusion that objects are tilted (torticpia; page 290) to the degree that straight lines are curved. Presumably this is due to a mismatch between the visual image and the otolithic or vestibular input to the visual system.

**Abnormalities of Color Vision**

Normal color vision depends on the integrity of cone cells, which are most numerous in the macular region. When activated, they convey information to special columns of cells in the striate cortex. Three different cone pigments with optimal sensitivities to blue, green, and orange-yellow wavelengths are said to characterize these cells; presumably each cone possesses only one of these pigments. Transmission to higher centers for the perception of color is believed to be effected by neurons and axons that encode at least two pairs of complementary colors: red-green in one system and yellow-blue in the other. In the optic nerves and tracts, the fibers for color are of small caliber and are preferentially sensitive to certain noxious agents and to pressure. The geniculostriate fibers for color are separate from fibers that convey information about form and brightness but course along with them; hence there may be a homonymous color hemianopia (hemichromatopsia). The visual fields for blue-yellow are smaller than those for white light, and the red and green fields are smaller than those for blue-yellow.

Diseases may affect color vision by abolishing it completely (achromatopsia) or partially by quantitatively reducing one or more of the three attributes of color—brightness, hue, and saturation. Or, one only of the complementary pairs of colors may be lost, usually red-green. The disorder may be congenital and hereditary or acquired. The commonest form, and the one to which the term color blindness is usually applied, is a male sex-linked inability to see red and green while white visual acuity is retained. A genetic abnormality of cone pigments is postulated, but the defect cannot be seen by inspecting the retina. A failure of the cones to develop or a degeneration of cones may cause a complete loss of color vision, but in these conditions visual acuity is often diminished, a central scotoma may be present, and, although the macula appears to be normal on ophthalmoscopic examination, fluorescein angiography shows the pigment epithelium to be defective. Congenital color vision defects are usually protan (red) or deutan (green), leaving yellow-blue color vision intact; acquired lesions may affect all colors. Lesions of the optic nerves usually affect red-green more than blue-yellow; the opposite is true of retinal lesions. An exception is a rare dominantly inherited optic atrophy, in which the scotoma mapped by a large blue target is larger than that for red.

Damasio has drawn attention to a group of acquired deficits of color perception with preservation of form vision, the result of focal damage (usually infarction) of the visual association cortex and subjacent white matter. Color vision may be lost in a quadrant, half of the visual field, or the entire field. The latter, or full-field achromatopsia, may be due to bilateral occipital infarcts, to an extensive collicular lesion (Lisch), or to a lesion involving the fusiform and lingual gyri, a location that accounts for its frequent association with visual agnosia (especially prosopagnosia; see page 491) and some degree of visual field defect. A lesion restricted to the inferior part of the right occipitotemporal region, sparing both the optic radiations and striate cortex, causes the purest form of achromatopsia (left hemichromatopsia). With a similar left-sided lesion, alexia may be associated with the right hemichromatopsia.

**Other Visual Disorders**

Finally, in addition to the losses of perception of form, movement, and color, lesions of the visual system may also give rise to a variety of positive visual sensory experiences. The simplest of these are called phosphenes, i.e., flashes of light and colored spots in the absence of luminous stimuli. Other visual hallucinations, notably in old age when vision fails (Bonnet syndrome), in the withdrawal state following chronic intoxication with alcohol and other sedative-hypnotic drugs (Meienberg), and a failure to recognize familiar faces is called prosopagnosia (left hemichromatopsia). With a similar left-sided lesion, alexia may be associated with the right hemichromatopsia.

Clinical effects and syndromes that result from occipital lobe lesions are discussed further in Chap. 22.

Ocular movement and vision are virtually inseparable. A moving object evokes ocular movement and almost simultaneously arouses attention and initiates the perception process. To look searchingly, i.e., to peer, requires stable fixation of the visual image on the center of the two retinas. One might say that the ocular muscles are at the beck and call of our visual sense. This is the logic of juxtaposing Chapter 13 and Chapter 14 and suggesting that they be read together.

Abnormalities of ocular movement are of four basic types. One disorder of motility can be traced to a lesion of the extracocular muscles themselves, the neuromuscular junction, or to the cranial nerves that supply them (nuclear or infranuclear palsies). The second type, of particular neurologic interest, is a derangement in the highly specialized neural mechanisms that enable the eyes to move together (supranuclear or internuclear palsies). Such a distinction, in keeping with the general concept of upper and lower motor neuron paralysis, hardly portrays the complexity of the neural mechanisms governing ocular motility; nevertheless, it constitutes an essential step in the approach to the patient with defective eye movements. In the third type, there is a mechanical restriction of the globe because of a mass or infiltrating lesion within the orbit. In all three types, a knowledge of the anatomic basis of normal movement is essential to an understanding of abnormal movement. Perhaps more common but not primarily neurologic is the fourth type, concomitant strabismus, in which there is a congenital imbalance of the yoked muscles of extracocular movement.

**SUPRANUCLEAR CONTROL OF EYE MOVEMENT**

**Anatomic and Physiologic Considerations**

In no aspect of human anatomy and physiology is the sensory guidance of muscle activity more instructively revealed than in the neural control of coordinated ocular movement. To focus the eyes voluntarily in searching the environment, to stabilize objects for scrutiny when one is moving, to maintain clear images of moving objects, to bring into sharp focus near and far objects—all require the perfect coordination of six sets of extracocular muscles and three sets of intrinsic muscles (ciliary muscles and sphincters and dilators of the irises). The neural mechanisms that govern these functions reside in the medulla, pons, midbrain, cerebellum, basal ganglia, and the frontal, parietal, and occipital lobes of the brain. Most of the nuclear structures and pathways concerned with fixation and stable ocular movements are now known, and much has been learned of their physiology both from clinical-pathologic correlations in humans and from experiments in monkeys. Different diseases may give rise to particular defects in ocular movement and pupillary function, and these are of diagnostic importance.

Accurate binocular vision is achieved by the associated action of the ocular muscles, which allows a visual stimulus to fall on exactly corresponding parts of the two retinas. The symmetrical and synchronous movement of the eyes is termed conjugate movement or gaze (conjugate = yoked or joined together). The simultaneous movement of the eyes in opposite directions, as in convergence, is termed disconjugate or dissociative. These two forms of normal ocular movement—conjugate and disconjugate—are also referred to as versional and vergence, respectively. Vergence movements are of two types—fusional and accommodative. Fusional movements are the convergence and divergence movements that maintain binocular single vision and depth perception (stereopsis); they are necessary at all times to prevent visual images from falling on noncorresponding parts of the retinas. Accommodative vergence movements are brought into action when one looks at a near object. The eyes turn inward (off their parallel axes) and at the same time the pupils constrict and the ciliary muscles relax to thicken the lens (accommodation). This synkinesis is called the near reflex or accommodative triad.

Voluntary conjugate movements of the eyes to the opposite side are probably initiated in area 8 of the frontal lobe and relayed to the pons. These movements are characteristically rapid or saccadic (peak velocity may exceed 700 degrees per second). Their purpose is to quickly change ocular fixation in order to bring images of new objects of interest onto the foveas. They can be elicited by instructing the individual to look to the right or left (commanded saccades) or to move the eyes to fixate on a target (reflex saccades). Saccadic movements, or saccades, may also be elicited reflexly, as when a sudden sound or the appearance of an object in the peripheral field of vision attracts attention and triggers an automatic movement of the eyes in the direction of the stimulus. Saccadic latency, the interval between the appearance of a target and the initiation of a saccade, is approximately 200 ms.

The neuronal firing pattern of pontine neurons that produces a saccade has been characterized as “pulse-step” in type. This refers to the sudden increase in neuronal baseline firing level (the step), which maintains the eyes in their new position by constant tonic contraction of the extraocular muscles (the neck). Such a pattern, in keeping with the general concept of upper motor neuron paralysis, hardly portrays the complexity of the neural mechanisms governing ocular motility; nevertheless, it constitutes an essential step in the approach to the patient with defective eye movements. In the third type, there is a mechanical restriction of the globe because of a mass or infiltrating lesion within the orbit. In all three types, a knowledge of the anatomic basis of normal movement is essential to an understanding of abnormal movement. Perhaps more common but not primarily neurologic is the fourth type, concomitant strabismus, in which there is a congenital imbalance of the yoked muscles of extracocular movement. **Chap. 13 and Chap. 14**
produced that is equal and opposite to movement of the head. The VOR generates a prompt (short latency) response to rapid transient head movements. During sustained rotation of the head, the VOR is supplemented by the optokinetic system, which enables one to maintain compensatory eye movements for a more prolonged period. If the VOR is lost, as occurs with disease of the vestibular apparatus or eighth nerve, the slightest movements of the head, especially those occurring during locomotion, cause a movement of images across the retina large enough to impair vision. When objects are tracked using both eye and head movements, the vestibulo-ocular movements induced by head turning must be suppressed, otherwise the eyes would remain stabilized in space; it appears likely that the smooth pursuit signals cancel the unwanted vestibular ones (Leigh and Zee).

**Horizontal Gaze**

**Saccades** As already mentioned, the signals for volitional horizontal gaze saccades originate in the eye field of the opposite frontal lobe (area 8 of Brodmann) and are modulated by the adjacent supplementary motor eye field and the posterior visual cortical areas. The corticofugal pathways for saccadic horizontal gaze have been traced in the monkey by Leichtheiz. He found that these fibers traverse the internal capsule and separate at the level of the rostral diencephalon into two bundles: a primary but indirect ventral "capsular-peduncular" bundle, which descends through the internal capsule and most medial part of the basis pedunculi. This more ventral pathway undergoes a partial decussation in the midbrain, at the level of the trochlear nucleus, and terminates mainly in the paramedian pontine reticular formation (PPRF). Further connections with the ipsilateral sixth nerve nucleus and contralateral medial longitudinal fasciculus are also indicated. Cranial nerve nuclei III and IV are labeled on left; nucleus of VI and vestibular nuclei (VN) are labeled on right. LR, lateral rectus; MR, medial rectus; MLF, medial longitudinal fasciculus.

**Brainstem Pathways** Ultimately, all the pathways mediating saccadic and pursuit movements in the horizontal plane as well as vestibular and optokinetic movements converge upon the pontine centers for horizontal gaze. These comprise the PPRF, the nuclei prepositus hypoglossi and commissure, the abducens and medial vestibular nuclei, and pathways in the pontine and mesencephalic tegmentum that interconnect the ocular motor nuclei (Fig. 14-1). Conventionally, the term oculomotor nucleus refers to the nuclei of the third, fourth, and sixth cranial nerves; the term oculomotor nucleus refers to the third nerve nucleus alone.) The pathway connecting the third and sixth nerve nuclei, and connecting both these nuclei with the vestibular nuclei, lies in the medial tegmentum of the brainstem; this pathway is termed the medial longitudinal fasciculus (MLF).

The PPRF and the prepositus and medial vestibular nuclei function as a neural integrator and relay station for horizontal saccade pathways. However, the neural signals that encode smooth pursuit and vestibular and optokinetic movements bypass the PPRF and project independently to the abducens nuclei (Hanson et al.).

The abducens nucleus contains two groups of neurons, each with distinctive morphologic and pharmacologic properties: (1) abducens motor neurons, which project to the ipsilateral lateral rectus muscle, and (2) abducens internuclear neurons, which project via the contralateral MLF to the medial (internal) rectus neurons of the oculomotor nucleus. Conjugate lateral gaze is accomplished by the simultaneous innervation of the ipsilateral external rectus and the contralateral medial rectus, the latter through fibers that run in the medial portion of the MLF. Interruption of the MLF accounts for the discrete impairment or loss of abduction of the eye ipsilateral to the MLF lesion, while the medial rectus still contracts and the eye adducts on convergence, a phenomenon referred to as internuclear ophthalmoplegia, the details of which are discussed further on (Fig. 14-1). Two other ascending pathways between the pontine centers and the mesencephalic reticular formation have been traced: one traverses the central tegmental tract and terminates in the pretectum, in the nucleus of the posterior commissure; the other is a bundle separate from the MLF that passes around the nuclei of Cajal and Darkschewitz to the rostral interstitial nucleus of the MLF (MLF). These nuclei are involved more in vertical gaze and are described below. In addition, each vestibular nuclei projects onto the abducens nucleus and the MLF of the opposite side; the functional significance of the latter pathways is not entirely clear.

Although projections from the frontal eye fields to the oculomotor nuclei, as described above, undoubtedly exist, indirect projections are probably more important in the voluntary control of conjugate eye movements. According to Leigh and Zee, a more accurate conceptualization of these voluntary influences is one of a hierarchy of cell stations and parallel pathways that do not project directly to ocular motor nuclei but to adjacent premotor or burst neurons, which discharge at high frequencies immediately preceding the saccade. The premotor or burst neurons for horizontal saccades lie within the PPRF and those for vertical saccades in the ri MLF (see below). Yet a third class of neurons (pause cells), lying in the midline of the pons, is involved in the inhibition of unwanted saccadic discharges.

**Vertical Gaze** In contrast to horizontal gaze, which is generated by unilateral aggregates of cerebral and pontine neurons, vertical eye movements, with few exceptions, are under bilateral control of the cerebral cortex and upper brainstem. The groups of nerve cells and fibers that govern upward and downward gaze as well as torsional saccades are situated in the pretectal areas of the midbrain and involve three integral structures—the rostral interstitial nucleus of the medial longitudinal fasciculus (MLF), the interstitial nucleus of Cajal (INC), and the nucleus and fibers of the posterior commissure (Fig. 14-2).
simultaneous activity of both frontal cortical eye fields. The riMLF serves as the generator of vertical saccades and the INC acts tonically to hold eccentric vertical gaze. The rMLF and riMLF connect with the contralateral nuclei via the posterior commissure where fibers are subject to damage. Projections for upgaze cross through the commissure before descending to innervate the third nerve nucleus, while those for downgaze may travel directly to the third nerve thus accounting for the frequency of selective upgaze palsies (see text). The rMLF carries signals from the vermis, mainly ipsilaterally, to stabilize the eyes in the vertical plane (VOR) and maintain tonic vertical position.

The riMLF lies at the junction of the midbrain and thalamus, at the rostral end of the medial longitudinal fasciculus, just dorsomedial to the rostral pole of the red nucleus. The riMLF functions as the “premotor” nucleus or “burst cells” for the production of fast (saccadic) versional and torsional movements. Input to the riMLF arises both from the PPRF and the vestibular nuclei. Each riMLF projects mainly ipsilaterally to the oculomotor and trochlear nuclei, but each riMLF is connected to its counterpart by fibers that traverse the posterior commissure. Bilateral lesions of the riMLF or of their interconnections in the posterior commissure (see below) are more common than unilateral ones and cause a loss either of downward saccades or of all vertical saccades.

The interstitial nucleus of Cajal (INC) is a small collection of cells that lies just caudal to the riMLF on each side. Each nucleus projects to the motor neurons of the elevator muscles (superior rectus and inferior oblique) by fibers that cross through the posterior commissure and project ipsilaterally to the depressor muscles (superior rectus and superior oblique). The functional role of the INC appears to be in holding eccentric vertical gaze, especially after a saccade; it is also integral to the vestibulo-ocular reflex. Lesions of the INC produce a vertical gaze-evoked and torsional nystagmus and an ocular tilt reaction (page 278) and probably impair conjugate eye movements, mainly vertical ones, to some extent.

Lesions of the posterior commissure interrupt signals crossing from the INC and the riMLF and characteristically produce a paralysis of upward gaze and of convergence, often associated with mydriasis and lid retraction (Collier’s “tucked lid” sign) and less commonly with ptosis. This is the . Slow saccades are also a consistent finding in Niemann-Pick disease type C (page 1014).

The MLF is the main conduit of vertical gaze signals from the vestibular nuclei in the medulla to the midbrain centers. For this reason, vertical pursuit and VOR are impaired with internuclear opthalomoplegia (INO), particularly when the lesion is bilateral, and a vertical deviation of the ipsilateral globe ( skew; see further on) may be seen in cases of unilateral INO, as discussed in a later section

**Vestibulocerebellar Influences on Eye Movements**

There are important vestibulocerebellar influences on both smooth pursuit and saccadic movements (see also Chap. 5). The flocculus and posterior vermis of the cerebellum receive abundant sensory projections from proprioceptors of the cervical musculature (responsive to head velocity), the retinas (sensitive to target velocity), proprioceptors of eye muscles (eye position and eye velocity), auditory and tactile receptors, and the superior colliculi and PPRF. Cerebellar efferents concerned with oculomotor movement project onto the vestibular nuclei; the latter, in turn, influence gaze mechanisms through several projection systems: one, for horizontal movements, consists of direct projections from the vestibular nuclei to the contralateral sixth nerve nucleus; another, for vertical movements, projects, via the contralateral MLF, to third and fourth nerve nuclei (Fig. 14-1 and Fig. 14-2).

Lesions of the flocculus and posterior vermis (lobules VI and VII) are consistently associated with deficits in smooth pursuit movements and an inability to suppress the vestibulo-ocular reflex by fixation (. RiMLF. Floccular lesions are also an important cause of downbeat nystagmus. Also, as indicated in Chap. 5, patients with cerebellar (floccular) lesions are unable to hold eccentric positions of gaze and must make repeated saccades to look at a target that is away from the neutral position (gaze-paretic nystagmus). This phenomenon is explained by the fact that with acute, one-sided lesions of the vestibulocerebellum, the inhibitory discharges of the Purkinje cells onto the ipsilateral medial vestibular nucleus are removed and the eyes deviate away from the lesion. When gaze to the side of the lesion is attempted, the eyes drift back to the midline and can be corrected only by a saccadic jerk. The head and neck may also turn away from the lesion (the occiput toward the lesion and the face away). In addition, the vestibular ocular reflexes, which coordinate eye movements with head movements, are improperly adjusted (. Extensive vestibular nuclear lesions impair all movements toward gaze (gaze-paretic nystagmus).

**Testing of Conjugate Gaze**

It is apparent from the foregoing remarks that there is considerable clinical information to be obtained about ocular movements and their central control mechanisms by the simple expedients of asking the patient to look quickly to each side as well as up and down and to follow a moving target (a light, the examiner’s or the patient’s finger, or an optokinetic drum) or, in patients with stupor and coma, by passively turning the head and irrigating the external auditory canals—the last two being vestibular stimuli.

Most individuals make accurate saccades to a target. Persistent alterations of saccadic movements, particularly overshooting of the eyes ( hypertetania), is characteristic of a cerebellar lesion. Slowness of saccadic movements are sometimes extreme in degree. Slow saccades may be seen in Huntington disease and also in Wilson disease, ataxia-telangiectasia, progressive super-nuclear palsy, olivopontocerebellar degeneration, and certain lipid storage diseases. Lesions involving the PPRF may be accompanied by slow saccadic movements to the affected side. Hypometric, slowed saccades the axons securing only in the adducting eye on quick lateral gaze, indicate an internuclear ophthalmoplegia due to a lesion of the ipsilateral MLF. When slow saccades are first observed in the vertical plane early in an extrapyramidal disease, the likeliest diagnosis is progressive supranuclear palsy; if upward gaze saccades are lost late in an extrapyramidal process, advanced Parkinson disease may be the explanation or any of a number of diseases that affect vertical gaze (Table 14-1). Slow up-and-down saccades are also a consistent finding in Niemann-Pick disease type C (page 1014).

<td>Yet another saccadic disorder takes the form of an inability to initiate voluntary movements, either vertically or horizontally. This abnormality may be congenital in nature, as in the ocular “apraxia” of childhood (Cogan syndrome, see below) and ataxia-telangiectasia; difficulty in the initiation of saccadic movements as an acquired abnormality may be seen in patients with Huntington disease or with a lesion of the contralateral frontal lobe or ipsilateral pontine tegmentum.</td>

Fragmentation of smooth pursuit movement is a frequent neuro-ophtalmic finding. Drug intoxication—with phenytoin, barbiturates, diazepam, and other sedative drugs—is probably the most common cause. As a manifestation of structural disease, it points to a lesion of the vestibulocerebellum. Smooth pursuit movements are found to be impaired in all basal ganglionic degenerations, according to Vidalhiet and colleagues. Also, in certain extrapyramidal diseases, such as Parkinson disease, with progressive supranuclear palsy—there is often an impairment of smooth pursuit movements in association with slow, hypometric saccades (“saccadic pursuit”). Asymmetrical impairment of smooth pursuit movements is indicative of a parietal lobe lesion; a right parietal lesion causes an impairment of smooth tracking to the patient’s right and a consequent decrease in the corrective nystagmus on rotating the optokinetic drum in that direction.

Zee has described a simple means of evaluating the VOR. In a dimly lit room, the patient is instructed to fixate on a distant target with one eye while the examiner observes the optic nerve head of the other eye with an ophthalmoscope. The subject is then instructed to rotate his head back and forth at a rate of one to two cycles per second. In a normal subject, the optic nerve head remains stationary; if the VOR is impaired, the optic nerve head appears to oscillate. Normally, movement of the head at this rate does not cause blurring of vision, because of the rapidity with which the VOR accomplishes compensatory eye movements. By contrast with the head in a fixed position, to-and-fro movement of the environment will cause blurring of vision because normal tracking movements are too slow to fixate the object in space. As a rule, the patient with impairment of smooth pursuit movements will have a commensurate inability to suppress the VOR.

Combined fusional-accommodative movements (tested by asking the patient to look at his thumbnail as it is brought toward the eyes) are frequently impaired in the elderly and in confused or inattentive patients. In others, the absence or impairment of these movements should suggest the presence of basal ganglionic disease, more particularly progressive supranuclear palsy, Parkinson disease, or some other lesion in the rostral midbrain. Convergence spasms and retraction nystagmus may accompany paralysis of vertical gaze. Such spasms, occurring alone, are characteristic of hysteria. In such patients, full movement can usually be obtained if each eye is tested separately. A cycloplegic (homatropine eyedrops) will abolish the accommodation and pupillary miosis, but its effect on the convergence spasm is less predictable.

Paralysis of Conjugate Gaze

Horizontal Gaze Palsy
An acute lesion of one frontal lobe, such as an infant, usually causes impersistence or paresis of contralateral gaze, and the eyes will turn involuntarily toward the side of the cerebral lesion. Occasionally a deep cerebral lesion, particularly a thalamic hemorrhage extending into the midbrain, will cause the eyes to deviate conjugately to the side opposite the lesion (‘‘wrong-way gaze’’). Most lesions of the cerebral infratentorial gaze pathways are complete and temporary, lasting for a day or two or for as long as a week. Almost invariably, it is accompanied by hemiparesis. In this circumstance, forced closure of the eyelids may cause the eyes to move paradoxically to the side of the hemiparesis rather than upward. During sleep, the eyes deviate conjugately from the side of the lesion to the side of the hemiplegia. Also, as indicated above, pursuit movements to the side of the lesion tend to fragment. With bilateral frontal lesions, the patient may be unable to turn his eyes voluntarily in any direction but retains fixation and following movements, probably because pursuit movements are initiated in the parieto-occipital cortex. Gaze paralysis of central origin is not attended by strabismus or diplopia. The usual causes are vascular occlusion with infarction, hemorrhage, and abscess or tumor of the frontal lobe.

A unilateral lesion in the rostral midbrain tegmentum, by interrupting the cerebral pathways for horizontal conjugate gaze before their decussation, will cause a gaze palsy to the opposite side. A lesion in the pontine horizontal gaze complex (PPRF) involving the abducens nucleus causes ipsilateral gaze palsy and deviation of the eyes to the opposite side. As a rule, the horizontal gaze palsy of tegmental origin is readily distinguished. The former are usually accompanied by hemiparesis, and the paraparesis of gaze is on the same side as the hemiparesis. Palsies of pontine origin are associated with other signs of pontine disease, particularly peripheral facial and external rectus palsies and internuclear opthalmoplegia on the same side as the paralysis of gaze; hemiparesis, if present, is on the side opposite to the gaze palsy. Gaze palsies due to cerebral lesions tend not to be as long-lasting as those due to pontine lesions. Also, in the case of a cerebral lesion (but not a pontine lesion), the eyes can be turned to the paralyzed side if they are fixated on the target and the head is rotated passively to the opposite side (i.e., by utilizing the VOR).

Vertical Gaze Palsy
Midbrain lesions affecting the pretectum on both sides of the midline (or at times a lesion confined to one side) and lesions in the region of the posterior commissure, with interference with conjugate movements in the vertical plane. Restated, paralysis of vertical gaze is a prominent feature of the Parinaud, or dorsal midbrain, syndrome (see above). Upward gaze is affected far more frequently than downward gaze because, as already explained, some of the fibers subserving upgaze cross rostrally and posteriorly between the ri MLF and INC nuclei and are subject to interruption before descending to the oculomotor nuclei. Whereas the pathways for downgaze apparently project directly from the two controlling nuclei. Optokinetic nystagmus in the vertical plane is usually lost in association with these abnormalities.

The range of upward gaze is frequently restricted by a number of extraneous factors, such as drowsiness, increased intracranial pressure, and particularly by aging. In patients who cannot elevate their eyes voluntarily, the presence of reflex upward deviation of the eyes in response to forced flexion of the head (“doll’s-head maneuver”) or to forced closure of the eyelids (Bell’s phenomenon) usually indicates that the nuclear and infranuclear mechanisms for upward gaze are intact and that the defect is supranuclear. However useful this rule may be, in some instances of Guillain-Barré syndrome and myasthenia gravis, in which voluntary upgaze is limited, the strong stimulus of eye closure may also cause upward deviation, whereas voluntary attempts at upgaze are unsuccessful. About 15 percent of normal adults do not show a Bell’s phenomenon, and in others deviation of the eyes is paradoxically downward.

In several patients who during life had shown an isolated palsy of downward gaze, autopsy has disclosed bilateral lesions (infarction) of the rostral midbrain tegmentum, just medial and dorsal to the red nuclei. In monkeys, a defect in downward gaze has been produced of bilateral circumscribed lesions centered in these regions (Kompf et al). A unique case, described by Bogousslavsky and colleagues, suggests that a paralysis of vertical gaze may follow a strictly unilateral infarction involving the posterior commissure, ri MLF, and INC. Hommel and Bogousslavsky have summarized the location of infarctions that cause monocular and binocular vertical gaze palsies.

Several degenerative and related processes exhibit selective upgaze or vertical gaze palsies (Table 14-1). In progressive supranuclear palsy, a characteristic feature is a selective paralysis of upward and then downward gaze, initially evident as difficulty with saccades (page 1139). Parkinson and Lewy body diseases (Chap. 39), corticobasal ganglionic degeneration (Chap. 39), and Whipple disease of the brain (Chap. 40) may produce vertical gaze palsies as the diseases progress.

Other Gaze Palsies
Skew deviation is a poorly understood disorder in which there is vertical deviation of one eye above the other. The deviation may be the same (comitant) in all fields of gaze or it may vary with different directions of gaze. The patient complains of vertical diplopia. Skew deviation does not have precise localizing value but occurs with a variety of lesions of the cerebellum and the brainstem, particularly those involving the MLF. With skew deviation due to cerebellar disease, the deviation of the lesion is on the side of the other eye (in a ratio of 2:1 in Kenner’s series), in distinction to unilateral internuclear ophthalmoplegia, in which the eye is typically higher on the side of the lesion. (Recall that the image from the affected side is always projected to the opposite direction to eye deviation.) Skew deviation has been known to alternate from one side to the other and has been seen with the condition known as periodic alternating nystagmus. Ford and coworkers have described a rare form of skew deviation due to monocular elevation palsy from a lesion immediately rostral to the ipsilateral oculomotor nucleus; a lesion of upgaze efficients from the ipsilateral ri MLF was postulated, but an abnormality of the vertical gaze holding mechanism related to the INC is an alternative explanation.

The ocular tilt reaction, in which skew deviation is combined with ocular torsion and head tilt, is usually attributed to an imbalance in otolith-ocular and otolith-collic reflexes. In unilateral lesions involving the vestibular bulb, as in lateral medullary infarction, the eye is lower on the side of the lesion. With lesions of the MLF or INC, which can also cause an ocular tilt reaction, the eye is higher on the side of the lesion.

Another unusual and now almost vanished disturbance of gaze is the oculogyric crisis, or spasm, which consists of a tonic spasm of conjugate deviation of the eyes, usually upward and less frequently laterally or downward. Recent attacks, sometimes associated with spasms of the neck, mouth, and tongue muscles and lasting from a few seconds to an hour or two, were pathognomonic of postencephalitic parkinsonism. Now this phenomenon is observed rarely as an acute reaction in patients being given phenothiazine drugs (page 1264) and in Niemann-Pick disease. The pathogenesis of these ocular spasms is not known.

Congenital ocular motor “apraxia” (Cogan syndrome) is a disorder characterized by abnormal eye and head movements during attempts to change the position of the eyes. The patient is unable to make normal voluntary horizontal saccades when the head is stationary. If the head is free to move and the patient is asked to look at an object, the head is thrust toward the target, and the eyes move only to the central position, fixate on the target. Both voluntary saccades and the quick phase of vestibular nystagmus are defective. The pathologic anatomy has never been studied. This phenomenon is also seen in ataxiatelangiectasia (page 1011) and in association with agenesis of the corpus callosum, in which both horizontal and
vertical saccades may be affected.

NUCLEAR AND INFRANUCLEAR DISORDERS OF EYE MOVEMENT

Anatomic Considerations

The third (oculomotor), fourth (trochlear), and sixth (abducens) cranial nerves innervate the extrinsic muscles of the eye. Since their actions are closely integrated and many diseases involve all of them at once, they are suitably considered together.

The oculomotor (third-nerve) nuclei consist of several paired groups of nerve cells, adjacent to the midline and ventral to the aqueduct of Sylvius, at the level of the superior colliculi. A centrally located group of nerve cells that innervate the pupillary sphincters and ciliary bodies (muscles of accommodation) is situated dorsally in the Edinger-Westphal nucleus; this is the parasympathetic portion of the oculomotor nucleus. Ventral to this nuclear group are cells that mediate the actions of the levator of the lid, superior and inferior recti, inferior oblique, and medial rectus in this dorsal-ventral order. This functional arrangement has been determined in cats and monkeys by extirpating individual extrinsic ocular muscles and observing the retrograde cellular changes (Warwick). Subsequent studies, utilizing radioactive tracer techniques, have shown that the medial rectus neurons occupy three disparate locations within the oculomotor nucleus rather than being confined to its ventral tip (Büttner-Ennever and Akert). These experiments also indicate that the medial and inferior recti and the inferior oblique have a strictly homolateral representation in the oculomotor nuclei; the superior rectus receives only crossed fibers; and the levator palpebrae superioris has a bilateral innervation. Vergence movements are under the control of medial rectus neurons and not an unpaired medial group of cells (“nucleus of Perlia”), as was once supposed.

It is important to note that the efferent fibers of the oculomotor and abducens nuclei have a considerable intramedullary extent (Fig. 14-3A and Fig. 14-3B). The fibers of the third-nerve nucleus course ventrally in the brainstem, crossing the medial longitudinal fasciculus, red nucleus, substantia nigra, and medial part of the cerebral peduncle; lesions involving these structures may therefore interrupt oculomotor fibers in their intramedullary course. The sixth nerve (abducens) arises at the level of the lower pons, from a paired group of cells in the floor of the fourth ventricle, adjacent to the midline. The intrapontine portion of the facial nerve loops around the sixth-nerve nucleus before it turns anterolaterally to make its exit; a lesion in this locality therefore causes a homolateral paralysis of the lateral rectus and facial muscles.

The cells of origin of the trochlear nerves are just caudal to those of the oculomotor nerves. Unlike the third and sixth nerves, the fourth nerve courses posteriorly and decussates a short distance from its origin before emerging from the dorsal surface of the brainstem, just caudal to the inferior colliculi. It therefore innervates the contralateral superior oblique muscle.

The oculomotor nerve, soon after it emerges from the brainstem, passes between the superior cerebellar and posterior cerebral arteries. The nerve (and posterior cerebral artery) may be compressed at this point by herniation of the uncus through the tentorium (see Chap. 17). The sixth nerve, after leaving the brainstem, sweeps upward and runs alongside the third and fourth cranial nerves; together they course anteriorly, pierce the dura just lateral to the posterior clinoid process, and run in the lateral wall of the cavernous sinus, where they are closely applied to the cavernous portion of the internal carotid artery and first and second divisions of the fifth nerve (Fig. 14-4).
Retrocavernous compressive lesions, notably intracranial aneurysms and tumors, tend to involve all three sensory divisions of the trigeminal nerve, together with the oculomotor nerves. In the posterior portion of the cavernous sinus, the first and second trigeminal divisions tend to be involved, along with the oculomotor nerves; in the anterior portion, only the ophthalmic division is affected. Just posterior and superior to the cavernous sinus, the oculomotor nerve crosses the terminal portion of the internal carotid artery at its junction with the posterior communicating artery. An aneurysm at the latter site frequently damages the third nerve, and this serves to localize the site of compression or bleeding.

Together with the first division of the fifth nerve, the third, fourth, and sixth nerves enter the orbit through the superior orbital fissure. The oculomotor nerve, as it enters the orbit, divides into superior and inferior branches, although a functional division occurs well before the anatomic bifurcation. The superior branch supplies the superior rectus and the voluntary (striated) part of the levator palpebrae (the involuntary part is under the control of sympathetic fibers); the inferior branch supplies the pupillary and ciliary muscles and all the other extrinsic ocular muscles except two—the superior oblique and the external rectus—which are innervated by the trochlear and abducens nerves, respectively. Superior branch lesions caused by an aneurysm or associated with diabetes or a viral infection cause ptosis and uniocular upgaze paresis.

Under normal conditions, all the extraocular muscles probably participate in every movement of the eyes; for proper movement, the contraction of any muscle requires relaxation of its antagonist. Clinically, however, an eye movement should be thought of in terms of the one muscle that is predominantly responsible for an agonist movement in that direction; e.g., outward rotation of the eye requires the action of the lateral rectus; inward rotation, action of the medial rectus. The action of the superior and inferior recti and the oblique muscles varies according to the position of the eye. When the eye is turned upward, the superior rectus and the depressor is the inferior rectus. When the eye is turned inward, the elevator and depressor are the inferior and superior oblique muscles, respectively. The actions of the ocular muscles in different positions of gaze are illustrated in Fig. 14-5 and Table 14-2. The clinical implications of flaws in these muscle actions are discussed below.

Strabismus (Squint)

This refers to a muscle imbalance that results in a misalignment of the visual axes of the two eyes. It may be caused by weakness of an individual eye muscle (paralytic strabismus) or by an imbalance of muscular tone, presumably due to a faulty "central" mechanism that normally maintains a proper angle between the two visual axes (nonparalytic strabismus). It is in the latter sense that the term is generally used. Almost everyone has a slight tendency to strabismus, i.e., to misalign the visual axes when a target is viewed with one eye. This tendency is referred to as a phoria and is normally overcome by the fusion mechanisms. A misalignment that is manifest from birth is referred to as a tropia and cannot be overcome, even when the patient is forced to fixate with the deviant eye, is called a tropia. The prefixes eso- and exo- indicate that the phoria or tropia is directed inward or outward, respectively, and the prefixes hyper- and hypo-, that the deviation is upward or downward. Paralytic strabismus is primarily a neurologic problem; nonparalytic strabismus (referred to as comitant strabismus if the angle between the visual axes is the same in all fields of gaze) is more strictly an ophthalmologic problem.

Once binocular fusion is established, usually by 6 months of age, any type of ocular muscle imbalance will cause diplopia, since images then fall on disparate or noncorresponding parts of the two functionally active retinas. After a time, however, the child eliminates the diplopia by suppressing the image in one eye. After a variable period, the suppression becomes permanent, and the individual grows up with a diminished visual acuity in that eye, the result of prolonged disuse amblyopia ex anopsia. With proper early treatment, the amblyopia can be reversed; but if it persists beyond the age of 5 or 6 years, recovery of vision rarely occurs. Occasionally, when the eyes are used alternately for fixation (alternating strabismus), visual acuity remains good in each eye.

Nonparalytic strabismus may pose a problem for neurologists. It has a way of appearing in early childhood for unclear reasons and conjures up possibilities of serious neurologic disease. Sometimes it is first noticed after a head injury or an infection, or it may be exposed by some other neurologic disorder or drug intoxication that impairs fusional mechanisms (vergence). In a cooperative patient, nonparalytic strabismus may be demonstrated by showing that each eye can be moved fully when the other eye is covered. Tropias and phorias can readily be detected by means of the simple "cover and "cover-uncover" tests. In the case of a tropia, in which one eye is not aligned with the target (for example when viewing the large E at 20 ft), covering the fixing eye will force the uncovered (deviating) eye to change its position abruptly and focus on the target (movement of redress). Similarly, the cover-uncover test can detect latent phorias that are suppressed by the fusion mechanism as long as both eyes are used. When fusion is disrupted by covering one eye, the covered eye will deviate as just noted; uncovering the eye results in a quick corrective movement designed to re-establish the fusion mechanism.

Clinical Effects of Lesions of Individual Ocular Nerves

Characteristic clinical disturbances result from lesions of the third, fourth, and sixth cranial nerves. A complete third-nerve lesion causes ptosis or drooping of the upper eyelid (since the levator palpebrae is supplied mainly by the third nerve) and an inability to rotate the eye upward, downward, or inward. When the lid is passively elevated, the eye is found to be deviated outward and slightly downward because of the unopposed actions of the intact lateral rectus and superior oblique muscles. In addition, one finds a dilated nonreactive pupil (iritidoplegia) and paralysis of accommodation (cycloplegia) due to interruption of the parasympathetic fibers in the third nerve. However, the extrinsic and intrinsic eye muscles may be affected separately. Infarction of the central portion of the oculomotor nerve, as occurs in diabetics, typically spares the pupil, since the parasympathetic preganglionic pupilloconstrictor fibers lie near the surface. Conversely, compressive lesions of the nerve usually dilate the pupil. After injury, regeneration of the third nerve fibers may be aberrant. For example, some of the fibers that originally moved the eye in a particular direction now reach another muscle or the iris; in the latter instance the pupil, which is unreactive to light, may constrict when the eye turns up and in.

A fourth nerve lesion is the commonest cause of symptomatic vertical diplopia. Paralysis of the superior oblique muscle results in exotropia and weakness of downward movement of the affected eye, most marked when the eye is turned inward, so that the patient complains of special difficulty in reading or going down stairs. The affected eye tends to deviate upward and inward. This defect may be overlooked in the presence of a third nerve palsy if the examiner fails to note the absence of intorsion as the patient tries to move the paralytic eye downward. Head tilting to the opposite shoulder (Bielchowsky sign) is especially characteristic of fourth nerve lesions; this maneuver causes a compensatory intorsion of the unaffected eye and ameliorates the double vision. Bilateral trochlear palsies, as occur after head trauma, give a characteristic alternating hyperdeviation depending on the direction of gaze.

Lesions of the sixth nerve result in a paralysis of lateral or outward movement and a crossing of the visual axes. The affected eye deviates medially, i.e., in the direction of the opposing muscle. With incomplete sixth nerve palsies, turning the head toward the side of the paralytic muscle may overcome the diplopia. The main causes of individual oculomotor palsies and of combined palsies are listed in Table 14-3 and are analyzed in Fig. 14-6 and below.
The Analysis of Diplopia

Almost all instances of diplopia (i.e., seeing a single object as double) are the result of an acquired paralysis or paresis of one or more extracocular muscles. The signs of the oculomotor palsies, as described above, are manifest in various degrees of completeness. Noting the relative positions of the corneal light reflections and having the patient perform common versional movements will usually disclose the faulty muscle(s) as the eyes are turned into the field of action of the paretic muscle. The muscle weakness may be so slight, however, that no squint or defect in ocular movement is obvious, yet the patient experiences diplopia. It is then necessary to study the relative positions of the images of the two eyes as a means of determining which muscle might be involved. Several tests are useful for this purpose.

Perhaps the simplest maneuver consists of asking the patient to follow an object or penlight into the six cardinal positions of gaze. When the position of maximal separation of images is identified, one eye is covered and the patient is asked to identify which image disappears. A more reliable way of distinguishing the weak muscle is by the red-glass test. The essential strategy of this test is also to determine the position of gaze that produces maximum diplopia. A red glass is placed in front of the patient's right eye (the choice of the right eye is arbitrary, but if the test is always done in the same way, interpretation is simplified). The patient is then asked to look at a flashlight (held at a distance of 1 m), to turn both eyes to the six cardinal points in the visual fields, and to state or indicate with his index fingers the position of the red and white images and the relative distances between them. The positions of the two images are plotted as the patient indicates them to the examiner (Fig. 14-6).

Three rules aid in the analysis of ocular movements by the red-glass test or simply from the reported separation of the images as viewed with both eyes:

1. The direction in which the images are maximally separated is the direction of action of a pair of muscles, one of which is paretic. For example, if the greatest horizontal separation is in looking to the right, either the right abductor (lateral rectus) or the left adductor (medial rectus) muscle is weak; when looking to the left, the left lateral rectus and right medial rectus are implicated (Fig. 14-6). A. Paralysis of right lateral rectus. Characteristic: right eye does not move to the right. Field: horizontal homonymous diplopia increasing on looking to the left. B. Paralysis of right medial rectus. Characteristic: right eye does not move to the left. Field: horizontal crossed diplopia increasing on looking to the left. C. Paralysis of right inferior rectus. Characteristic: right eye does not move downward when eyes are turned to the right. Field: vertical diplopia (image of right eye lowermost) increasing on looking to the right and down. D. Paralysis of right superior rectus. Characteristic: right eye does not move upward when eyes are turned to the right. Field: vertical diplopia (image of right eye uppermost) increasing on looking to the right and up. E. Paralysis of right superior oblique. Characteristic: right eye does not move downward when eyes are turned to the left. Field: vertical diplopia (image of right eye lowermost) increasing on looking to left and down. F. Paralysis of right inferior oblique. Characteristic: right eye does not move upward when eyes are turned to the left. Field: vertical diplopia (image of right eye uppermost) increasing on looking to left and up. (Adapted by permission from Cogan DG: Neurology of the Ocular Muscles, 2nd ed. Springfield, IL, Charles C. Thomas, 1956.)

2. If the separation is mainly horizontal, the paresis will be found in one of the horizontally acting recti (a small vertical disparity should be disregarded); if the separation is mainly vertical, the paresis will be found in the vertically acting muscles, and a small horizontal deviation should be disregarded.

3. The image projected farther from the center belongs to the paretic eye. With a red glass over the right eye, if the patient looks to the right and the red image is farther to the right, then the right rectus muscle is weak.

It must be remembered that the red-glass test distinguishes one of two muscles responsible for the movement in the direction of maximal separation of images. If the white image on right lateral gaze is to the right of the red (i.e., the image from the left eye is projected outward), then the left medial rectus muscle is weak. In testing vertical movements, again, the image seen with the eye with the paretic muscle is the one projected most peripherally in the visual field. For example, if the maximum vertical separation of images occurs on looking downward and to the left and the white image is projected farther down than the red, the paretic muscle is the left inferior rectus; if the red image is lower than the white, the paretic muscle is the right superior oblique. As already mentioned for a supplementary test, correction of vertical diplopia by a tilting of the head implicates the superior oblique muscle of the opposite side. Separation of images on looking up and to the right or left will similarly distinguish paresis of the inferior oblique and superior rectus muscles. The examiner is aided by committing to memory the cardinal actions of the ocular muscles shown in Fig. 14-5 and Table 14-2.

The red-glass test and other similar tests are most useful when a single muscle is responsible for the diplopia. If more than one muscle seems to be involved, one must be certain not to overlook myasthenia gravis and thyroid ophthalmopathy.

There are several alternative methods for studying the relative positions of the images of the two eyes. One, a refinement of the red-glass test, is the Maddox rod, in which the occluder consists of a transparent red lens with series of parallel cylindrical bars that transform a point source of light into a red perpendicular to the cylinder axes; the position of the red line is compared with the position of a white point source of light seen with the other eye. Another, the alternate cover test, requires less cooperation than the red-glass test and is, therefore, more useful in the examination of young and inattentive patients. It does, however, require sufficient visual function to permit central fixation with each eye. The test consists of rapidly alternating an occluder from one eye to another and observing the deviations from and return to the point of fixation, as described above in the discussion of tropias and phorias. Detailed descriptions of the Maddox rod and alternate cover test, which are the ones favored by neuro-ophthalmologists, can be found in the monographs of Leigh and Zee and of Glaser, listed with the references.

Monocular diplopia occurs most commonly in relation to diseases of the cornea and lens rather than the retina; usually the images are overlapping or superimposed rather than discrete. In most cases, monocular diplopia can be traced to a lenticular distortion or displacement, but in some no abnormality can be found. Monocular diplopia has been reported in association with cerebral disease (Safran et al.), but this must be a very rare occurrence. Occasionally patients with homonymous scotomas due to a lesion of the occipital lobe will see multiple images (polyplopia) in the defective field of vision, particularly when the target is moving.

Rarely, the acute onset of convergence paralysis may give rise to diplopia and blurred vision at all near points; most cases are due to head injury, some to
enzephalitis or multiple sclerosis. Many cases of convergence paralysis do not have a demonstrable neurologic basis. The acute onset of divergence paralysis causes diplopia at a distance because of crossing of the visual axes; in patients with divergent paralysis, images fuse only at a near position. This disorder, the pathologic basis of which is unknown, is difficult to distinguish from mild bilateral sixth nerve palsies and from convergence spasm, which is common in malingering and hysterics.

**Causes of Divergence Paralysis**

Paradoxical head trauma, ischemic infarction of a nerve (generally associated with diabetes), and aneurysms of the circle of Willis, in that order. In Rucker's series, the sixth nerve was affected in about half of the cases; third nerve palsies were about half as common as those of the sixth nerve; and the fourth nerve was involved in less than 10 percent of cases by Ruck, and Young, trauma was the cause of the unexplained sixth nerve palsy, particularly in diabetics. Tumor (either primary or metastatic) is the cause of the most obvious of these conditions. Aneurysms of the carotid and vertebrobasilar arteries, particularly in diabetics, are implicated in the majority of cases. The most common aneurysms are located in the internal carotid artery and the terminal portion of the vertebral artery. Mass lesions due to neoplasms or other causes may also produce secondarily secondary oculomotor palsy.

**Sixth Nerve Palsy**

An isolated sixth nerve palsy frequently proves to be caused by neoplasms. In children, the most common tumor involving the sixth nerve is a pontine glioma; in adults, it is a metastatic tumor arising from the nasopharynx. Thus it is essential that the nasopharynx be examined carefully in every case of unexplained sixth nerve palsy, particularly if it is accompanied by sensory symptoms on the side of the face. As the abducens nerve passes near the apex of the petrous bone, it is in close relation to the trigeminal nerve. Both may be implicated by petrositis, manifest by facial pain and diplopia (Gradengio syndrome). Fractures at the base of the skull and petrous clivus may tumors have an effect on the sixth nerve because of the proximity of the two nerves. Infarction of the sixth nerve occurs in cases of cerebral infarction, in which case there is usually pain in the inner canthus of the eye. An idiopathic form that occurs in the absence of diabetes, possibly arteritic or phlebitic, is also well known.

Unilateral or bilateral abductor weakness may be a non-specific sign of increased intracranial pressure from any source—including brain tumor, meningitis, and pseudotumor cerebriti; rarely, it may appear after lumbar puncture, epidual injections, or insertion of a ventricular shunt. Occasionally the nerve is compressed by a congenitally persistent trigeminal artery.

**Fourth Nerve Palsy**

The fourth nerve is particularly vulnerable to head trauma (this was the case in 43 percent of 323 cases of trochlear nerve lesions collected by Wray from the literature). A fair number of cases remain idiopathic even after careful investigation. The fourth and sixth nerves are practically never involved by aneurysms or tumors. This reflects the relative infrequency of carotid artery aneurysms in the infracavernous portion of the cavernous sinus, where they might impinge on the sixth nerve. (In contrast, supraclinoid aneurysms commonly involve the third nerve.) Herpes zoster ophthalmicus may affect any of the ocular motor nerves but particularly the trochlear, which shares a common sheath with the ophthalmic division of the trigeminal nerve. Diabetic infarction of the fourth nerve occurs, but far less frequently than the third nerve, and the sixth nerves. Trochlear nerve palsy may also be a false localizing sign in cases of increased intracranial pressure, but again not nearly as often as abducens palsy. Entrapment of the superior oblique tendon is a rare cause (Brown syndrome). In addition to the appropriate diplopia, there is focal pain at the corner of the orbit; hence it may be mistaken for the Tolosa-Hunt syndrome, discussed further on. Most cases are idiopathic. There have been instances of trochlear nerve palsy in patients with lupus erythematosus and with Sjogren syndrome, but their fundamental nature is not known.

**Superior Oblique Myokymia**

Another unusual condition, characterized by recurrent episodes of diplopia, monocular blurring of vision, and a tremulous sensation in the affected eye. It is usually benign and responds to carbamazepine, but rare instances presage pontine glioma or demyelinating disease. Compression of the fourth nerve by a small looped branch of the basilar artery has been suggested as the cause of the idiopathic variety, analogous to several other better documented cranial nerve vascular compression syndromes.

**Third Nerve Palsy**

The third nerve is commonly compressed by aneurysm, tumor, or temporal lobe herniation. In a series of 206 cases of third nerve palsy collected by Wray, neoplastic diseases accounted for 25 percent and aneurysms for 18 percent. Of the neoplasms, 25 percent were parasellar meningiomas and 4 percent pituitary adenomas. The palsy is usually chronic, progressive, and painless. As mentioned earlier, enlargement of the pupil is a sign of extracranial third nerve compression because of the peripheral location in the nerve of the pupilloconstrictor fibers. By contrast, as indicated above, infarction of the nerve, as occurs in diabetics, spares the pupils, since the lesion characteristically involves the central portion of the nerve. The oculomotor palsy that complicates diabetes (this was the cause in 11 percent of the Wray and Taylor series) develops over a few hours and is accompanied by pain, usually severe, in the forehead and around the eye. The prognosis for recovery (as in other nonprogressive lesions of the ocular motor nerves) is usually good because of the potential of the nerve to regenerate. Infarction of the third nerve may occur in nondiabetics as well.

In chronic compressive lesions of the third nerve (distal carotid, basilar, or, most commonly, posterior communicating artery aneurysm), pupillary involvement (miosis, miosis, vomitose statismata, etc.), the chronicity of the lesion may permit abberant nerve regeneration. This may be manifest by pupillary constriction on adduction of the eye or by retraction of the upper lid on downward gaze or adduction.

Rarely, children or young adults may have one or more attacks of oculomotor paralysis in conjunction with an otherwise typical migraine (ophthalmoplegic migraine). The muscles (both extrinsic and intrinsic) innervated by the oculomotor or, very rarely, by the abducens nerve, are affected. Presumably, intense strain of the vessels supplying these nerves or compression by edematous arteries causes a transitory ischemic paralysis. Arteriograms done after the onset of the palsy usually disclose no abnormality. The oculomotor palsy of migraine tends to recover; after repeated attacks, however, there may be permanent paresis.

**Painful Ophthalmoplegia**

The slow development of a painful unilateral ophthalmoplegia is most often traceable to an aneurysm, a tumor, or an inflammatory or granulomatous process in the anterior portion of the cavernous sinus or at the superior orbital fissure—Tolosa-Hunt syndrome, or an extension of the process known as orbital pseudotumor. Although there is little pathology on which to base an understanding of the latter two processes, they are both idiopathic orbital inflammations—Tolosa-Hunt syndrome involving the superior orbital fissure or the anterior cavernous sinus, and orbital pseudotumor causing inflammatory infiltration and enlargement of the extraocular muscles but sometimes including the globe and other orbital contents.

Orbital pseudotumor is accompanied by injection of the conjunctiva and lid and slight proptosis. The Tolosa-Hunt syndrome lacks these features but causes intra- and retro-orbital pain that may simulate migraine or cluster headache. In pseudotumor, pain is usually not so prominent as in the latter, which is discussed further on. When only the superior oblique muscle is involved, theBilateral pseudotumor can be considered. The various intracranial and extradural syndromes involving the oculomotor and other cranial nerves are summarized in Table 47.1 and Table 47.2.

**Acute Bilateral Ophthalmoplegia**

When this syndrome evolves within a few days, it raises a number of diagnostic considerations. Keane, who analyzed 60 such
cases, found the responsible lesion to lie within the brainstem in 18 (usually infarction and less often Wernicke disease), in the cranial nerves in 26 (Guillain-Barré syndrome or tuberculosis meningitis), within the cavernous sinus in 8 (tumors or infection), and at the myoneural junction in 8 (myasthenia gravis and botulism). The Guillain-Barré ophtalmoplegic form is almost always associated with circulating antibodies to GQ1b ganglioside. The chronic development of bilateral ophtalmoplegia is most often due to an ocular myopathy [the mitochondrial disorder known as progressive external ophthalmoplegia (page 1503), a restricted muscular dystrophy (page 1503), or thyroid ophtalmopathy (see page 1520)].

Several causes of pseudoparalysis of ocular muscles must be distinguished. In thyroid disease, a swollen and tight inferior or superior rectus muscle may limit upward and downward gaze; less frequently, involvement of the medial rectus limits abduction. In most instances of thyroid ophtalmopathy, diagnosis is not difficult. This disease is discussed further, on page 1525. In the number of cases, however (10 percent, according to Bahn and Heufelder), there are no signs of hypothyroidism. However, most of these patients have laboratory evidence of thyroid autoimmune disease. The extracocular muscle enlargement can be demonstrated by CT scans and ultrasonography, and their inelasticity by forced duction tests (the insertions of the extracocular muscles are anesthetized and grasped by toothed forceps and attempts to move the globe are restricted).

The Duane retraction syndrome (so called because of the retraction of the globe and narrowing of the palpebral fissure that are elicited by attempted adduction) is due to a congenital absence or hypoplasia of the abducens nucleus and nerve and aberrant innervation of the lateral rectus by branches of the third nerve. Conversely, the isolated involvement of the medial rectus, the superior rectus, or the inferior rectus results from an intrapontine or intracerebellar lesion. When both eyes move a few degrees toward the midline, it usually has no clinical significance. These movements are probably analogous to the tremulousness of skeletal muscle.

The pendular type is always a sign of an intrapontine or mesencephalic lesion due to a wide variety of pathologic changes.

Internuclear Ophthalmoplegia (INO) and Other Pontine Gaze Palsies

This abnormality has been alluded to sever times earlier as it is involved in numerous brainstem syndromes affecting both horizontal and vertical gaze. A lesion of the lower pons in or near the sixth nerve nucleus causes a hor oralateral paralysis of the lateral rectus muscle and a failure of adduction of the opposite eye—i.e., a combined paralysis of the sixth nerve and of conjugate lateral gaze. As already indicated, the pontine center accomplishes horizontal conjugate gaze by simultaneously innervating the ipsilateral lateral rectus (via the abducens neurons) and the contralateral medial rectus via fibers that originate in the internuclear neurons of the abducens nucleus and cross at the level of the nucleus to run in the medial longitudinal fasciculus (MLF) of the opposite side (Fig. 14-1). With a lesion of the left MLF, the right eye fails to adduct when the patient looks to the right; this condition is referred to as left internuclear ophthalmoplegia. With a lesion of the right MLF, the right eye fails to adduct when the patient looks to the left (right internuclear ophthalmoplegia). The limitation of ocular adduction is most evident with saccadic movements, brought about by large side-to-side refixation between two targets or by ocular rotation against corrected eye position may be caused by optokinetic stimulation. The two medial longitudinal fasciculi lie close together, each being situated adjacent to the midline, so that they are frequently affected together, yielding a bilateral internuclear ophthalmoplegia; this condition should always be suspected when adduction of both eyes is affected. Quite often, rather than a complete paralysis of adduction, there are greatly slowed adducting saccades in the affected eye while its opposite quickly arrives at its fully abducted position upon commanded gaze or refixation.

A second component of the INO is nystagmus that is limited to or more prominent in the abducting eye. Several explanations have been offered to account for this dissociated nystagmus, all of them hypothetical. The most favored explanation invokes Hering’s law—that activated yoke muscles receive equal and simultaneous innervation; because of an adaptive increase in innervation of the weak adductor, a commensurate increase in innervation to the strong abductor occurs (manifest as nystagmus). Whatever the afferent stimulus for this overdrive, it is probably proprioceptive, since occluding the affected eye does not suppress the nystagmus. Since the MLF contains axons that originate in the vestibular nuclei and govern vertical eye movements, a lesion of the MLF may also cause vertical nystagmus and impairment of vertical fixation and pursuit.

Lessions involving the MLF in the high midbrain may be associated with a loss of convergence (“anterior” internuclear ophtalmoplegia); if the MLF is involved by a lesion in the pons, convergence is spared, but some degree of horizontal gaze or sixth nerve palsy is often associated (“posterior” internuclear ophtalmoplegia).

The main cause of unilateral INO is a small paramedian pontine infarction. Other common causes are lateral medullary infarction (where skew deviation is often added), multiple sclerosis (more common as a cause of bilateral INO), lupus erythematosus, and inflammatory brainstem and fourth ventricular tumors. Occasionally INO is an unexplained finding after mild head injury or with subdural hematoma or hydrocephalus.

**Bilateral INO** is most often the result of a demyelinating lesion (multiple sclerosis) in the posterior part of the midpontine tegmentum. Pontine myelolysis, infarction, Wernicke disease, or infiltrating tumors are other causes bilateral INO.

Another pontine disorder of ocular movement combines an internuclear ophtalmoplegia in one direction and a horizontal gaze palsy in the other. One eye lies fixed in the midline for all horizontal movements; the other eye can make only abducting movements and may be engaged in horizontal nystagmus in the direction of abduction (“one-and-a-half syndrome” of Fisher; see Wall and Wray). The lesion in such cases involves the pontine center for gaze plus the ipsilateral MLF; it is usually due to vascular or demyelinating disease. Caplan has summarized the features of other mixed oculomotor defects that occur with throtbic occlusion of the upper or lower division of the basilar artery (“top of the basilar” syndromes). These include upgaze or complete vertigo gaze palsy and so-called pseudoabducens palsy. The latter is characterized by bilateral incomplete esotropia that simulates bilateral sixth nerve paresis but appears to be a type of sustained convergence or a pariesis of divergence; it can be overcome by vestibular stimulation.

Among the most unusual of the complex ocular disturbances is a subjective tilting of the entire visual field that may produce any angle of divergence but most often creates an illusion of 45 to 90 degrees (tortopia) or of 180-degree vision (upside-down vision). Objects normally on the floor, such as chairs and tables, are perceived to be on the wall or ceiling. Although this symptom may arise as a result of a lesion of the parietal lobe or in the otolithic apparatus, it is most often associated with an internuclear ophtalmoplegia and presumably with impaired function of the vestibular-otolithic nucleus or its central connections. Lateral medullary infarction has been the most common cause in our experience (Ropper).

**Nystagmus**

Nystagmus refers to involuntary rhythmic movements of the eyes and is of two general types. In the more common jerk nystagmus, the movements alternate between a slow component and a fast corrective component, or jerk, in the opposite direction. In pendular nystagmus, the oscillations are roughly equal in rate in both directions, although on lateral gaze the pendular type may be converted to the jerk type, with the fast component to the side of gaze.

**Jerk nystagmus** is the more common type. It may be horizontal or vertical, particularly on ocular movement in these planes, or it may be rotatory and rarely retractive or vertgent. By custom in the English-speaking world, the direction of the nystagmus is named according to the direction of the fast component. There are several varieties of jerk nystagmus. Some occur spontaneously; others are readily induced in normal persons by drugs or by labyrinthine or visual stimulation. Deviations from the patterns of normally induced nystagmus may provide important clues to the locus of disease.

In testing for nystagmus, the eyes should be examined first in the central position and then during upward, downward, and lateral movements. Nystagmus of labyrinthine origin is best thought out by eliminating visual fixation, facilitated by the use of Frenzel lenses. On the other hand, nystagmus of brainstem and cerebellar origin is brought out best by having the patient fixate upon and follow a moving target. Characteristically, labyrinthine nystagmus varies with position of the head; in particular, the benign positional vertigo of Barany (described more fully on page 321) is evoked by hypoperfusion and rotation of the neck, with the head being placed below the horizontal plane of the bed and turned to the side. Nystagmus of the vertical torsional type and vertigo develop in 10 to 15 s and persist for another 10 to 15 s. When the patient sits up quickly, the nystagmus reappears in the opposite direction.

In some normal individuals, a few irregular jerks are observed as they turn their eyes far to one side (“nystagmoid” jerks), but no sustained rhythmic movements occur once fixation is attained. A fine rhythmic nystagmus may occur in extreme lateral gaze, beyond the range of binocular vision; but if it is bilateral and disappears as the eyes move a few degrees toward the midline, it usually has no clinical significance. These movements are probably analogous to the tremulousness of skeletal muscle.
muscles that are maximally contracted.

Pendular nystagmus is found in a variety of conditions in which central vision is lost early in life, such as albinism and various other diseases of the retina and refractive media (congenital ocular nystagmus). Occasionally it is observed as a congenital abnormality, even without poor vision. The defect is postulated to be an inability of the gaze-holding, pursuit, or gazeholding mechanisms. Examples are occasionally seen in patients with multiple sclerosis. The nystagmus is always binocular and in one plane; i.e., it will remain horizontal even during vertical movement. It is purely pendular (sinuosoidal) except in extremes of gaze, when it comes to resemble jerk nystagmus. Head oscillation may accompany the nystagmus and is probably the compensatory. The formerly common syndrome of "miner's nystagmus" occurs in patients who have worked for many years in comparative darkness. The oscillations of the eyes are usually very rapid, increase on upward gaze, and may be associated with compensatory oscillations of the head and intolerance of light. Spasmus nutans, a specific type of pendular nystagmus of infancy, is accompanied by head nodding and occasionally by wry positions of the neck. Most cases begin between the fourth and twelfth months of life, never after the third year. The nystagmus may be horizontal, vertical, or rotatory; it is usually more pronounced in one eye than the other (or limited to one eye) and can be intensified by immobilization or straightening the head. Most infants recover within a few months or years. Rarely, symptoms like those of spasmus nutans betray the presence of a chiasmal or third ventricular tumor.

Apart from the pendular variety, nystagmus occurring spontaneously may signify the presence of labyrinthine-vestibular, brainstem, or cerebellar disease. Labyrinthine-vestibular nystagmus may be horizontal, vertical, or oblique, and that of purely labyrinthine origin characteristically has a torsional component. Tinnitus and hearing loss are often associated with disease of the peripheral labyrinthine mechanism; vertigo, nausea, vomiting, and staggering may accompany disease of any part of the labyrinthine-vestibular apparatus or its central connections. These points are elaborated in Chap. 15.

Nystagmus due to Brainstem-Cerebellar Disease Brainstem lesions often cause a coarse, unidirectional, gaze-dependent nystagmus, which may be horizontal or vertical, meaning that the nystagmus is exaggerated when the eyes sustain a position of gaze; vertical nystagmus is brought out usually on upward gaze, less often on downward gaze. The presence of bidirectional vertical nystagmus usually indicates disease in the pontomedullary or pontomesencephalic tegmentum. Vertigo is uncommon, but signs of disease of other nuclear structures and tracts in the brainstem are frequent. Upbeat nystagmus is observed frequently in patients with demyelinating or vascular disease, tumors, and Wernicke disease. There is still uncertainty about the precise anatomy of coarse upbeat nystagmus. According to some authors, it has been associated with lesions of the anterior vermis, but we have not observed such an association. Kato and associates cite cases with a lesion at the pontomedullary junction, involving the nucleus prepositus hypoglossi, which receives vestibular connections and projects to all brainstem and cerebellar regions concerned with oculomotor function.

Downbeat nystagmus, which is always of central origin, may be observed in Wernicke disease and is characteristic of syringobulbia, Chiari malformation, basilar idiopathy, and other lesions in the lateral stalk of patients with downward-fixation palsies. Downbeat nystagmus may also be demonstrated in those patients in whom the eye movements are bidirectional, and that in half of them this abnormality was associated with the Chiari malformation and various forms of cerebellar degeneration; in most of the remainder, the cause could not be determined. Downbeat nystagmus, in association with oscillopsia, has also been observed in patients with lithium intoxication or with profound magnesium depletion (Saul and Setsonh). The paraneoplastic opsoclonic disorder can begin with downbeat nystagmus.

Cerebellar-vestibular abnormalities may cause a coarse bilateral horizontal nystagmus, coarser to the side of the lesion. Nystagmus of several types—including gaze-evoked nystagmus, downbeat nystagmus, and “rebound” nystagmus (gaze-evoked nystagmus that changes direction with fatigue or reflexion to the primary position)—occurs with cerebellar disease (more specifically with lesions of the vestibulocerebellum) or with brainstem lesions that involve the nucleus prepositus hypoglossi and medial vestibular nucleus (see above, in relation to upbeat nystagmus). Characteristic also of cerebellar disease are several closely related disorders of saccadic movement (opsoclonus, flutter, dysmetria) described below.

Nystagmus that occurs only in the abducting eye is referred to as dissociated nystagmus and is a common sign of multiple sclerosis. Probably it represents an incompletely developed form of internuclear ophthalmoplegia; on attempted lateral gaze, the adducting eye (which does not show nystagmus) lags behind the abducting one.

Drug intoxication is the most frequent cause of induced nystagmus. Alcohol, barbiturates, other sedative-hypnotic drugs, and phenytoin are the common offenders. This form of nystagmus is most prominent on deviation of the eyes in the horizontal plane, but occasionally it may appear in the vertical plane as well. It rarely appears in the vertical plane alone, suggesting then a tegmental brainstem disorder. It may be asymmetrical in the two eyes, for no known reason.

Optokinetic Nystagmus When one is watching a moving object (e.g., the passing landscape from a train window or a rotating drum with vertical stripes or a strip of cloth with similar stripes), a rhythmic jerk nystagmus, optokinetic nystagmus (OKN), normally appears. The usual explanation of this phenomenon is that the slow component of the nystagmus represents an involuntary pursuit movement to the limit of comfortable conjugate gaze; the eyes then make a quick saccadic movement in the opposite direction in order to fixate a new target that is entering the visual field. With unilateral lesions of the parietal lobe (and transiently with acute frontal lobe lesions), OKN may be lost or diminished when a moving stimulus, e.g., the striped OKN drum, is rotated toward the side of the lesion, whereas rotation of the drum to the opposite side elicits a normal response. It should be again noted that patients with hemianopia may show a normal optokinetic response; patients with a parietal lobe lesion, with or without hemianopia, frequently have an abnormal optokinetic response with the stripes moving in the direction of the affected hemisphere. The same nystagmus is present in an abnormal patient with the geniculocortical syndrome (i.e., it is not due to a defect in the visual cortex). The condition exists in very different pathways from the parietal cortex to the brainstem centers for conjugate gaze. Frontal lobe lesions allow the eyes to deviate tonically in the direction of the target, with little or no fast-phase correction. An important fact about OKN is that its demonstration proves that the patient is not blind. Each eye can be tested separately to exclude monocular blindness. Thus it is of particular value in the examination of hysterical patients and malingerers who claim that they cannot see and of neonates and infants (a nascent OKN is established in within hours after birth and becomes more easily elicitable over the first few months of life).

Labyrinthine stimulation—e.g., irrigation of the external auditory canal with warm or cold water—produces nystagmus; cold water induces a slow tonic deviation of the eyes toward the interior of the affected ear, whereas a warm stimulus produces a corrective movement of the eyes toward the contralateral ear. Labyrinthine-vestibular nystagmus may be horizontal, vertical, or oblique, and that of purely labyrinthine origin characteristically has a torsional component. Head oscillation may accompany the nystagmus, which is really a tremor, is due to a lesion of the central tegmental tract and may be accompanied by a convergence-retraction nystagmus that has the same beat as the palatal and pharyngeal muscles as discussed on page 106.

Other Spontaneous Ocular Movements

Seesaw nystagmus is a torsional-vertical oscillation in which the intorting eye moves up and the opposite (extorting) eye moves down, then both move in the reverse direction. It is occasionally observed in conjunction with bitemporal hemianopia due to sellar or parasellar masses. So-called palatal nystagmus, which is really a tremor, is due to a lesion of the central tegmental tract and may be accompanied by a convergence-retraction nystagmus that has the same beat as the palatal and pharyngeal muscles as discussed on page 106.

Roving conjugate eye movements are characteristic of light coma. Slow horizontal ocular deviations that shift every few seconds from side to side ("ping-pong gaze") is a variant of roving eye movements that occurs with bihemispheric infarctions or sometimes with posterior fossa lesions. Fisher has noted a similar slow, side-to-side pendular oscillation of the eyes ("windshield-wiper eyes"). This phenomenon has been associated with bilateral hemispheric lesions that have presumably resulted from either ischemia or hemorrhage. Occasionally a distinctive spontaneous fast downhill jerk of the eyes followed by a slow upward drift to the midposition. It is usually observed in comatose patients in whom horizontal eye movements are absent and has been associated most often with large destructive lesions of the pons, less often of the cerebellum. The eye movements may be conjugate in the vertical plane, especially if there is an associated
third nerve palsy on one side.

Other spontaneous vertical eye movements, many identical to each other, have been given a variety of confusing names: *atypical bobbing, inverse bobbing, reverse bobbing*, and *ocular dipping*. For the most part, they are observed in coma of metabolic or anoxic origin and in the context of preserved horizontal eye movements (in dissociation). Ocular dipping is a term we have used to describe an arrhythmic slow conjugate downward movement followed in several seconds by a more rapid upward movement; it occurs unusually but may at times be elicited by pressing the limbs or neck. Anoxic encephalopathy has been the most common cause.

Opsoclonus is the term applied to rapid, conjugate oscillations of the eyes in horizontal, rotatory, and vertical directions, made worse by voluntary movement or the need to fixate the eyes. These movements are continuous and chronic, without an intersecassidic pause (saccocollomiraneum), and persist in sleep. Often, as indicated in Chap. 6, they are part of a widespread myoclonus (associated with parainfectious disease, occasionally with AIDS and rickettsial infections, but most characteristically they occur as a paraneoplastic manifestation (page 725). Opsoclonus may also be observed in patients intoxicated with antidepressants, anticonvulsants, organophosphates, cocaine, lithium, thallium, and haloperidol; in the nonketotic hyperosmolar state; and in cerebral Whipple disease, where it is coupled with rhythmic jaw movements (page 748). A childhood form associated with limb ataxia and myoclonus that is responsive to adrenocorticotropic hormone (ACTH) may persist for years without explanation, as in the "dancing eyes" of child-ren (Kinsbourne syndrome), although neuroblastoma remains the main consideration. There is also a self-limited benign form in neonates. Similar movements have been produced in monkeys by creating bilateral lesions in the pretectum.

Ocular dysmetria consists of an overshoot of the eyes on attempted fixation followed by several cycles of oscillation of diminishing amplitude until fixation is attained. The overshoot may occur on eccentric fixation or on refraction to the primary position of gaze. This abnormality probably reflects dysfunction of the anteroseverus vermis and underlying deep cerebellar nuclei. Ocular flicker refers to occasional bursts of very rapid horizontal nystagmus around the point of fixation; this abnormality is also associated with cerebellar disease. Flutter at the end of a saccade, called *flutter dysmetria* (*fish-tail nystagmus*), has the appearance of dysmetria, but careful analysis indicates that it is probably a different phenomenon. While the inaccurate saccades of ataxia are separated by normal intersaccadic intervals, *flutter dysmetria* consists of consecutive saccades without an intersaccadic interval (*Zee and Robinson*).

Opsoclonus, ocular dysmetria, and flutter-like oscillations may occur together, or a patient may show only one or two of these ocular abnormalities, either simultaneously or in sequence. One hypothesis relates opsoclonus and ocular flutter to a disorder of the sadic "pause neurons" (see above), but their exact anatomic basis has not been elucidated.

Disorders of the Eyelids and Blinking

A consideration of oculomotor disorders would be incomplete without some reference to the eyelids and blinking. In the normal individual, the eyelids on both sides are at the same level with respect to the limbus of the cornea and there is a variable prominence of the eyes, depending on the width of the palpebral fissure. The function of the eyelids is to protect the delicate corneal surfaces against injury and the retinae against glare; this is done by blinking and lacrimation. Eyelid movement is normally coordinated with ocular movement—the upper lids elevate when looking up and descend when looking down. Turning the eyes quickly to the side is usually attended by a single blink, which is necessarily brief so as not to interfere with vision.

Closure and opening of the eyelids is accomplished through the reciprocal action of thelevator palpebrae and orbicularis oculi muscles. Relaxation of the levator and contraction of the orbicularis effect closure; the reverse action of these muscles effects opening of the closed eyelids. Opening of the lids is aided by the tonic sympathetic innervation of Müller's muscles. The levator is innervated by the oculomotor nerve, and the orbicularis, by the facial nerve. The trigeminal nerves provide sensation to the eyelids and are also the afferent limbs of corneal and palpebral reflexes. Central mechanisms for the control of blinking, in addition to the reflexive brainstem connections between the third, fifth, and seventh nerve nuclei, include the cerebrum, basal ganglia, and hypothalamic. Voluntary closure is initiated through frontobasal ganglionic connections.

The eyelids are kept open by the tonic contraction of thelevator muscles, which overcomes the elastic properties of the periorbital muscles. The eyelids close during sleep and certain altered states of consciousness due to relaxation of thelevator muscles. Facial paralysis causes the closure to become incomplete.

*Blinking* occurs irregularly at a rate of 12 to 20 times a minute, the frequency varying with the state of concentration and with emotion. The natural stimuli for the blink reflex is a tap on the brow or around the eye, visual threat, an unexpected loud sound, and, as indicated above, turning of the eyes to one side. There is normally a rapid adaptation of blink to visual and auditory stimuli but not to corneal stimulation.

Electromyography of the orbicularis oculi reveals two components of the blink response, an early and an late one, a feature that is readily corroborated by clinical observation. The early response consists of only a slight movement of the upper lids; the later response is more forceful and approximates the upper and lower lids. Whereas the early part of the blink reflex is beyond volitional control, the second part can be inhibited voluntarily.

*Blepharospasm*, an excessive and forceful closure of the lids, which is described on page 114, is a common disorder that occurs in isolation or as part of a number of dyskinesias and drug-induced movement disorders (pages 1254 and 1637). Increased blink frequency occurs with corneal irritation, with sensitization of trigeminal nociceptive fibers, and with certain neurological diseases such as dystonic syndromes, such as blepharospasm. A reduced frequency of blinking (<10 per minute) is characteristic of progressive supra–nuclear palsy and Parkinson disease. In the latter, adaptation to repeated supraorbital tapping at a rate of about 1 per second is impaired; therefore the patient continues to blink with each tap on the forehead or glabella. The failure to inhibit this response is referred to as the glabellar, or *Myerson sign*.

A lesion of the oculomotor nerve, by paralyzing the levator muscle, causes *ptosis*, i.e., drooping of the upper eyelid. A lesion of the facial nerve, as in Bell's palsy, results in an inability to close the eyelids due to weakness of orbicularis oculi, a slight retraction of the upper lid (due to the unopposed action of the levator), and loss of the blink reflex. In some instances of Bell's palsy, even after nearly full recovery of facial movements, the blink frequency may be reduced on the affected side. Of neurologic importance is the fact that a trigeminal nerve lesion on one side, by reducing corneal sensation, interferes with the blink reflex on both sides, while a Bell's palsy does not abolish the contralateral blink. Afferent regeneration of the third nerve may result in a condition wherein the upper lid retracts on lateral or downward gaze (pseudo–von Graefe sign). Afferent regeneration of the facial nerve after Bell's palsy has an opposite effect—closure of the lid with jaw movements or speaking. A useful clinical rule is that a combined paralysis of the levator and orbicularis oculi muscles (i.e., the muscles that open and close the lids) nearly always indicates a myopathic disease, such as myasthenia gravis or myotonic dystrophy. This is because the third and seventh cranial nerves are rarely affected together in peripheral nerve or brainstem disease.

Bilateral ptosis is a characteristic feature of muscular dystrophies and myasthenia gravis; congenital ptosis and progressive sagging of the upper lids in the elderly are other common forms. Unilateral ptosis is a notable feature of third nerve lesions (see above) and of sympathetic paralysis, as in the Horner syndrome. It may be accompanied by an overaction (compensation) of the frontalis and the contralateral levator palpebrae muscles. This combination of abnormalities may be observed with myasthenia gravis and with compensatory ptosis in diplopia. Patients with myasthenia, Cogan has described a "lid twitch" phenomenon, in which there is a transient retraction of the upper lid when the patient moves visual fixation from the down position to straight ahead. Brief flltering of the lid margins is also characteristic of myasthenia.

The opposite of ptosis, i.e., *retraction* of the upper lids, often with a staring expression, is observed with orbital tumors and thyroid disease, the most common causes of unilateral and bilateral ptosis. A staring appearance alone is observed in Parkinson disease, progressive supranuclear palsy, and hydrocephalus, in which there is downturnint of the eyes ("sunset sign") and paralysis of upward gaze. Retraction of the eyelids (Collier sign), when part of a dorsal midbrain syndrome, is accompanied by a light-near pupillary dissociation; it is not accompanied by a lid lag (von Graefe sign) on downward gaze, in distinction to what is observed in thyroid opthalmopathy. Lid retraction has been observed in patients with hepatic cirrhosis. Congenital or myopathic congenital ptosis is often associated with periodic paralytic attacks; in these conditions, lid lag is also absent. Lid retraction can be a reaction to ptosis on the other side; this is clarified by lifting the ptotic lid manually and observing the disappearance of contralateral retraction.

In myotonic dystrophy and other less common myotonic disorders, forceful closure of the eyelids may induce a strong aftercontraction. In certain extrapyramidal diseases, particularly progressive supranuclear palsy and Parkinson disease, even gentle closure may elicit blepharochoroniun and blepharospasm on attempted opening of the lids; or there may be a delay in the opening of the tightly closed eyelids. An acute right parietal lesion or bifrontal lesions often produce a peculiar disinhibition to open the eyelids, even to the point of offering active resistance upon attempts at forced opening.
THE PUPILS

The testing of pupillary size and reactivity, which can be accomplished by the use of a flashlight and simple pupillometer (we have used the circular laminated card known as the Iowa pupal gauge), yields important, often vital clinical information. Essential, of course, is the proper interpretation of the pupillary reactions, and this requires some knowledge of their underlying neural mechanisms.

The diameter of the pupil is determined by the balance of innervation between the autonomically innervated sphincter and radially arranged dilator muscles of the iris, the sphincter muscle playing the major role. The pupilloconstrictor (parasympathetic) fibers arise in the Edinger-Westphal nucleus in the high midbrain, join the third cranial (oculomotor) nerve, and synapse in the ciliary ganglion, which lies in the posterior part of the orbit. The postganglionic fibers then enter the globe via the short ciliary nerves; approximately 3 percent of the fibers innervate the sphincter pupillae and 97 percent, the ciliary body. The sphincter of the pupil comprises 50 motor units, according to Corbett and Thompson. The pupillodilator (sympathetic) fibers arise in the posterior lateral part of the hypothalamus and descend, uncrossed, in the lateral tegmentum of the midbrain, pons, medulla, and cervical spinal cord to the eighth cervical and first and second thoracic segments, where they synapse with the lateral horn cells. The latter cells give rise to preganglionic fibers, most of which leave the cord by the second ventral thoracic root and proceed through the stellate ganglion to synapse in the superior cervical ganglion; the postganglionic fibers course along the internal carotid artery and traverse the cavernous sinus, where they join the first division of the trigeminal nerve, finally reaching the eye as the long ciliary nerve. Some of the postganglionic fibers also innervate the sweat glands and arterioles of the face and Müller’s muscle in the eyelid.

The Pupillary Light Reflex

The commonest stimulus for pupillary constriction is exposure of the retina to light. Reflex pupillary constriction is also part of the act of convergence and accommodation for near objects (near-synkinesis).

The pathway for the pupillary light reflex consists of three parts (Fig. 14-7):

1. An afferent limb, whose fibers originate in the retinal receptor cells, pass through the bipolar cells, and synapse with the retinal ganglion cells; axons of these cells run in the optic nerve and tract. The light reflex fibers leave the optic tract just rostral to the lateral geniculate body and enter the midbrain, where they synapse in the pretectal nucleus.

2. Interneuronal neurons that give rise to the pupillomotor fibers, which pass ventrally to the ipsilateral Edinger-Westphal nucleus and, via fibers that cross in the posterior commissure, to the contralateral Edinger-Westphal nucleus (labeled “pretecto-oculomotor” tract in Fig. 14-7).

3. An efferent two-neuron pathway from the Edinger-Westphal nucleus, synapsing in the ciliary ganglion, by which all motor impulses reach the pupillary sphincter, as described above.

Alterations of the Pupils

The pupils tend to be large in children and small in the aged, sometimes markedly miotic but still reactive (serile miosis). An asymmetry of the pupils of 0.3 to 0.5 mm is found in 20 percent or more of normal individuals. A lesion that destroys only a small number of nerve cells in the Edinger-Westphal nucleus or ciliary ganglion will cause paralysis of a sector or sectors of the iris and deform the pupil.

Normally the pupil constricts under a bright light (direct reflex), and the other unexposed pupil also constricts (consensual reflex). With complete or nearly complete interruption of the optic nerve, the pupil will fail to react to direct light stimulation; however, the pupil of the blind eye will still show a consensual reflex, i.e., it will constrict when light is shone in the healthy eye. The lack of a direct reflex in the blind eye together with lack of a consensual reflex in the sound one means that the afferent limb of the reflex arc (optic nerve) is the site of the lesion. A lack of direct and consensual light reflex with retention of the consensual reflex in the opposite eye places the lesion in the afferent limb of the reflex arc, i.e., in the homolateral oculomotor nerve or its nucleus. A lesion of the afferent limb of the light reflex pathway will not affect the near responses of the pupil and lesions of the visual pathway caudal to the point where the light reflex fibers leave the optic tract won’t alter the pupillary light reflex (Fig. 14-7).

Following initial constriction, the pupil may dilate slightly in spite of a light shining steadily in one or both eyes. Slowness of response along with failure to sustain pupillary constriction, or “pupillary escape,” is sometimes referred to as the Gunn pupillary sign; a mild degree of it may be observed in normal persons, but it is far more prominent in cases of damage to the retina or optic nerve. A variant of this pupillary response may be used to expose mild degrees of retrobulbar neuropathy (relative afferent pupillary defect). This is best tested in a dimly lit room with the patient fixating on a distant target. If a light is shifted quickly from the normal to the impaired eye, the direct light stimulus is no longer sufficient to maintain the previously evoked consensual pupillary constriction and both pupils dilate. These abnormal pupillary responses form the basis of the “swinging-flashlight test,” in which each pupil is alternately exposed to light at 3-s intervals.

The Gunn pupillary sign is not to be confused with the Gunn “jaw-winking” phenomenon, a congenital and sometimes hereditary anomaly, in which a ptotic eyelid retracts momentarily when the mouth is opened or the jaw is moved to one side. In other cases, inhibition of the levator muscle and ptosis occurs with opening of the mouth (“Inverse Marcus Gunn phenomenon,” or Marín Amat syndrome). Hippus, a rapid alternation in pupillary size, is common in metabolic encephalopathy but has no particular significance.

Interruption of the sympathetic fibers—either centrally, between the hypothalamus and their points of exit from the spinal cord (C8 to T3, mainly T2), or peripherally (cervical sympathetic chain, superior cervical ganglion, or along the carotid artery)—results in miosis and ptosis (because of paralysis of the pupillary dilator muscle and of Müller’s muscle, respectively), loss of sweating on the same side of the face, and redness of the conjunctiva. The entire complex is called the Horner syndrome, Bernard-Horner syndrome, or oculosympathetic palsy (page 566). It may be due to ipsilateral lesions of the medulla or cervical cord or to peripheral lesions. The pattern of sweating may be helpful in localizing the lesion (Morris et al.). With lesions of the common carotid artery, loss of sweating involves the entire side of the face. With lesions distal to the bifurcation, loss of sweating is confined to the medial aspect of the forehead and side of the nose. Retraction of the eyebrow (enophthalmos) is probably an illusion created by narrowing of the palpebral fissure. A hereditary form (autosomal dominant) of the Horner syndrome is known, associated with a congenital absence of pigment in the affected iris (heterochromia iridum). Bilateral Horner syndrome is a rare occurrence; usually it is found in autonomic neuropathies and in high cervical cord transaction. Although difficult to appreciate, it may be detected (using pupillometry) by noting a lag in the redilation of the initially small pupils when light is withdrawn (Smith and Smith).

Stimulation or irritation of the sympathetic fibers has the opposite effect, i.e., lid retraction, dilatation of the pupil, and apparent proptosis. The ciliospinal pupillary reflex, evoked by pinching the neck (afferent, C2, C3), is effected through the effenter sympathetic fibers, but we have not found it to be a reliable test.
Extreme constriction of the pupils (miosis) is commonly observed in pontine lesions, presumably because of bilateral interruption of the pupillodilator fibers. Narcotic ingestion is the commonest cause. Interruption of the parasympathetic fibers causes an abnormal dilation of the pupils (mydriasis), often with loss of pupillary light reflexes; this is frequently the result of midbrain lesions and is a common finding in cases of deep coma (the “blown pupil,” or Hutchinson pupil, described in Chap. 17) and where the descending pupillodilator fibers are in close proximity to the light reflex fibers (Fig. 14-7). The possibility of a partial third nerve lesion extending to the ciliary ganglion seems more plausible to us. A similar pupillary abnormality has also been observed in the meningococcalies of Lyme disease. A dissociation of the light reflex from the accommodation-convergence reaction is also sometimes observed with a variety of midbrain lesions—e.g., pinealoma, multiple sclerosis—and occasionally in patients with diabetes mellitus; in these diseases, miosis, irregularity of pupils, and failure to respond to a mydriatic are usually not present. S. A. K. Wilson referred to this condition as the Argyll Robertson pupil phenomenon, in contrast to the Argyll Robertson pupil.

Another interesting pupillary abnormality is the tonic reaction, also referred to as the Adie pupil. This syndrome is due to a degeneration of the ciliary ganglia and the postganglionic parasympathetic fibers that normally constrict the pupil and effect accommodation. The patient may complain of unilateral blurring of vision or may have noticed that one pupil is larger than the other. The affected pupil is slightly enlarged in ambient light and the reaction to light is absent or greatly reduced if tested in the customary manner; although the size of the pupil will change slowly with prolonged maximal stimulation. Characteristically, there is a light-near dissociation, i.e., the Adie pupil responds better to near than it does to light. Once the pupil has constricted, it tends to remain tonically constricted and redilate very slowly. Once dilated, the pupil remains in this state for many seconds, up to a minute or longer. Light and near paralysis of a segment or segments of the pupillary sphincter is also characteristic of the syndrome; this segmental irregularity can be seen with the high plus lenses of an ophthalmoscope. The affected pupil constricts promptly in response to the common miotic drugs and is unusually sensitive to a 0.1% solution of pilocarpine, a concentration that has only minimal effect on a normal pupil (deneration supersensitivity). The tonic pupil usually appears during the third or fourth decade of life and is much more common in women than in men; it may be associated with absence of knee or ankle jerks (Holmes-Adie syndrome) and hence be mistaken for tabs dorsalis. From all available data, it represents a mild polyneuropathy, often familial.

Finally, mention should be made of a rare pupillary phenomenon characterized by transient episodes of unilateral mydriasis for which no cause can be found (the “springing pupil”). These episodes of mydriasis, which are more common in women, last for minutes to days and may recur at random intervals. Ocular motor palsies and ptosis are notably lacking, but sometimes the pupil is distorted during the attack. Some patients complain of blurred vision and head pain on the side of the mydriasis, suggesting an atypical form of ophthalmoplegic migraine. In children, following a minor or major seizure, one pupil may remain dilated for a protracted period of time. The main consideration in an awake patient is that the cornea has inadvertently (or purposefully) been exposed to mydriatic solutions, among them vasopressor agents used in cardiac resuscitation.

**Differential Diagnosis of Anisocoria**

In regard to pupillary disorders, there are two main issues with which the neurologist has to contend. One is the problem of the relative afferent pupillary defect and how to recognize it; this is discussed above. The second problem is one of unequal pupils (anisocoria) and determining whether this abnormality depends upon sympathetic or parasympathetic denervation.

As stated above, in dealing with anisocoria, it is important to remember that at any given examination, 20 percent of normal persons show an inequality of 0.3 to 0.5 mm or more. This is “simple” or physiologic anisocoria, and it may be a source of confusion in patients with small pupils. It is characteristically variable from day to day and even from hour to hour and often will have disappeared at the time of the second examination (Loewenfeld; Lam et al.). Also, in first dealing with the problem of pupil size, one has to determine which of the pupils is abnormal. If it is the larger one, the light reaction will be muted on that side; if it is the smaller pupil, it will fail to enlarge in response to shading both eyes. More simply stated, light exaggerates the anisocoria due to a third-nerve lesion, and darkness accentuates the anisocoria in the case of a Horner syndrome.

A persistently small pupil always raises the question of a Horner syndrome, a diagnosis that may be difficult if the ptosis is slight and facial anesthesia undetectable. In darkness, the Horner pupil dilates more slowly and to a lesser degree than the normal one because it lacks the pull of the dilator muscle (dilation lag). The diagnosis can be confirmed by placing 1 or 2 drops of 2 to 10% cocaine in each eye; the Horner pupil dilates not at all or much less than the normal one—a response that can be documented by photos taken after 5 and 15 s of darkness. Such a response to cocaine will occur with a defect at any point along the sympathetic pathway (page 552) because lesions of the first- or second-order sympathetic neurons deplete norepinephrine at the synapses with third-order neurons. The reduction of neurotransmitter at the nerve endings in the ciliary dilator muscle greatly reduces the reuptake blocking effects of cocaine. If the subsequent (24 h after cocaine) application of the adrenergic mydriatic hydroxyamphetamine (1%) has no effect, the lesion can be localized to the postganglionic portion of the pathway since this drug releases any norepinephrine that may remain in the third order neuron. Localization of the lesion to the central or preganglionic parts of the sympathetic pathway depends upon the associated symptoms and signs (Chap. 26).

A variety of lesions, some of them equally, such as uveitis, may give rise to a dilated pupil. Neuropsychologically, there are three main diagnostic considerations:

1. An interruption of the parasympathetic preganglionic pupilloconstrictor fibers in the third nerve. It is a safe clinical rule that the interruption of these fibers is practically always associated with ptosis, palsy of the extracocular muscles, or signs of other brainstem or cerebral disease. The importance of unilateral pupillary enlargements in the diagnosis of coma is discussed in Chap. 17. Often in this circumstance the pupil goes through an early phase of miosis followed by irregularly shaped enlargement.

2. The presence of a tonic, or Adie, pupil. Here one requires that the pupillary abnormalities conform to the diagnostic criteria for this disorder, enumerated above.

3. Drug-induced iridoplegia. Not infrequently, particularly among nurses and pharmacists, a mydriatic fixed pupil is the result of accidental or deliberate application of pupilconstricting drugs. Atrophy of the iris is associated in some cases. This is known as the Argyll Robertson pupil. The exact locality of the lesion is not certain; it is generally believed to be in the tectum of the midbrain proximal to the oculomotor nuclei, where the descending pupillodilator fibers are in close proximity to the light reflex fibers (Fig. 14-7). The possibility of a partial third nerve lesion extending to the ciliary ganglion seems more plausible to us. A similar pupillary abnormality has also been observed in the meningococcalies of Lyme disease. A dissociation of the light reflex from the accommodation-convergence reaction is also sometimes observed with a variety of midbrain lesions—e.g., pinealoma, multiple sclerosis—and occasionally in patients with diabetes mellitus; in these diseases, miosis, irregularity of pupils, and failure to respond to a mydriatic are usually not present. S. A. K. Wilson referred to this condition as the Argyll Robertson pupillary phenomenon, in contrast to the Argyll Robertson pupil.

As a rule, bilateral smallness of pupils does not pose a difficult diagnostic problem. The clinical associations, acute and chronic, have already been discussed. Long-standing bilateral Adie pupils tend to be small and show tonic near responses. They can be readily distinguished from Argyll Robertson pupils, which constrict quickly to near and redilate quickly on release from the near stimulus.

**Figure 14-8** is a useful schematic, devised by Thompson and Pilley, for sorting out the various types of anisocoria.
Orbital Mass Lesions

Ocular movement, pupillary reaction, and visual acuity may be affected by diseases that alter the contents of the orbit. The most frequent of these is thyroid disease, causing bilateral or unilateral exophthalmos. Orbital tumors (dermoids, hemangiomas, adenoma of lacrimal gland, optic nerve glioma, neurofibroma, metastatic carcinoma, meningioma), granuloma (including sarcoid and orbital pseudotumor), orbital cellulitis or abscess, or cavernous sinus thrombosis are other causes of unilateral exophthalmos.
Hearing is one of our most precious possessions. Sounds alert us to danger; spoken words are the universal means of communication; music is one of our most exalted aesthetic pleasures. The loss of this sense excludes the individual from much of what is going on around him, and adjustment to this deprivation imposes a profound reorientation. Prevention of deafness is a goal toward which medicine strives. Likewise, our vestibular function assures our ability to stand steadily and erect and to move about gracefully. Hence an understanding of the functions of the eighth cranial nerves and their derangements by disease is the legitimate concern of the neurologist.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

The vestibulocochlear or eighth cranial nerve has two separate components: the cochlear nerve, which subserves hearing, or acoustic function, and the vestibular nerve, which is concerned with equilibrium, or balance, and orientation of the body to the surrounding world.

The acoustic division has its cell bodies in the spiral ganglion of the cochlea. This ganglion is composed of bipolar cells, the peripheral processes of which convey auditory impulses from the specialized neuroepithelium of the inner ear, the spiral ganglion of Corti. This is the end organ of hearing, wherein sound is transduced into nerve impulses. It consists of approximately 15,000 neuroepithelial (hair) cells, resting on the basilar membrane, which extends along the entire 21/2 turns of the cochlea. Projecting from the inner surface of each hair cell are approximately 60 very fine filaments, or stereocilia, which are embedded in the tectorial membrane, a gelatinous structure overlying the organ of Corti (Fig. 15-1). Sound causes the basilar membrane to vibrate; upward displacement of the basilar membrane bends the relatively fixed stereocilia and provides the adequate stimulus for activating the hair cells. The stimulus is then transmitted to the sensory fibers of the cochlear nerve, which end synaptically at the base of each hair cell. Each afferent auditory fiber and the hair cell with which it is connected has a minimum threshold at one frequency (“characteristic” or “best” frequency). The basilar membrane vibrates at different frequencies throughout its length, according to the frequency of the sound stimulus. In this way the fibers of the cochlear nerve respond to the full range of audible sound and can differentiate and resolve complexes of sounds.
Secondary acoustic fibers project via the trapezoid body and lateral lemniscus to the medial geniculate bodies (Fig. 15-2). Some fibers terminate in the trapezoid body and superior olivary complex and subserve such reflex functions as auditory attention, sound localization, auditory startle, and oculo-postural orientation to sound. Both excitatory and inhibitory neurons are located at every level of these pathways. From the medial geniculate bodies fibers project to the cortex via the auditory radiations—relatively compact bundles that course ventrolaterally to the posterior parts of the putamens before dispersing and ending in the transverse gyri of Heschl and other auditory cortical areas (Tanaka et al).

**Figure 15-2** The ascending auditory pathways. The lower part of the diagram is a horizontal section through the upper medulla. (Reproduced with permission from Noback CR: The Human Nervous System, 3rd ed. New York, McGraw-Hill, 1981.)

The auditory cortical field comprises the superior temporal gyrus and the upper bank of the sylvian fissure (area 41), or primary auditory cortex, and the surrounding secondary and tertiary cortices in the adjacent temporal lobe. The latter are of particular importance in the interpretation of sound (Celesia). Bilateral temporal lobe lesions involving the geniculocortical fasciculi result in cortical deafness although such lesions are rare; unilateral cortical lesions do not affect hearing. At every level of these ascending fiber systems there is feedback to lower structures.

The vestibular fibers of the eighth nerve terminate in the four vestibular nuclei: superior (Bechterew), lateral (Deiters), medial (triangular, or Schwalbe), and inferior (spinal, or descending). In addition, some of the fibers from the semicircular canals project directly to the cerebellum via the juxtarestiform body and terminate in the flocculonodular lobe and adjacent vermal cortex ("vestibulocerebellum"). Efferent fibers from this portion of the cerebellar cortex project ipsilaterally to the vestibular nuclei and to the fastigial nucleus; in turn, fibers from the fastigial nucleus project to the contralateral vestibular nuclei, again via the juxtarestiform body. Thus each side of the cerebellum exerts an influence on the vestibular nuclei of both sides (Fig. 15-3; see also Chap. 5).

**Figure 15-3** A simplified diagram of the vestibulocerebellar and vestibulo-spinal pathways and connections between vestibular and ocular motor nuclei. The medial longitudinal fasciculi (dotted vertical lines) are the main pathways for ascending vestibular impulses. (See text and also Fig. 14-1.)

The lateral and medial vestibular nuclei also have important connections with the spinal cord, mainly via the uncrossed lateral vestibulospinal tract and the crossed and uncrossed medial vestibulospinal tracts (Fig. 15-4). Presumably, vestibular effects on posture are mediated via these pathways—the axial muscles being acted upon predominantly by the medial vestibulospinal tract and the limb muscles, by the lateral tract. The nuclei of the third, fourth, and sixth cranial nerves come under the influence of the vestibular nuclei, mainly the superior and medial nuclei, through the projection pathways, mainly the medial longitudinal fasciculus described in Chap. 14. In addition, all the vestibular nuclei have afferent and efferent connections with the pontine reticular formation (Fig. 15-4). The latter connections subserve vestibulo-ocular and vestibulospinal reflexes that are essential for clear vision and stable posture. Finally, there are projections from the vestibular nuclei to the cerebral cortex, specifically to the regions of the intraparietal sulcus and superior sylvian gyrus. In the monkey, these projections are almost exclusively contralateral, terminating near the "face area" of the first somatosensory cortex (area 2 of Brodmann). Lesions in the posterior insula impair the sense of verticality, body orientation, and movement.

**Figure 15-4** The vestibular reflex pathways. (Reproduced by permission from House EL, et al: A Systematic Approach to Neuroscience. New York, McGraw-Hill, 1979.)

These brief remarks convey some notion of the complexity of the anatomic and functional organization of the vestibular system (for a full discussion, see the monographs of Brodal and of Baloh and Honrubia). In view of the proximity of cochlear and vestibular elements, it is understandable that acoustic and vestibular function are often affected together in the course of disease; each may be affected separately, however.

**DEAFNESS, TINNITUS, AND OTHER DISORDERS OF AUDITORY PERCEPTION**

**Deafness**

This is a problem of immense proportions. In 1969, Konigsmark estimated that there were in the United States at least 6 million persons with hearing loss of sufficient severity to impair the understanding of speech; there were probably three times this many with some impairment of hearing. Konigsmark also estimated that in about
half of the affected children and about one-third of the affected adults, the deafness was on a hereditary basis. Figures from a more recent (1989) National Health Survey indicated that approximately 28 million Americans of all ages had a significant degree of deafness and that 2 million of this group were profoundly deaf. More than one-third of persons over the age of 75 were handicapped to some extent by hearing loss.

Deafness is of three general types: (1) Conductive deafness, due to a defect in the mechanism by which sound is transformed (amplified) and conducted to the cochlea. Disorders of the external or middle ear—obstruction of the external auditory canal by atresia or cerumen, thickening of the tympanic membrane from infection or trauma, chronic otitis media, otosclerosis (the cause of deafness in early adult life), and obstruction of the eustachian tube—are the main causes. (2) Sensorineural deafness (also called nerve deafness), which is due to disease of the cochlea or of the cochlear division of the eighth cranial nerve. Although cochlear and eighth nerve causes of deafness have conventionally been combined in one (sensorineural) category, the neurologist recognizes that the symptoms and causes of the two are quite different and that it is more practical to think of them separately. (3) Central deafness, due to lesions of the cochlear nuclei and their connections with the primary auditory receptive areas in the temporal lobes. Complete tone deafness, which is probably inherited as an autosomal dominant trait, is another central disorder.

The two peripheral forms of deafness, conductive and nerve deafness, must be distinguished, since important remedial measures are available for the former. In differentiating conductive from nerve deafness, the tuning-fork tests are often of value. When a vibrating fork, preferably of 512-Hz frequency, is held about 2.5 cm from the ear (the test for air conduction), sound waves can be appreciated only as they are transmitted through the middle ear; they will be reduced with disease in this location. When the vibrating fork is applied to the skull (test for bone conduction), the sound waves are conveyed directly to the cochlea, without intervention of the sound-transmission apparatus of the middle ear, and will therefore not be reduced or lost. Normally air conduction is better than bone conduction. These principles form the basis for several simple tests of auditory function.

In the Weber test, the vibrating fork is applied to the forehead in the midline. A normal person hears the bone-conducted sound equally in both ears. In nerve deafness, the sound is localized in the normal ear; in conductive deafness, the sound is localized in the affected ear. In the Rinne test, the fork is applied to the mastoid process. At the moment the sound ceases, the fork is held at the auditory meatus. In middle ear deafness, the sound cannot be heard by air conduction after bone conduction has ceased (abnormal or negative Rinne test). In nerve deafness, the reverse is true (normal or positive Rinne test), although both air and bone conduction may be quantitatively decreased. The Schwabach test consists of comparing the patient's bone conduction with that of a normal examiner.

In general, early sensorineural deafness is characterized by a partial loss of perception of high-pitched sounds and conductive deafness by a partial loss of low-pitched sounds. This can be ascertained by the use of tuning forks of different frequencies but most accurately by the use of an audiometer and the construction of an audiogram, which reveals the entire range of hearing at a glance. The audiogram is the one essential test in the evaluation of hearing loss and the point of departure for subsequent diagnostic evaluation.

A cochlear type of hearing loss can be recognized by eliciting the symptoms of recruitment and diplacusis. There is a heightened perception of loudness, or recruitment, once the threshold for hearing has been exceeded; thus the common retort “You don’t have to shout” when the examiner raises his voice. Diplacusis refers to a defect in frequency discrimination that is manifest by a lack of clarity of spoken syllables or by the perception that music is out of tune and unpleasant.

Since each cochlear nucleus is connected with the cortex of both temporal lobes, hearing is unaffected by unilateral cerebral lesions. Deafness due to brainstem lesions is observed only rarely, since a massive lesion is required to interrupt both the crossed and uncrossed projections from the cochlear nuclei—so massive, as a rule, that other neurologic abnormalities make the testing of hearing impossible.

The main causes of sensorineural and conductive hearing loss are discussed further on.

Special Audiologic Procedures

A number of special tests have proved to be helpful in distinguishing cochlear from retrocochlear (nerve) lesions. Although an absolute distinction cannot be made on the basis of any one test, the results of the tests when taken together (particularly loudness recruitment and threshold tone decay) make it possible to predict the site of the lesion with considerable accuracy. These tests, usually carried out by an otologist or audiologist, include the following:

1. **Loudness recruitment.** This phenomenon, alluded to above, is thought to depend upon the selective destruction of low-intensity elements subserved by the external hair cells of the organ of Corti. The high-intensity elements are preserved, so that loudness is appreciated only at high intensities. In testing for loudness recruitment, the difference in hearing between the two ears is estimated and the loudness of the pure tone stimulus of a given frequency delivered to each ear is then increased by regular increments. In *nonrecruiting deafness* (characteristic of a nerve lesion), the original difference in hearing persists in all comparisons of loudness above threshold, while both high- and low-intensity fibers are affected. In recruiting deafness (which occurs with a lesion in the organ of Corti—e.g., Ménière disease), the more affected ear gains in loudness and may finally be equal to the better one. In bilateral disease, recruitment is assessed by the intensity of the stimulus that causes discomfort. In the normal person, the threshold of discomfort is about 100 dB (decibels).

2. **Threshold “tone decay” (abnormal auditory adaptation).** This test requires only a conventional pure-tone audiometer. With lesions of the nerve, e.g., acoustic neuroma, a continuous tone presented at or above threshold intensity gradually seems to decrease in loudness, in contrast to what happens with cochlear lesions.

3. **Short-increment sensitivity index (SISI).** The patient is asked to respond to a series of twenty 1-dB increments in amplitude superimposed on a steady tone of the same frequency presented at a sensation level of 20 dB. In normal persons and in those with retroco-chlear (nerve) lesions, most of these small 1-dB pips of sound are not heard; with cochlear lesions, most of them are heard.

4. **Speech discrimination.** This consists of presenting the patient with a list of 50 phonetically balanced monosyllabic words (e.g., *thin, sin*) at suprathreshold levels. The speech-discrimination score is the percentage of the 50 words correctly repeated by the patient. Marked reduction (less than 30 percent) in the speech-discrimination test scores is characteristic of eighth-nerve lesions.

5. **Békésy audiometry.** Continuous and interrupted tones are presented at various frequencies. Tracings are made, measuring the increments by which the patient must increase the volume in order to continue to hear the continuous and interrupted tones just above threshold. Analysis of many tracings has shown that there are four basic configurations, referred to as types I to IV Békésy audiograms. Types I or IV usually indicate the presence of a retrocochlear lesion, the type II response points to a lesion of the cochlea itself, and type I is considered normal.

6. **The acoustic-stapedial reflex can be used as a measure of conduction in the auditory (and the facial) nerve. This reflex normally protects the cochleas from excessively loud sound. When sound of greater intensity than 70 to 90 dB above threshold hearing reaches the inner ear, the stapedius muscles on both sides contract reflexly, relaxing the tympanum and offering impedance to further sound. It may be tested by insufflating the external auditory canal with pressurized air and measuring the change in pressure that follows immediately after a loud sound is introduced to either ear. The response is muted in patients with conductive hearing loss because of the mechanical restriction of ossicular movement; but otherwise the test is sensitive to cochlear nerve lesions and also can be used to test recruitment.

7. **Brainstem auditory evoked potentials (BAER; page 36).** This method provides information as to the integrity of primary and secondary auditory pathways from the cochlea to the temporal lobe cortex. This method can be used in uncooperative and even comatose patients. It is of particular value in detecting small acoustic neuromas; in localizing brainstem lesions such as areas of demyelination; in corroborating the state of brain death, where all waves except occasionally the eighth nerve (wave V) responses are abolished; and in assessing sensorineural damage in neonates who have had meningitis or been exposed to ototoxic Tinnitus

Tinnitus is the other major manifestation of cochlear and auditory disease. **Tinnitus aurium** literally means “ringing of the ears” (Latin *tinnitus, to ring or jingle*) and refers to sounds originating in the ear, although they need not be in character. Buzzing, humming, whistling, roaring, hissing, clicking, chirping, or pulse-like sounds are also reported. Some otologists use the term tinnitus cerebri to distinguish other head noises from those that arise in the ear, but the term tinnitus when used without qualification refers to tinnitus aurium.

Tinnitus is a remarkably common symptom, affecting more than 37 million Americans, according to Marion and Cevette. It may be defined as any sensation of sound for which there is no source outside the individual. Two basic types are recognized, tona1 and non-tonal (nonvibratory and vibratory, in the terminology of Fowler). The tonal type is by far the more common and is also called subjective tinnitus, because it is heard only by the patient. The nontonal form is sometimes objective, in the sense that under certain conditions the tinnitus can be heard by the examiner as well as by the patient. In either case, whether tinnitus is produced in the inner ear or in some other part of the head and neck, sensory auditory neurons must be stimulated, for only the auditory neural pathways can transmit an impulse that will be
perceived as sound.

**Nontonal and Pulsatile Tinnitus** These head noises are mechanical in origin and are conducted to the inner ear through the various hard or soft structures or the fluid or gaseous media of the body. They are not due to a primary dysfunction of the auditory neural mechanism but have their origin in the contraction of muscles of the eustachian tube, middle ear (stapedius, tensor tympani), palatine (palatal myoclonus) or pharynx (muscles of deglutition), or in vascular structures near the ear. One of the most common forms of subjective tinnitus is a self-audible bruit, the source of which is the turbulent flow of blood in the large vessels of the neck or in an arteriovenous malformation or glomus jugulare tumor. The sound is pulsatile and asymmetrically appreciated by the patient but is rarely detectable by the examiner. Normal variations in the size and location of the jugular bulb may explain the symptom in some patients (Adler and Ropper). Other noteworthy causes of pulsatile tinnitus are related to an increase in intracranial pressure of any type, in which the pulsatile quality is attributed to a pressure gradient between the cranial and cervical venous structures, thyroid enlargement with increased venous blood flow, intracranial aneurysm, aortic stenosis, and vascular tumors of the skull, such as histiocytosis X. In the case of a vascular tumor or a large arteriovenous malformation, the examiner may hear the bruit over the mastoid process. Obliteration of the sound by gentle compression of the jugular vein on the symptomatic side is a useful indicator of a venous origin. Carotid artery disease is a relatively uncommon cause of a self-audible bruit. A flow-related bruit originating from fibromuscular dysplasia, atherosclerotic stenosis, dissection, and enhanced blood flow in a vessel contralateral to a carotid occlusion have all been incriminated. In 100 consecutive cases of pulsatile tinnitus, intracranial hypertension, glomus tumors, and carotid disease were found to be the most common causes (Gissi and Sissons). One must always be cautious in interpreting this symptom, because normal persons can hear their pulse when lying with one ear on a pillow, and introspective individuals may worry about it.

**Tonal Tinnitus** This form of tinnitus arises in the middle or inner ear. Under ideal acoustic circumstances (in a soundproof room having an ambient noise level of 18 dB or less), its presence is in 60 to 90 percent of adults (“physiologic tinnitus”). The ambient noise level in ordinary living conditions usually exceeds 35 dB and is of sufficient intensity to mask physiologic tinnitus, which remains inaudible. Tinnitus due to disease of the middle ear and auditory neural mechanisms may also be masked by environmental noise and hence becomes troublesome only in quiet surroundings—at night, in the country, etc.

Most often, tinnitus signifies a disorder of the tympanic membrane, ossicles of the middle ear, inner ear, or eighth nerve. A majority of patients who complain of persistent tinnitus have some degree of deafness as well. Tinnitus that is localized to one ear and is described as having a tonal character (such as a ringing, bell-like, or high steady musical tone) is usually associated with an impairment of cochlear or neural function. Tinnitus associated with sensorineural hearing loss of high frequency is often described as “chirping” and that of low frequency as “whooshing” or blowing (Marion and Cevette). Tinnitus due to middle ear disease (e.g., otosclerosis) tends to be more constant than the tinnitus of sensorineural disorders, is of variable intensity and lower pitch, and is characterized by clicks, pops, and rushing sounds. The more common of these are the rhythmic clicking of palatal myoclonus and intermittent clicking from contraction of the tensor tympani and stapedius muscles, termed “middle ear myoclonus.” The latter has been treated with a variety of medications, including di-azepam, or, in extremely annoying cases, by section of the offending muscles (Badia et al.). Ear-clicking noises due to palatal myoclonus have been successfully treated by botulinum toxin injections of the soft palatal tissues (Jamiens et al.).

As was remarked, the pitch of tinnitus associated with a conductive hearing loss is of low frequency (median frequency of 480 Hz, with a range of 90 to 1450 Hz). That which accompanies sensorineural loss is higher (median frequency of 3900 Hz, with a range of 545 to 7500 Hz). This rule does not apply to Menière’s disease, in which the tinnitus is usually described as a low-pitched whoseh, buzz, or roar (median frequency of 320 Hz, with a range of 90 to 900 Hz), thus resembling the tinnitus that accompanies a conductive rather than a sensorineural hearing loss (Nodar and Graham). The tinnitus of Menière disease often fluctuates in intensity, like the hearing loss.

The mechanism of tonal tinnitus has not been established, although a number of theories have been postulated. One supposition attributes tinnitus to an overactivity or disinhibition of hair cells adjacent to a part of the cochlea that has been injured. Another postulates a decoupling of hair cells from the tectorial membrane. Yet another theory is based on the finding of an abnormal discharge pattern of afferent neurons, attributed to ephaptic transmission between nerve fibers that have been damaged by vascular compression (Meller). Relief of tinnitus in special cases has reportedly been achieved by vascular decompression of the eighth nerve (Jannetta).

For most forms of tinnitus, there is little effective treatment. Most patients become reconciled to its presence once the nature of the disorder is explained to them. It is possible to fit some patients with a special audiologic instrument, like a hearing aid, which masks the tinnitus by delivering a sound of like pitch and intensity. Also, a hearing aid that improves audition may suppress or diminish tinnitus. Drugs such as anticonvulsants and tocainide hydrochloride have not been helpful in our experience. If tinnitus is the basis of persistent complaints, one often discovers that the patient is anxious or depressed, in which case a careful medical history will reveal the other symptoms of the psychiatric illness. Treatment then must be directed to the psychiatric symptoms.

Tinnitus that is unilateral, pulsatile, or fluctuating and associated with vertigo must be investigated by appropriate neurologic and audiologic studies.

**Other Disorders of Auditory Perception**

On occasion, pontine lesions may be accompanied by complex auditory illusions, sometimes with the qualities of true hallucinations (pontine auditory hallucinosis). These hallucinations are musical tones, including musical noises, like an organ; a jumble of sound, like a symphony orchestra tuning up; or siren-like or buzzing sounds, like a swarm of bees. These auditory sense disturbances are more complex than nonsensory tinnitus but less formed than temporal lobe hallucinations. They are usually associated with impairment of hearing in one or both ears and other neurologic signs related to the pontine lesion. An unpleasant degree of hyperacusis in the contralateral ear has also been reported with upper pontine tegmental lesions. Brainstem evoked potentials reveal intact cochlear, auditory nerve, and cochlear nucleus responses. As in the case of peduncular visual hallucinosis, patients realize that the sounds are unreal, i.e., they have insight into their illusory nature (Cascino and Adams).

Another well-recognized but inexplicable type of auditory hallucinosis occurs in aged patients with long-standing neurosensory deafness. All day long, they hear singing, musical sounds, clanging or jangling, or a sound that is totally dissonant and discordant. These auditory hallucinations occur in the form of music, including musical noises, like an organ; a jumble of sound, like a symphony orchestra tuning up; or siren-like or buzzing sounds, like a swarm of bees. These auditory sense disturbances are more complex than nonsensory tinnitus but less formed than temporal lobe hallucinations. They are usually associated with impairment of hearing in one or both ears and other neurologic signs related to the pontine lesion. An unpleasant degree of hyperacusis in the contralateral ear has also been reported with upper pontine tegmental lesions. Brainstem evoked potentials reveal intact cochlear, auditory nerve, and cochlear nucleus responses. As in the case of peduncular visual hallucinosis, patients realize that the sounds are unreal, i.e., they have insight into their illusory nature (Cascino and Adams).

**Causes of Middle Ear Deafness**

The common causes are otosclerosis, otitis media, and trauma. Of the various types of progressive conductive deafness, otosclerosis is the most frequent, being the cause of about half the cases of bilateral (but not necessarily symmetrical) deafness that have their onset in early adult life (usually in the second or third decade). Otosclerosis is transmitted as an autosomal dominant trait with variable penetrance; pathologically, it is characterized by an overgrowth of labyrinthine bone at the neck of the stapes, conduction, and stapes bar. The symptom in some cases (Adler and Ropper). Other noteworthy causes of pulsatile tinnitus are related to an increase in intracranial pressure of any type, in which the pulsatile quality is attributed to a pressure gradient between the cranial and cervical venous structures, thyroid enlargement with increased venous blood flow, intracranial aneurysm, aortic stenosis, and vascular tumors of the skull, such as histiocytosis X. In the case of a vascular tumor or a large arteriovenous malformation, the examiner may hear the bruit over the mastoid process. Obliteration of the sound by gentle compression of the jugular vein on the symptomatic side is a useful indicator of a venous origin. Carotid artery disease is a relatively uncommon cause of a self-audible bruit. A flow-related bruit originating from fibromuscular dysplasia, atherosclerotic stenosis, dissection, and enhanced blood flow in a vessel contralateral to a carotid occlusion have all been incriminated. In 100 consecutive cases of pulsatile tinnitus, intracranial hypertension, glomus tumors, and carotid disease were found to be the most common causes (Gissi and Sissons). One must always be cautious in interpreting this symptom, because normal persons can hear their pulse when lying with one ear on a pillow, and introspective individuals may worry about it.

Complex auditory hallucinations may occur as part of temporal-lobe seizures, arising from a variety of temporal-lobe lesions. Conversely, seizures may be induced by musical sounds as well as by other auditory stimuli. These topics are discussed in Chap. 16 and Chap. 22. Paracoccus, a condition in which a sound, tone, or voice is repeated for several seconds, is also a cerebral auditory phenomenon similar in a sense to the visual phenomenon of palinopsia. The precise anatomy is unknown.

Complex auditory hallucinations may occur as part of temporal-lobe seizures, arising from a variety of temporal-lobe lesions. Conversely, seizures may be induced by musical sounds as well as by other auditory stimuli. These topics are discussed in Chap. 16 and Chap. 22. Paracoccus, a condition in which a sound, tone, or voice is repeated for several seconds, is also a cerebral auditory phenomenon similar in a sense to the visual phenomenon of palinopsia. The precise anatomy is unknown.

**Causes of Sensorineural Deafness**

This has many causes. Explosions or intense, sustained noise in certain industrial settings or from gun blasts or even rock music may result in a high-tone
sensoryneural hearing loss. Certain antimicrobial drugs (namely, the aminoglycoside group and vancomycin) damage cochlear hair cells and, after prolonged use, can result in severe hearing loss. If these drugs have been used to treat bacterial meningitis, it may be difficult to determine if the antibiotic or the infection is the cause. A variety of other commonly used drugs have been reported to be ototoxic (see Nadol). Quinine and acetylsalicylic acid may impair sensoryneural function transiently. The common high-frequency sensoryneural type of hearing loss in the aged (presbycusis) is probably due to neuronal degeneration, i.e., progressive loss of spiral ganglion neurons (Sugs and Lindsay).

The cochlea may be damaged by rubella in the pregnant mother. Mumps, acute purulent meningitis (particularly from pneumococcus and Haemophilus), or chronic infection spreading from the middle to the inner ear may cause nerve deafness in childhood. The meningeal infection may spread along the cochlear aqueduct, a structure that connects the cerebrospinal fluid (CSF) space with the perilymph of the cochlea. The inner ear contains melanocytes, and their involvement in Vogt-Koyanagi-Harada disease adds dysacusis, tinnitus, and sensoryneural deafness to the usual manifestations of vitiligo of the eyebrows, iridocyclitis, retinal depigmentation, and recurrent meningitis. Measles vaccination, Mycoplasma pneumoniae infection, and scarlet fever are sometimes associated with acute deafness with or without vestibular symptoms. It is uncertain whether the deafness in these cases is due to direct infection or is an autoimmune reaction directed to the inner ear. Meningeal hemoderosis, a rare process that results from repeated bouts of subarachnoid hemorrhage, also causes eighth nerve damage and deafness, presumably as a toxic effect of iron deposition in the meninges.

Of most concern to neurologists is the onset, in an adult, of sudden unilateral hearing loss without vertigo. Many patients can date the onset by noting that they have changed from their customary ear when using the telephone or that they need to turn their head in order to carry on a conversation. Little is known about the pathogenesis of this syndrome. A vascular causation (occlusion of the auditory artery or its cochlear branch or presumed arterial spasm in the course of migraine) has been postulated on uncertain grounds. A few cases have complicated herpes zoster and mumps parotitis, but aside from these there is no proven relationship to the usual viral respiratory infections. **Episodic deafness in one ear without vertigo** proves in most instances to be Ménière disease (see further on). In a prospective study of 88 cases of acute sensoryneural hearing loss, two-thirds recovered their hearing completely within a few days or a week or two (Mattox and Simmons). In the remaining patients, recovery was much slower and often incomplete; in this latter group, the hearing loss was predominantly for high tones and in some cases was associated with varying degrees of vertigo and hypoactive caloric responses.

The **sudden onset of bilateral sensoryneural hearing loss** has been reported to follow cardiopulmonary bypass surgery and has been ascribed to microemboli. Less often such an event follows general anesthesia for nonotologic surgery (Evan et al); the pathogenesis is quite obscure. None of the currently popular therapeutic agents—such as histamine, calcium channel blockers, anticoagulants, carbogen inhalation, and steroids—seem to affect the outcome of sudden unilateral or bilateral deafness without vertigo.

Otologists have described a progressive sensoryneural type of hearing loss as a late manifestation of congenital syphilis, allegedly occurring despite prior treatment with adequate doses of penicillin. It has been claimed that the long-term maintenance of steroids may be useful in such cases. The pathologic basis of the hearing loss has not been determined and the causal relationship to congenital syphilis remains to be established.

The auditory nerve may be involved by tumors of the cerebellopontine angle or by myotic, lymphomatous, carcinomatous, tuberculous, or other types of chronic meningitis. Lymphomatous meningitis appears particularly liable to cause unilateral hearing loss, and we have seen several such cases in which no other cranial nerves were infiltrated. Of the solid tumors, the ones that involve the auditory nerve most frequently are neurofibromas (schwannomas), meningiomas, dermoids, and metastatic carcinoma. In central neurofibromatosis (type II) the involvement by acoustic neuromas is often bilateral. Unilateral deafness may also result from demyelinating plaques, infarction of a tumor involving the cochlear nerve fibers or nuclei in the brainstem. Rarely, deafness is the result of bilateral lesions of the temporal lobes (Chap. 22). The condition called pure word deafness is also due to temporal lobe disease; despite normal pure-tone detection and audiometry and normal brainstem auditory evoked potentials, spoken words cannot be understood. This condition is discussed in Chap. 23.

A large number of **genetically determined syndromes** that feature a neural or conductive type of deafness—some congenital and others having their onset in childhood or early adult life—have come to light (see articles by Konigsmark and by Proctor and Proctor). About 70 percent of cases of congenital deafness are inherited as an autosomal recessive trait. In most of the remainder, inheritance is autosomal dominant in type and in 2 percent it is sex-linked (Sank and Kaliman). The most important advance in this field has been the identification in recessive nonsyndromic deafness of a mutation of the connexin-26 gene on chromosome 13. This mutation is found in half of recessive familial cases and, what is more striking, the same gene abnormality occurs in 37 percent of cases of apparently sporadic congenital deafness (Estivill et al, and Morel et al). The connexin protein is a component of gap junctions and the mutation is theorized to interfere with the recycling of potassium from the cochlear hair cells to the endolymph. There are few complete histopathologic studies of congenital and hereditary deafness. From available data, two groups can be recognized—aplasias and degenerations. Four types of inner ear aplasia have been described: (1) Michel defect, a complete absence of the otic capsule and eighth nerve; (2) Mondini defect, an incomplete development of the bony and membranous labyrinths and the spiral ganglion; (3) Scheibe defect, a membranous cochleovestibular dysplasia with atrophy of the vestibular and cochlear nerves; and (4) rare chromosomal aberrations (trisomies) characterized by abnormality of the end organ and absence of the spiral ganglion.

In addition to these more or less pure aplasias of the peripheral auditory system, cochleovestibular atrophies and degenerations occur as part of many other hereditary and congenital and heredodegenerative syndromes. Konigsmark has classified these hereditary forms of deafness on the basis of associated defects caused by the same gene: malformations of the external ear; integumentary abnormalities such as hyperkeratosis, hyperplasia or scantiness of eyebrows, alopecia, large hyperpigmented or hypopigmented areas, brittle twisted hair, and conform and missing teeth; ocular abnormalities such as hyperelorism, severe myopia, optic atrophy, congenital and juvenile catactics, and retinitis pigmentosa; neurologic abnormalities such as polynucleopathy and sensory ataxia (Refsum disease), progressive ophthalmoplegia and cerebellar ataxia, bilateral cerebellar ataxia, or ataxia or dementia associated with cortical dysplasia; and renal, thyroid, or cardiac abnormalities. Deafness is also a feature of several mitochondrial disorders, particularly the Kearns-Sayre syndrome and occasionally the MELAS syndrome (page 1042). The Wolfram syndrome can have either a nuclear or mitochondrial genetic origin. This and other hereditary syndromes are summarized in Table 15-1. The most important advance in this field has been the identification in recessive nonsyndromic deafness of a mutation of the connexin-26 gene on chromosome 13. This mutation is found in half of recessive familial cases and, what is more striking, the same gene abnormality occurs in 37 percent of cases of apparently sporadic congenital deafness (Estivill et al, and Morel et al). The connexin protein is a component of gap junctions and the mutation is theorized to interfere with the recycling of potassium from the cochlear hair cells to the endolymph. There are few complete histopathologic studies of congenital and hereditary deafness. From available data, two groups can be recognized—aplasias and degenerations. Four types of inner ear aplasia have been described: (1) Michel defect, a complete absence of the otic capsule and eighth nerve; (2) Mondini defect, an incomplete development of the bony and membranous labyrinths and the spiral ganglion; (3) Scheibe defect, a membranous cochleovestibular dysplasia with atrophy of the vestibular and cochlear nerves; and (4) rare chromosomal aberrations (trisomies) characterized by abnormality of the end organ and absence of the spiral ganglion.

In addition to these more or less pure aplasias of the peripheral auditory system, cochleovestibular atrophies and degenerations occur as part of many other hereditary and congenital and heredodegenerative syndromes. Konigsmark has classified these hereditary forms of deafness on the basis of associated defects caused by the same gene: malformations of the external ear; integumentary abnormalities such as hyperkeratosis, hyperplasia or scantiness of eyebrows, alopecia, large hyperpigmented or hypopigmented areas, brittle twisted hair, and conform and missing teeth; ocular abnormalities such as hyperelorism, severe myopia, optic atrophy, congenital and juvenile catactics, and retinitis pigmentosa; neurologic abnormalities such as polynucleopathy and sensory ataxia (Refsum disease), progressive ophthalmoplegia and cerebellar ataxia, bilateral cerebellar ataxia, or ataxia or dementia associated with cortical dysplasia; and renal, thyroid, or cardiac abnormalities. Deafness is also a feature of several mitochondrial disorders, particularly the Kearns-Sayre syndrome and occasionally the MELAS syndrome (page 1042). The Wolfram syndrome can have either a nuclear or mitochondrial genetic origin. This and other hereditary syndromes are summarized in Table 15-1, and the mitochondrial causes of deafness have recently been summarized by Chinnery et al. The association of neurosensory deafness with degenerative neurologic disease is discussed further in Chap. 37 and Chap. 39.

### Table 15-1 Hereditary cochlear and cochleovestibular atrophies

**Hysterical Deafness**

It is possible to distinguish hysterical and feigned deafness from that due to structural disease in several ways. In the case of bilateral deafness, the distinction can be made by observing a blink (cochleo-orbicular reflex) or an alteration in skin sweating (psychogalvanic skin reflex) in response to loud sound. Unilateral hysterical deafness may be detected by an audiometer, with both ears connected, or by whispering into the bell of a stethoscope attached to the patient's ears, closing first one and then the other tube without the patient's knowledge. The elicitation of the first several waves of the brainstem auditory evoked potentials provides indisputable evidence that sounds are reaching the receptive auditory structures. It should be kept in mind that a brief episode of deafness with fully preserved consciousness may be caused by seizure activity in one temporal lobe (epileptic suppression of hearing).
DIZZINESS AND VERTIGO

Dizziness and other sensations of imbalance are, along with headache, back pain, and fatigue, the most frequent complaints among medical out-patients (Kroenke and Mangelsdoff). The significance of these complaints varies greatly. For the most part they are benign, but always there is the possibility that they signal the presence of a neurologic disorder. A commonologic diagnosis is that the vertiginous feeling be determined correctly—the nature of the disturbance of function being determined first and then its anatomic localization. This classical approach to neurologic diagnosis is nowhere more valuable than in the patient whose main complaint is dizziness.

The term dizziness is applied by the patient to a number of different sensory experiences—a feeling of rotation or whirling as well as nonrotatory swaying, weakness, faintness, light-headedness, or unsteadiness. Blurring of vision, feelings of unreality, syncope, and even petit mal or other seizure phenomena may be called “dizzy spells.” Hence a close questioning of the patient as to how he is using the term becomes a necessary first step in clinical study. Essentially, the physician must determine whether the symptoms have the specific qualities of vertigo—which in this chapter refers to all subjective and objective illusions of motion or position—or whether they are more properly categorized as nonrotatory giddiness or pseudovertigo. The distinction between these two groups of symptoms is elaborated after a brief discussion of the factors involved in the maintenance of equilibrium.

Physiologic Considerations

Several mechanisms are responsible for the maintenance of a balanced posture and for awareness of the position of the body in relation to its surroundings. Continuous afferent impulses from the eyes, labyrinths, muscles, and joints inform us of the position of different parts of the body. In response to these impulses, the adaptive movements necessary to maintain equilibrium are carried out. Normally we are unaware of these adjustments, since they operate largely at a reflex level.

The most important of the afferent impulses are the following:

1. Visual impulses from the retina and possibly proprioceptive ones from the ocular muscles, which enable us to judge the distance of objects from the body. This information is coordinated with sensory information from the retinas and neck (see below) to stabilize gaze during movements of the head and body.
2. Impulses from the labyrinths, which function as highly specialized spatial proprioceptors and register changes in the velocity of motion (either acceleration or deceleration) and position of the body. The crystal of the three semicircular canals sense angular acceleration of the head (side-to-side or rotary), and the maculae of the saccule and utricle sense linear acceleration and gravity. In the semicircular canals, this is accomplished by movement of the endolymphatic fluid, which, in turn, is induced by rotation of the head and results in an illusion of rotation. In the utricle and saccule, the hairs are displaced in response to the force of gravity on the otoliths, giving rise to a sensation of linear displacement. In either case, these impulses generate an electrical signal in the nerve which travels to the brain along the vestibular nerve, in the production of two main reflex responses: the vestibulo-ocular, which stabilizes the eyes, and the vestibulospinal, which stabilizes the position of the head and body.
3. Impulses from the proprioceptors of the joints and muscles, which are essential to all reflex, postural, and volitional movements. Those from the neck are of special importance in relating the position of the head to the rest of the body. The sense organs listed above are connected with the cerebellum and with certain ganglionic centers and pathways in the brainstem, particularly the vestibular nuclei, and, via the medial longitudinal fasciculi, with the ocular motor nuclei. These cerebellar and brainstem structures are the important coordinators of the sensory data and provide for postural adjustments and the maintenance of equilibrium. They also have a role of “what is what” to maintain the position of the body. The sense organ which plays the most important role in this function is the semicircular canals, which sense angular acceleration of the head (side-to-side or rotary), and the maculae of the saccule and utricle sense linear acceleration and gravity. In the semicircular canals, this is accomplished by movement of the endolymphatic fluid, which, in turn, is induced by rotation of the head and results in an illusion of rotation. In the utricle and saccule, the hairs are displaced in response to the force of gravity on the otoliths, giving rise to a sensation of linear displacement. In either case, these impulses generate an electrical signal in the nerve which travels to the brain along the vestibular nerve, in the production of two main reflex responses: the vestibulo-ocular, which stabilizes the eyes, and the vestibulospinal, which stabilizes the position of the head and body.

Clinical Characteristics of Vertigo and Giddiness (Pseudovertigo)

Vertigo A careful history and physical examination usually afford the basis for separating true vertigo from the dizziness of the anxious patient and from the other types of pseudovertigo. The recognition of vertigo is not difficult when the patient states that objects in the environment seem to spin around or move rhythmically in some direction or that he had a sensation of whirling of the head and body. (A distinction is sometimes drawn between subjective vertigo, meaning a sense of turning of one’s head, and true vertigo, an illusion of turning of the environment.) The patient may have a true vertigo if, with only a head movement, the feeling may be described as a to-and-fro or up-and-down movement of the body, usually of the head, or the patient may compare the feeling to that imparted by the pitch and roll of a ship. Or the floor or walls may seem to tilt or to sink or rise up. In walking, the patient may have felt unsteady and veered to one side. Or he may have had a sensation of leaning or being pulled to the ground or to one side or another (a static tilt), as though being drawn by a strong magnet. This feeling of impulsion, or pulsion, is particularly characteristic of vertigo. Osciopia, an illusory movement of the environment, is another effect of vestibular disorder, especially if induced by movement of the head. Some observers may actually note a rhythmic movement of the environment due to nystagmus.

Some patients may be able to identify their symptoms only when asked to compare them with the feeling of movement they experience when they come to a halt after rapid rotation. If the patient is unobservant or imprecise in his descriptions, a helpful tactic is to provoke a number of dissimilar sensations by rotating him rapidly, irrigating his ears with warm and cold water, and then asking him to stoop for a minute and straighten up; having him stand relaxed for 3 min and checking his blood pressure for orthostatic effect; and having him hyperventilate for 3 min. Should the patient be unable to distinguish between these several types of induced dizziness or to ascertain the similarity of one of the types to his own condition, the history is probably too inaccurate for purposes of diagnosis.

When the patient’s symptoms are mild or poorly described, small items of the history—a disinclination to stoop or walk during an attack; a tendency to list to one side; spells.” Hence a close questioning of the patient as to how he is using the term becomes a necessary first step in clinical study. Essentially, the physician must determine whether the symptoms have the specific qualities of vertigo—which in this chapter refers to all subjective and objective illusions of motion or position—or whether they are more properly categorized as nonrotatory giddiness or pseudovertigo. The distinction between these two groups of symptoms is elaborated after a brief discussion of the factors involved in the maintenance of equilibrium.

commonly occur (“supermarket syndrome,” “motorist disorientation syndrome,” “phobic postural vertigo,” “street neurosis,” etc.). Furman and Jacobs have related psychiatric dizziness to minor degrees of vestibular dysfunction, but we have not found it possible to determine if there is a genuine labyrinthine disorder in these patients.

Oculomotor disorders, such as ophthalmoplegia with diploria of abrupt onset, may be a source of spatial disorientation and brief sensations of vertigo, mild nausea, and staggering. These symptoms are maximal when the patient looks in the direction of action of the paralyzed muscle; it is attributable to the receipt of two conflicting visual images. Some normal persons may experience such symptoms for brief periods when first adjusting to bifocal glasses. In a peculiar symptom called the Tutiio phenomenon, a loud sound or, rarely, yawning produces a brief sensation of vertigo. Some patients with this symptom are found to have an absence or thinning of the bony roof of the superior semicircular canal. Occasionally, this symptom is reported by patients with Ménière disease.

Other pseudovertiginous symptoms are less definite. In severe anemic states, particularly pernicious anemia, and in aortic stenosis, easy fatigability and languor may be attended by light-headedness, related particularly to postural change and exertion. In the emphysematous patient, physical effort may be associated with weakening cephalic sensation, and violent paroxysms of coughing may lead to giddiness and even fainting (fusive syncope) because of impaired venous return to the heart. The dizziness that often accompanies hypertension is difficult to evaluate; sometimes it is an expression of anxiety, or it may conceivably be due to an unstable adjustment of cerebral blood flow. Postural dizziness is another state in which unstable vasomotor reflexes prevent a constant cerebral circulation. Old age, alcoholism, and infections with primary orthostatic hypotension and in those taking antihypertensive drugs, and in patients with a polyneuropathy that has an autonomic component. Such persons, on rising abruptly from a recumbent or sitting position, experience a swaying type of dizziness, diminishing of vision, and spots before the eyes that last for several seconds. The patient is forced to stand still and steady himself by holding onto a nearby object. Occasionally, a syncopal attack may occur at this time (see Chap. 15). Hypoglycemia gives rise to another form of pseudovertigo, marked by a sense of hunger and attended by trembling, sweating, and other autonomic symptoms. Drug intoxication—particularly with alcohol, sedatives, and anticoagulants—may induce a nonspecific dizziness and, at advanced stages of intoxication, true vertigo.

In practice, it is usually not difficult to separate these types of pseudovertigo from true vertigo, for there is none of the feeling of rotation, impulsion, up-and-down movement, oscillosia, or other disturbance of motion so characteristic of the latter. Lacking also are the ancillary symptoms of true vertigo—namely, nausea, vomiting, tinnitus and deafness, staggering, and the relief obtained by sitting or lying still.

The Neurologic and Otolologic Causes of Vertigo

The fact that vertigo may constitute the aura of an epileptic seizure supports the view that this symptom may have a cerebrocortical origin. Indeed, electrical stimulation of the cerebral cortex in an unanesthetized patient, either of the posterolateral aspects of the temporal lobe or the inferior parietal lobule adjacent to the Sylvian fissure, may evoke vertigo. Postural vertigo is often a complaint of a sensory origin, but in many instances, a sensation of movement—either of the body away from the side of the lesion or of the environment in the opposite direction—lasts for a few seconds before being submerged in other seizure activity. Vertiginous seizures of this type should be differentiated from vestibulogenic seizures, in which an excessive vestibular discharge serves as the stimulus for a seizure. The latter is a rare form of reflex epilepsy, in which tests that induce vertigo may provoke the seizure.

Whether lesions of the cerebellum produce vertigo seems to depend on which part of this structure is involved. Large, destructive processes in the cerebellar hemispheres and vermis may cause no vertigo. However, strokes in the territory of the median branch of the posterior inferior cerebellar artery (which arises distal to the branches to the cerebellum and therefore does not involve the lateral medulla) may cause intense vertigo that is, indistinguishable from that due to labyrinthine disorder. In two such pathologically studied cases, a large zone of infarction extended to the midline and involved the flocculonodular lobe (Duncan et al. Failing, in these cases, was toward the side of the lesion; nystagmus was present on gaze to each side but was more prominent on gaze to the side of the infarct. These findings have been confirmed by CT scanning and MRI (Amaratunga et al.). Labyrinthine disease, on the other hand, causes predominantly unidirectional nystagmus to the side opposite the impaired labyrinth and swaying or falling toward the involved side—i.e., the direction of the nystagmus is opposite to that of the falling and past pointing (the latter referring to overshooting a target with eyes closed, as originally described by Bárány). Early in the course of an acute attack of vertigo, when it may be difficult to assess the gait and the quality of nystagmus, it is necessary to exclude a cerebellar infarct or hemorrhage by use of imaging procedures.

Biemond and De Jong have described a kind of nystagmus and vertigo originating in the upper cervical roots and the muscles and ligaments that they innervate (so-called cervical vertigo). Spasm of the cervical muscles, trauma to the neck, and irritation of the upper cervical sensory roots are said to produce asymmetrical spinovestibular stimulation and thus to evoke nystagmus, prolonged vertigo, and disequilibrium. Downbeat nystagmus, vertigo, and postural instability have been observed with paramedian lesions at the cranocervical junction, and upbeat nystagmus with oscillosia and vertigo has been traced to two separate brainstem lesions—one in the perihypoglossal nuclei and the other in the pontomesencephalic tegmentum (Brandt). Cervical vertigo has also been attributed to circulatory insufficiency in the vertebrobasilar territory. Toole and Tucker demonstrated a reduced flow through these vessels (in cadavers) when the head was rotated or hyperextended. In our view, the existence of “cervical vertigo” and nystagmus, or at least these interpretations of it, are still open to question. Occasionally, vertigo lasting a few minutes occurs as a prelude to a basilar migraine headache (Grad and Baloh).

In summary, although lesions of the cerebral cortex, eyes, cerebellum, and perhaps the cervical muscles may give rise to vertigo, they are not common sources of vertigo; and it is rarely the dominant manifestation of these lesions. For all practical purposes, vertigo indicates a disorder of the vestibular end organs, the vestibular division of the eighth nerve, or the vestibular nuclei in the brainstem and their immediate connections. The clinical problem resolves itself into deciding which portion of the labyrinthine-vestibular apparatus is primarily involved. Usually this decision can be made on the basis of the form of the vertiginous attack, on the nature of the ancillary symptoms and signs, and tests of labyrinthine function. The latter are described below, followed by a description of the common labyrinthine-vestibular syndromes.

Tests of Labyrinthine Function

Irrigation of the ear canal alternately with cold and warm water (caloric, or oculovestibular, testing) may be used to disclose an impairment or loss of thermally induced nystagmus on the involved side. In caloric testing, the patient’s head is tilted forward 30° from the horizontal; this brings the horizontal semicircular canal into a vertical plane, the position of maximal sensitivity of this canal to thermal stimuli. Each external auditory canal is irrigated for 30 s, first with water at 30°C and then at 44°C (7°C below and above body temperature), with a pause of at least 5 min between each irrigation. In normal persons, cold water induces a slight tonic deviation of the eyes to the side being irrigated, followed, after a latent period of about 20 s, by nystagmus to the opposite side (direction of the fast phase). Warm water induces nystagmus to the irrigated side. In normal subjects, the nystagmus usually persists for 90 to 120 s, although the range is considerably larger. Nausea and symptoms of excessive reflex vagal activity may occur in sensitive individuals.

Simultaneous irrigation of both canals with cold water causes a tonic downward deviation of the eyes, with nystagmus (quick component) upward. Bilateral irrigation with warm water yields a tonic upward movement and nystagmus in the opposite direction.

Caloric testing, as described above, will reliably answer whether the vestibular end organs react, and comparison of the responses from the two ears will indicate which one is paretic. The presence of “directional preponderance” can be determined (if the two stimuli that induce nystagmus to one side provoke a stronger reaction than the two stimuli that induce nystagmus to the other side) and is a means of quantifying the caloric responses. Galvanic stimulation of the labyrinths offers no particular advantage over caloric stimulation.

Vertebrobasilar (labyrinthine) stimulation can also be produced by rotating the patient in a Bárány chair or any type of swivel chair. The patient’s eyes are kept closed or defocused with Frenzel lenses during rotation to avoid the effects of optokinetic nystagmus. In a peculiar symptom called the Tullio phenomenon, a loud sound or, rarely, yawning produces a brief sensation of vertigo. Some patients with this symptom are found to have an absence or thinning of the bony roof of the superior semicircular canal. Occasionally, this symptom is reported by patients with Ménière disease.

Ménière Disease and Other Forms of Labyrinthine Vertigo

Labyrinthine disease is the most common cause of vertigo. The classic variety, Ménière disease, is characterized by recurrent attacks of vertigo associated with fluctuating tinnitus and deafness. One or the other of the latter symptoms—rarely both—may be absent during the initial attacks of vertigo, but invariably they assert themselves as the disease progresses and increase in severity during an acute attack. Ménière disease affects the sexes about equally and has its onset most frequently in the fifth decade of life, although it may begin earlier or later. Cases of Ménière disease are usually sporadic, but hereditary forms, both autosomal dominant and recessive, have been described (see reviews by Konigsmark). The main pathologic changes consist of an increase in the volume of endolymph and distention of the endolymphatic system (endolymphic hydrops). It has been speculated that the paroxysmal attacks of vertigo are related to ruptures of the
membranous labyrinth and a dumping of potassium-containing endolymph into the perilymph, changes that have a paralyzing effect on vestibular nerve fibers and lead to degeneration of the delicate cochlear hair cells (Friedmann).

In typical Ménière disease the attacks of vertigo are characteristically abrupt and last for several minutes to an hour or longer. The vertigo is unmistakably whirling or rotary in type and usually so severe that the patient cannot stand or walk. Varying degrees of nausea and vomiting, low-pitched tinnitus, a feeling of fullness in the ear, and a diminution in hearing are practically always associated. Nystagmus is present during the acute attack; it is horizontal in type, usually with a rotary component and with the slow phase to the side of the affected ear. At an attempt to touch a target with the eyes closed, there is past pointing as well as a tendency to fall toward the affected ear. The patient prefers to lie with the faulty ear uppermost and is disoriented to look toward the normal side, which exaggerates the nystagmus and dizziness. As the attack subsides, hearing improves, as does the sensation of fullness in the ear; with further attacks, however, there is a progressive increase of deafness.

The attacks vary considerably in frequency and severity. They may recur several times weekly for many weeks on end, or there may be remissions of several years’ duration. Frequently recurring attacks may give rise to a mild chronic state of disequilibrium and a reluctance to move the head or to turn quickly. With milder forms of the disease, the patient may complain more of head discomfort and of difficulty in concentrating than of vertigo and may be considered neurotic. Symptoms of anxiety are common in patients with Ménière disease, particularly in those who suffer frequent severe attacks.

As indicated earlier a small proportion of patients with Ménière disease experience sudden, violent falling attacks. These episodes have been referred to by the quaint name of “otolithic catastrophe of Tumarkin,” who attributed them, with little evidence, to deformation of the otolithic membrane of the utricle and saccule. Patients characteristically describe a sensation of being pushed or knocked to the ground without warning, or there may be a sudden movement or lift of the environment just before the fall. The consciousness is not lost, and vertigo of the usual type and its accompaniments are not part of the falling attack, although some patients become aware of these symptoms after falling. The attacks may occur early or late in the course of the disease. Typically, several attacks occur over a period of a year or less and remit spontaneously (Bárány et al.). An initial attack must be distinguished from other types of drop attacks (see page 399), but the occurrence of the more typical vertiginous attacks of Ménière disease, with deafness and tinnitus, clarifies the diagnosis.

The hearing loss in Ménière disease usually precedes the first attack of vertigo, but it may appear later. Episodic deafness without vertigo has been called cochlear Ménière syndrome. As already mentioned, with recurrent attacks, there is a salutary progressive unilateral hearing loss (in most series only 10 percent of cases involve both ears, but Bárány places the figure closer to 30 percent). Early in the disease, deafness affects mainly the low tones and fluctuates in severity. Without the fluctuations in pure-tone audiometric thresholds, the diagnosis is uncertain. Later the fluctuations cease and high tones are affected. Speech discrimination is relatively preserved. The attacks of vertigo usually cease when the hearing loss is complete. Audiometry reveals a sensorineural type of deafness, with air and bone conduction on the affected side.

Provided that the paroxysm is not completed, loudness recruitment cannot be demonstrated in the involved ear (see above). In general, the association of vertigo and deafness signifies a disease process of the end organ or eighth nerve. The precise locus of the disease is determined by tests of labyrinthine and auditory function described above and by findings, on neurologic examination and imaging studies, that implicate structures adjacent to the eighth cranial nerve.

During an acute attack of Ménière disease, rest in bed is the most effective treatment, since the patient can usually find a position in which vertigo is minimal. The antihistaminic agents cyclizine (Marzene), meclizine (Bonine, Antivert), or transdermal scopolamine are useful in the more protracted cases. Promethazine (Phenergan) helps to suppress the nausea and vomiting, as does trimethobenzamide (Tigan), given in 200-mg suppositories. For many years a low-salt diet in combination with ammonium chloride, and diuretics has been used in the treatment of Ménière disease, but the value of this regimen has never been established. The same is true for dehydrating agents such as oral glycerol and the more recently popular calcium channel blockers. Mild sedative drugs may help the anxious patient between attacks. If the attacks are very frequent and disabling, permanent relief can be obtained by surgical means. Destruction of the labyrinth should be considered only in patients with strictly unilateral disease and complete or nearly complete loss of hearing. In patients with bilateral disease or significant restriction of hearing, the vestibular portion of the eighth nerve can be sectioned. An endolymphatic-subarachnoid shunt is the operation favored by some surgeons, and selective destruction of the vestibule by a cryogenic probe or transtympanic injection of streptomycin is favored by others. Decompression of the eighth cranial nerve, by separating it from an adjacent vessel, as suggested by Janetta, is still a controversial measure and probably better suited to the treatment of sustained and disabling but unexplained vertigo, and it is discussed further in the treatment of class II benign disease. The decision to undertake any surgical procedure must be tempered by the fact that a majority of the patients, who are middle-aged, stabilize spontaneously in a few years.

Benign Positional Vertigo (of Bárány)

This disorder of labyrinthine function is more common than Ménière disease. It is characterized by paroxysmal vertigo and nystagmus that occur only with the assumption of certain critical positions of the head, particularly lying down or rolling over in bed, bending over and straightening up, and tilting the head backward. Brandt prefers the descriptive adjective positioning to positional, insofar as this type of vertigo is induced not by a particular head position relative to the gravitational vector, but only by rapid changes in head position. This disorder was first described by Bárány; Dix and Halpike were responsible for its further characterization and emphasized its benign nature. Individual episodes last for less than a minute, but these may recur periodically for several days or for many months—rarely for years. As a rule, examination discloses no abnormalities of hearing or other identifiable lesions in the ear or elsewhere. However, if patients are subjected to careful bithermal caloric testing, a considerable number will show mild abnormalities of vestibular function (Brandt et al.).

The diagnosis of this disorder is at the bedside by quickly moving the patient from the sitting position to recumbency, with the head tilted 30 to 40 degrees over the side of the table and 30 to 45 degrees to one side, as originally described by Dix and Halpike. After a latency of a few seconds, this maneuver provokes a paroxysm of vertigo; the patient may become frightened and grasp the examiner or the table or struggle to sit up. The vertigo is accompanied by oscillopsia and nystagmus, predominantly torsional in type, with the upper pole of the eye beating toward the floor. Electronystagmography discloses both a vertical and horizontal nystagmus, with the rapid components in the direction of the forehead and away from the floor, respectively (Brandt et al.). The vertigo and nystagmus last no more than 20 to 30 seconds, usually less than 15 s. The Dix–Hallpike maneuver often reverses the direction of nystagmus (position changing nystagmus). With repetition of the maneuver, vertigo and nystagmus become less apparent, and after three or four trials, they can no longer be elicited (referred to as “fatigue”); they can be reproduced in their original severity only after a protracted period of rest. The head-hanging maneuver does not always evoke vertigo and nystagmus in patients whose histories are otherwise consistent with the diagnosis of benign paroxysmal vertigo—for which reason Froehling and co-workers do not insist upon it for diagnosis.

A common variant of benign positional vertigo is one in which sudden turning induces vertigo for a few seconds. Such attacks of vertigo may come and go for years, paradoxically in the elderly, and require no treatment. At the other end of the scale is the rare patient with positional vertigo of such persistence and severity as to require surgical intervention.

Bárány and colleagues, in their study of 240 cases of benign positional vertigo, found that 17 percent had their onset within several days or weeks after cerebral trauma and 15 percent after presumed viral neural infections. The significance of these conditions as clinical signs of certain acute or subacute labyrinthine or vestibular disorders is unclear, although Bárány associates them with the vestibular symptoms or course of the otologic disorder. It should be pointed out that sudden changes in position, particularly of the head, may induce vertigo and nystagmus or cause a worsening of these symptoms in patients with all types of vestibular-labyrinthine disease, including Ménière disease and the types associated with vertebro-basilar stroke, trauma, and posterior fossa tumors. However, only if the paroxysm has the special characteristics noted above—namely, latency of onset, brevity, reversal of direction of nystagmus on sitting up, fatigability with repetition of the test, and the presence of distressing subjective symptoms of vertigo or the recurrence for months or years without other symptoms—can it be regarded as “benign paroxysmal” in type.

Shuknecht originally proposed that benign positional vertigo was due to cupulolithiasis, in which otolithic crystals become detached and attach themselves to the cupula of the posterior semicircular canal. It is now generally believed that the debris, probably detached from the otolith, forms a free-floating clot in the endolymph of the canal (canalolithiasis), and as such gravitates to the most dependent portion of the canal changes in the position of the head (see Brandt et al.). The clots are thought to act as a plug, inducing push-and-pull forces on the cupula and triggering an attack of vertigo. Based on this presumed mechanism, a cochlear repositioning maneuver has been devised (Semont et al. Epley), allowing the clot to gravitate out of the semicircular canal into the utricle where it will not induce a current during angular acceleration.

The first part of the canalith repositioning maneuver (Fig. 15-5) is identical to the diagnostic Hallpike maneuver, outlined above. With the patient in the head-hanging position that causes symptoms, the head is turned in a series of three steps, each separated by about 20 s: first the head is turned 45 to 60 degrees toward the opposite ear; the patient is then turned onto his side and the head turned an additional 45 degrees, until the head is parallel to the ground; then the head is turned once more until it nearly faces the floor. After 20 s, the patient is returned to the upright position, and must remain at least 45 degrees upright for the next 24 h. Often
It is important to reiterate that in some patients with positional vertigo, the disorder is neither benign nor paroxysmal. Jannetta and colleagues have described a group of patients in whom symptoms of vertigo and disequilibrium were almost constant (even in the upright position) and disabling and unresponsive to habituation and other medical therapy (disabling positional vertigo). They attributed this disorder to cross-compensation of the root entry zone of the eighth cranial nerve by an adjacent blood vessel and have reported that decompression of the nerve provides lasting relief of symptoms.

Toxic and Idiopathic Bilateral Vestibulopathy

The common and serious ototoxic effects of the aminoglycoside antibiotics have already been mentioned—both upon the cochlear hair cells, with loss of hearing (page 310), and, often independently, upon the vestibular labyrinth. Prolonged exposure to these agents can produce a bilateral vestibulopathy without vertigo. Instead, there tends to be a disequilibrium associated with oscillopsia (page 292). The symptoms are especially troublesome when the patient moves. Often the disequilibrium is not discovered until a bedfast patient tries to walk.

Less well appreciated is the occurrence of a slowly progressive vestibulopathy for which no cause can be discerned. The latter disorder affects men and women alike, with onset in middle or late adult life. The main abnormalities are unsteadiness of gait, which is worse in the dark or with eyes closed, and oscillopsia, which occurs with head movements and is particularly noticeable when walking. Vertigo and hearing loss are notably absent, as are other neurologic abnormalities. The bilateral vestibular loss can be documented with caloric and rotational testing. Baloh and colleagues, in a report of 22 patients with bilateral idiopathic vestibulopathy, found that a significant proportion (9 of 22 cases) had a prior history of prolonged episodes of vertigo consistent with the diagnosis of bilateral sequential vestibular neuritis.

Vestibular Neuronitis (Labyrinthitis)

This is the term applied originally by Dix and Hallpike to a distinctive disturbance of vestibular function, characterized clinically by a paroxysmal and usually a single attack of vertigo and by a conspicuous absence of tinnitus and deafness.

This disorder occurs mainly in young to middle-aged adults (children and older individuals may be affected), without preference for either sex. The patient frequently gives a history of an antecedent upper respiratory infection of nonspecific type. Usually the onset of vertigo is abrupt, although some patients describe a protracted period of several hours or days in which they felt "top-heavy" or "off balance." The vertigo is severe as a rule and is associated with nausea, vomiting, and the need to remain immobile. Examination discloses vestibular paresis on one side, i.e., an absent or diminished response to caloric stimulation of the horizontal semicircular canal. Halmagyi and Cremer, whose review of the assessment of dizziness is recommended, favor the rapid head impulse test as the best means of demonstrating absent function of one lateral semicircular canal. This test is essentially a method of comparing the vestibulo-ocular reflex (VOR) between the two sides. It consists of performing a quick 10 degree rotation of the patient's head while he is fixating a distant target. The patient with vestibular neuritis is unable to maintain fixation when the head is turned toward the affected side and must make a saccade to stay on target. The test does not elicit a corrective eye movement in cases of cerebellar infarction. Nystagmus (quick component) and sense of body motion are to the opposite side, whereas falling and past pointing are to the side of the lesion. In some patients the caloric responses are abnormal bilaterally, and in some the vertigo may recur, affecting the same or the other ear. Auditory function is normal.

Vestibular neuritis is a benign disorder. The severe vertigo and associated symptoms subside in a matter of several days, but lesser degrees of these symptoms, made worse by rapid movements of the head, may persist for several weeks or months. The caloric responses are gradually restored to normal as well. In some patients there has been a recurrence months or years later.

The portion of the vestibular pathway that is primarily affected in this disease is thought to be the superior part of the vestibular nerve trunk, which was observed to show degenerative changes by Shuknecht and Kitamura. Earlier, Dix and Hallpike had reasoned that the lesion was located central to the labyrinth, since hearing is spared and vestibular function usually returns to normal. They used the term vestibular neuritis because of the uncertainty of more precise localization within the peripheral vestibular pathway. The cause is uncertain. It may be a viral infection, analogous to Bell's palsy, and from time to time enhancement of the eighth nerve or the membranous labyrinth is seen after gadolinium administration on MRI. For want of more specific etiologic or pathologic data, many neurologists prefer the term vestibular neuritis or neurolabyrinthitis, or acute unilateral peripheral vestibulopathy. It is likely that many of the conditions described under the terms epidemic vertigo, epidemic labyrinthitis, and acute labyrinthitis or neurolabyrinthitis. These many names attest to the fact that the distinction between vestibular neuritis and labyrinthitis has never been clarified; some oto-neurologists consider labyrinthitis to be a vestibular neuritis with mild hearing loss. Certainly herpes zoster oticus causes this syndrome (as well as affecting the seventh nerve (Ramsay Hunt syndrome; page 799).

During the acute stage, antihistamine drugs, phenergan, and scopolamine may be helpful in reducing the symptoms.

Other Causes of Vertigo of Vestibular Nerve Origin

This may occur with diseases that involve the nerve in the petrous bone or the cerebellopontine angle. Aside from vestibular neuritis, discussed above, the most common cause of vertigo of eighth nerve origin is probably an acoustic neuroma. Vertigo is rarely the initial symptom; the usual sequence is deafness affecting the high-frequency tones initially, followed some months or years later by chronic vertigo and impaired caloric responses, and then by additional cranial nerve palsies (involving the seventh, fifth, and tenth nerves), ipsilateral ataxia of limbs, and headache (see page 709). Variations in the sequence of development of symptoms are frequent, however. In the diagnosis of acoustic neuroma, MRI and BAER are the most important ancillary examinations. Others include the special audiologic tests that have been described on page 307 and serve to separate lesions of the eighth nerve from those of the cochlea (absence of loudness recruitment, low SISI scores, poor speech discrimination, pronounced tone decay, and type III or IV Bekesy audiograms).

As mentioned earlier, a disabling positional vertigo may be due to compression of the eighth nerve by an abnormal vessel (Jannetta et al).

A clinical syndrome of unknown nature consists of a single abrupt attack of severe vertigo, nausea, and vomiting without tinnitus or hearing loss but with permanent ablation of labyrinthine function on one side. It has been suggested that this syndrome is due to occlusion of the labyrinthine division of the internal auditory artery, but so far anatomic confirmation of this idea has not been obtained. Labyrinthine hemorrhage has been demonstrated by MRI in some of these patients.

A particular form of paroxysmal vertigo occurs in childhood. The attacks occur in a setting of good health and are of sudden onset and brief duration. Pallor, sweating, and immobility are prominent manifestations; occasionally vomiting and nystagmus occur. No relation to posture or movement has been observed. The attacks are recurrent but tend to cease spontaneously after a period of several months or years. The outstanding abnormality is demonstrated by caloric testing, which shows

**Figure 15-5** Dix-Hallpike maneuver to elicit benign positional vertigo (A and B) and treatment with the canalith repositioning maneuver (C–F). To utilize the repositioning treatment, the affected side must first be determined by evocation of symptoms from the lowermost ear during the Dix-Hallpike maneuver. (Adapted by permission from Fife.)
improvement or loss of vestibular function, bilateral or unilateral, frequently persisting after the attacks have ceased. Cochlear function is unimpaired. The pathologic basis of this disorder has not been determined and a suggested connection with migraine is tenuous. The special case of basilar artery migraine is discussed below.

Cogan has described a not infrequent syndrome in young adults in which a nonsyphilitic interstitial keratitis is associated with vertigo, tinnitus, nystagmus, and rapidly progressive deafness. The prognosis for vision is good, but the deafness and loss of vestibular function are usually permanent. The cause and pathogenesis of this syndrome are unknown, although approximately half of the patients later develop aortic insufficiency or a systemic vasculitis that resembles polyarteritis nodosa. These vascular complications proved fatal in 7 of 78 cases reviewed by Vollertsen and colleagues.

There are many other causes of aural vertigo, such as purulent labyrinthitis complicating mastoiditis or meningitis; serous labyrinthitis due to infection of the middle ear; “toxic labyrinthitis” due to intoxication with alcohol, quinine, or salicylates; motion sickness; and hemorrhage into the inner ear. Bárány was the first to draw attention to the nystagmus and positional vertigo, worse on closing the eyes, that occurs at a certain level of intoxication with alcohol and lasts only a few hours. Such an episode of alcohol-induced vertigo tends to last longer than a vertiginous attack of Ménière disease, but in other respects the symptoms are similar.

Vertigo with varying degrees of spontaneous or positional nystagmus and reduced vestibular responses is a frequent complication of head trauma. Vertigo, often of the nonrotatory, to-and-fro type, may follow cerebral concussion or whiplash injury, in which the head has not been impacted. Brandt has attributed this vertigo to a loosening or dislocation of the otoconia in the otoliths. The vertigo in these circumstances usually improves in a few days or weeks and is rarely accompanied by impairment of hearing—in distinction to the vertigo that follows fractures of the temporal bones (as described earlier in this chapter in the discussion of deafness). Dizziness is also a common complaint as part of the syndrome of posttraumatic nervous instability (page 945); usually this proves to be giddiness rather than true vertigo.

Vertigo of Brainstem Origin

Reference was made above to the occurrence of vertigo and nystagmus with lower and upper brainstem lesions. In these cases, vestibular nuclei and their connections are implicated. Auditory function is nearly always spared, since the vestibular and cochlear fibers diverge upon entering the brainstem, at the junction of the medulla and pons. The vertigo of brainstem origin as well as the accompanying nausea, vomiting, nystagmus, and dis-equilibrium are generally more protracted than with labyrinthine lesions, but one can think of exceptions to this statement. Nevertheless, with brainstem lesions, one often observes marked nystagmus without the slightest degree of vertigo—which does not happen with labyrinthine disease. The nystagmus of brainstem origin may be uni- or bidirectional, purely horizontal, vertical or rotary, and is characteristically worsened by attempted visual fixation. In contrast, nystagmus of labyrinthine origin is unidirectional, and past pointing and falling are in the direction of the slow phase; a purely vertical nystagmus does not occur, and a purely horizontal nystagmus without a rotary component is unusual. Furthermore, labyrinthine nystagmus is inhibited by visual fixation.

The central localization of vertigo is confirmed by finding signs of involvement of other structures within the brainstem (cranial nerves, sensory and motor tracts, etc.). Mode of onset, duration, and other features of the clinical picture depend upon the nature of the causative disease, which may be vascular, demyelinative, or neoplastic.

Vertigo is a prominent symptom of ischemic attacks and brainstem infarction occurring in the territory of the vertebrobasilar arteries, particularly the Wallenberg syndrome of lateral medullary infarction (page 844). On the other hand, vertigo as the sole manifestation of brainstem disease is rare. Unless other symptoms and signs of brainstem disorder appear within several days, one can postulate that the vertigo has an aural origin and nearly always exclude vascular disease of the brainstem. The same is true of multiple sclerosis, which may be the explanation of a persistent vertigo in an adolescent or young adult. Vertigo of cerebellar origin is exceptional in this respect that it may be the sole manifestation of cerebellar infarction or hemorrhage, as described on pages 846 and 885. One explanation attributes the vertigo to small concomitant infarctions or compression of the lateral medulla, but this does not appear to be necessary. The nystagmus and ataxia of gait that accompany the cerebellar lesions do not differentiate them from acute vestibulopathies, but limb ataxia and dysarthria are reliable indicators of a cerebellar origin.

Attacks of vertigo followed by an intense unilateral and often suboccipital headache and vomiting are the characteristic features of basilar artery migraine (see page 183). The prodromal visual symptoms take the form of blindness or of photopsia that occupies all of the visual fields. Between headaches, tests of cochlear and vestibular function in these patients are normal. The relationship of this form of migraine to disease of the vertebral and basilar arteries is obscure.

Finally, mention should be made of a familial vestibulocerebellar syndrome, beginning in childhood or early adult life and characterized by recurrent episodes of vertigo and imbalance. Diplopia and dysarthria complicate some attacks, which seem to be precipitated by extreme exertion and emotion. Repeated attacks are followed by a mild, persistent ataxia, mainly of the trunk. This disorder was first described by Farmer and Mustian and more recently by Baloh and Winder, who have pointed out that both the episodic vertigo and ataxia are markedly reduced or abolished by the administration of acetazolamide.

The features of the various vertiginous syndromes are summarized in Table 15-2.

**CHAPTER REFERENCES**

In contemporary society, the frequency and importance of epilepsy can hardly be overstated. From the epidemiologic studies of Hauser and colleagues, it can be extrapolated that, at the time of the last census, approximately 1.77 million individuals in the United States were subject to epilepsy (i.e., chronically recurrent cerebral cortical seizures) and that about 44 new cases per 100,000 population occur each year. These figures are exclusive of patients in whom convulsions complicate febrile and other intercurrent illnesses or injuries. It has also been estimated that approximately 1 percent of persons in the United States will have epilepsy by the age of 20 years (Hauser and Annegers). Over two-thirds of all epileptic seizures begin in childhood (most in the first year of life), and this is the age period when seizures assume the widest array of forms. The incidence increases again slightly after age 60. In the practice of pediatric neurology, epilepsy is one of the most common disorders. The chronicity of childhood forms and their persistence in patients of all ages adds to their importance. For all these reasons, every physician should know something of the nature of seizure disorders and their treatment.

Epilepsy may be defined as an intermittent derangement of the nervous system due to “an excessive and disorderly discharge of cerebral nervous tissue on muscles.” This was the postulate, in 1870, of Hughlings Jackson, the eminent British neurologist, and modern electrophysiology offers no evidence to the contrary. The discharge may result in an almost instantaneous loss of consciousness, alteration of perception or impairment of psychic function, convulsive movements, disturbance of sensation, or some combination thereof. A terminologic difficulty arises from the diversity of the clinical manifestations. The term convolution, referring as it does to an intense paroxysm of involuntary repetitive muscular contractions, is inappropriate for a disorder that may consist only of an alteration of sensation or psychic seizure. The word epilepsy is derived from Greek words meaning “to seize upon” or a “taking hold of.” Our predecessors referred to it as the “falling sickness” or the “falling evil.” Although it is a useful and motor or convulsive seizure is therefore not tautologous, and one may likewise speak of a sensory seizure or psychic seizure. The word epilepsy is derived from Greek words meaning “to seize upon” or a “taking hold of.” Our predecessors referred to it as the “falling sickness” or the “falling evil.” Although it is a useful and less grave circumstance is for a seizure to be but one in an extensive series occurring over a long period of time, with most of the attacks being more or less similar in type. In this instance they may be the result of a burned-out lesion that originated in the past and remains as a scar. The original disease may have passed unnoticed; or perhaps it occurred in utero, at birth, or in infancy, in parts of the brain too immature to manifest signs. It may have affected a very small or “silent” area in a mature brain. The increasingly refined techniques of magnetic resonance imaging (MRI) are revealing small zones of cortical dysplasia and hippocampal sclerosis, both of which tend to be epileptogenic. Patients with such long-standing lesions probably make up the majority of those with recurrent seizures but are necessarily classified as having “idiopathic” or “cryptogenic epilepsy,” because it is impossible to ascertain the nature of the original disease and the seizures may be the only sign of brain abnormality.

There are other types of epilepsy for which no pathologic basis has been established and for which there is no apparent underlying cause except perhaps a genetic one. These epilepsies have been referred to as primary. Included in this category are hereditary forms, such as certain generalized tonic-clonic (grand mal) and absence seizure states. Some authors (Lennov and Lennov Fould) have reserved the term idiopathic for recurrent seizures of the latter types.

### CLASSIFICATION OF SEIZURES

Seizures have been classified in several ways: according to their supposed etiology, i.e., idiopathic (primary) or symptomatic (secondary); their site of origin; or on the basis of their clinical form (generalized or focal), their frequency (isolated, cyclic, prolonged, or repetitive), or their electrophysiologic correlates. A distinction needs to be drawn between the classification of seizures, considered below, and the classification of the epilepsies, or epileptic syndromes, which will be commented upon later in the chapter.

The classification to be followed here was first proposed by Gastaut in 1970 and was then refined repeatedly by the Commission on Classification and Terminology of the International League Against Epilepsy (1981). This classification, based mainly on the clinical form of the seizure and its electroencephalographic (EEG) features, has been adopted worldwide and is generally referred to as the International Classification of Epileptic Seizures. A modified version of it is reproduced in Table 16-1.

The strength of the International Classification lies in its easy applicability to patients with epilepsy and its clinical usefulness. The main value of classifying a seizure by its clinical and EEG features is the reasonable predictability of response to specific medications and to some extent its prognosis. Basically, this classification divides seizures into two types—partial, in which a focal or localized onset can be discerned, and generalizes, in which the seizures appear to begin bilaterally. Seizures that begin locally may evolve into tonic-clonic seizures, in which case they are called secondarily generalized seizures.

Partial or focal seizures are classified as simple when consciousness is undisturbed and complex when consciousness is altered or impaired. Simple partial seizures are further classified according to their main clinical manifestations—motor, sensory, autonomic, or psychic. When one of these subjective manifestations precedes the progression of the attack to a loss of consciousness, it is referred to as an aura and has commonly been regarded as a premonitory sign or warning of the impending seizure. In reality, the aura represents the initial phase of a focal or partial seizure; and in some instances it may constitute the entire epileptic attack.

Generalized seizures are of two types—convulsive and nonconvulsive. The common convulsive type is the tonic-clonic (grand mal) seizure. Less common is a purely tonic, purely clonic, or clonic-tonic-clonic generalized seizure. The classic nonconvulsive generalized seizure is the brief lapse of consciousness or absence (petit mal), included also under this heading are minor motor phenomena such as brief myoclonic, atonic, or tonic seizures.

The classification of seizures and of the epilepsies is constantly being modified. In the latest version, the so-called syndromic classification (Epilepsia 30:389, 1989), an attempt has been made to incorporate all of the seizure types, epilepsies, and epileptic syndromes and to categorize them not only as partial and generalized but also according to their age of onset, their primary or secondary nature, the cortical loci of the epileptogenic lesions, and the many clinical settings in which they occur. This classification is semantically difficult and, in our view, too complicated as yet for general clinical application. Since many epileptic syndromes share overlapping features, it is often not possible to fit a newly diagnosed case of epilepsy into a specific category of this new classification (Harford et al). Currently the commission is engaged in an extensive revision of terminology and classification in the field of epilepsy. Until this revision is agreed upon, we propose to begin our discussion with the 1981 classification of seizures, with certain modifications and additions, to be followed by a consideration of a number of well-defined epilepsies and epileptic syndromes.

**GENERALIZED SEIZURES**

The **Generalized Tonic-Clonic Seizure (Grand Mal)**

As has already been intimated, it is always important to distinguish between a primary (generalized) type of seizure, with widespread EEG abnormalities at the onset, and a secondarily generalized type, which begins as a focal, or partial, seizure and then becomes generalized.

The patient sometimes senses the approach of a seizure by one of several subjective phenomena (a prodrome). For some hours, the patient may feel apathetic, depressed, irritable, or, very rarely, the opposite—ecstatic. One or more myoclonic jerks of the trunk or limbs on awakening may herald a seizure later in the day. In more than half the cases, there is some type of movement for a few seconds before consciousness is lost (turning of the head and eyes or whole body or intermittent jerking of a limb). Abdominal pain or cramps, a sinking, rising, or gripping feeling in the epigastrium, pallor or redness of the face, throbbing headache, constipation, or diarrhea have also been given prodromal status, but we have not found them consistently enough to be helpful.

Most often, the seizure strikes "out of the blue," i.e., without warning, beginning with a sudden loss of consciousness and fall to the ground. The initial motor signs are a brief flexion of the trunk, an opening of the mouth and eyelids, and upward deviation of the eyes. The arms are elevated and abducted, the elbows semiflexed, and the hands pronated. These are followed by a more protracted extension (tonic) phase, involving first the back and neck, then the arms and legs. There may be a piercing cry as the whole musculature is seized in a spasm and air is forcibly emitted through the closed vocal cords. Since the respiratory muscles are caught up in the tonic spasm, breathing is suspended, and after some seconds the skin and mucous membranes become cyanotic. The pupils are dilated and unreactive to light. The bladder may empty at this stage or later, during the postictal coma. This is the tonic phase of the seizure and lasts for 10 to 20 s.

There then occurs a transition from the tonic to the clonic phase of the convolution. At first there is a mild generalized tremor, which is, in effect, a repetitive relaxation of the muscles. The clonic spasms begin at a rate of 8 per second and coarsen to 4 per second and then rapidly gains the way to violent flexor spasms that come in rhythmical salvos and agitate the entire body. The face becomes violaceous and contorted by a series of grames, and often the tongue is bitten. Autonomic signs are prominent: the pulse is rapid, blood pressure is elevated, pupils are dilated, and salivation and sweating are abundant; bladder pressure may increase sixfold during this phase. The clonic jerks decrease in amplitude and frequency over a period of about 30 s. The patient remains apneic until the end of the clonic phase, which is marked by a deep sleep.

The terminal phase of the seizure, all movements have ended and the patient lies still and limp, in a deep coma. The pupils, equal or unequal, now begin to contract to light. Breathing may be quiet or stertorous. This state persists for several minutes, after which the patient opens his eyes, begins to look about, and is obviously bewildered and confused. The patient may speak and later not remember anything that was said. Often, undisturbed, he becomes drowsy and falls asleep for several hours, then awakens with a pulsatile headache. When fully recovered, such a patient has no memory of any part of the spell but knows that something has happened because of the strange surroundings (in ambulance or hospital), the obvious concern of those around him, and a sore, bitten tongue and aching muscles from the violent contractions. The contradictions may even have crushed a vertebral body, or a serious injury (fracture, periorbital hemorrhages, subdural hematoma, or burn) may have been sustained in the fall.

Each of these phases of the generalized tonic-clonic seizure has its characteristic electroencephalographic (EEG) accompaniment. Initially, the EEG changes are obscured by movement artifacts; sometimes there are repetitive spikes or spike-wave discharges lasting a few seconds, followed by an approximately 10-s period of 10-Hz spikes. As the clonic phase asserts itself, the spikes become mixed with slow waves and then the EEG slowly assumes a polyspike-and-wave pattern. When all movements have ceased, the EEG tracing is nearly flat for a variable time, and then the brain waves resume their preseizure pattern.

Convolutions of this type ordinarily come singly or in groups of two or three and may occur when the patient is awake and active or during sleep or frequently when he is falling asleep or awakening. Some 5 to 8 percent of such patients will at some time have a prolonged series of such seizures without completely regaining consciousness between them; this is called convulsive status epilepticus and demands urgent treatment. Sometimes the first outburst of seizures takes the form of convulsive status. Instead of the whole dramatic sequence described above, the seizures may be abbreviated or limited in scope by anticonvulsant medications.

Few clinical states closely simulate a grand mal convolution, but several are worthy of mention. One is a clonic jerking of the extended limbs (usually less severe than those of a grand mal seizure) that occurs with vasopressor presyncope or a Stokes-Adams attack. In contrast to an epileptic type of EEG, the brain waves are slow and flat during the jerking movements. A rarer phenomenon that may be indistinguishable from a generalized convolution occurs as part of basilar artery occlusion (Ropper). This presumably has its basis in ischemia of the corticospinal tracts in the pons; a similar mechanism has been invoked for “limb-shaking TIAs” (transient ischemic attacks), in which there are clonic movements of one limb or one side of the body during an episode of cerebral ischemia. Hysterical (nonepileptic, “psychogenic”) seizures, as discussed further on, are often difficult to distinguish from the true variety. Rarely, in adults, an attack of panic (page 531) or the rare entity of rapid-eye-movement (REM) sleep behavior disorder may resemble a seizure. In infants, a breath-holding spell may resemble the tonic phase of a generalized
seizure.

Idiopathic Nonconvulsive Seizures (Absence, Petit Mal)

In contrast to major generalized seizures, absence seizures (formerly referred to as petit mal or pyknon-epilepsy) are notable for their brevity and the paucity of motor activity. Indeed, they may be so brief that the patients themselves are sometimes not aware of them; to an onlooker, they resemble a moment of absentmindedness or daydreaming.

The attack, coming without warning, consists of a sudden interruption of consciousness, for which the French word absence (“not present,” “not in attendance”) has been retained. The patient stares and briefly stops talking or ceases to respond. Only about 10 percent of such patients are completely motionless during the attack; in the remainder, one observes a brief burst of fine clonic movements of the eyelids, facial muscles, or fingers or synchronous movements of both arms at a rate of 3 per second, i.e., a rate that corresponds to that of the EEG abnormality, which takes the form of a generalized 3 per second spike-and-wave pattern (Fig. 2-3). Minor automatisms—in the form of lip-smacking, chewing, and fumbling movements of the fingers—are common during an attack but do not assume prominence. Postural tone may be slightly decreased or increased, and occasionally there is a mild vasomotor disorder. As a rule, such patients do not fall; they may even continue such complex acts as walking or riding a bicycle. After 2 to 10 s, occasionally longer, the patient reestablishes full contact with the environment and resumes his presense activity. Lack of the thread of conversation or the place in reading betrays the occurrence of a momentary “blank” period (the absence). In many such patients, voluntary hyperventilation for 2 to 3 min is an effective way of inducing absence attacks.

Typical absence seizures constitute the most characteristic epileptic of childhood; rarely do the seizures begin before 4 years of age or after puberty. Another attribute is their great frequency; the old term pyknos, meaning “compact” or “thick”, as many as several hundred may occur in a single day, sometimes in bursts at certain times of the day. Most often they relate to periods of inattention and may appear in the classroom when the child is sitting quietly rather than participating actively in his lessons. If frequent, they may disturb attention and thinking to the point that the child does poorly in school. Such attacks may last for hours with no interval of normal mental activity between them—so-called absence or petit mal status. Small, subtle 3-per-second myoclonic movements are the only motor display (myoclonic petit mal), and are accompanied by a continuous 3-per-second spike-and-wave abnormality in the EEG. Most cases of absence status have been described in adults with frontal lobe epilepsy (see below). Such attacks begin or end with a generalized tonic-clonic seizure or a burst of seizures and may be provoked by the abrupt withdrawal of anticonvulsant drugs.

Absence may be the only type of seizure during childhood. The attacks tend to diminish in frequency in adolescence and often disappear, only to be replaced in many instances by major generalized seizures. Absence epilepsy responds well to treatment with ethosuximide or valproate.

Absence or Petit Mal Variants To be distinguished from typical absence seizures are varieties in which the loss of consciousness is less complete or in which myoclonus is prominent, and others in which the EEG abnormalities are less regularly of a 3-per-second spike-and-wave type (they may occur at the rate of 2 to 2.5 per second or take the form of 4- to 6-Hz polyspike-and-wave complexes). Atypical petit mal is a term that was coined to describe long runs of slow spike-and-wave activity, usually with no apparent loss of consciousness. External stimuli such as asking the patient to answer a question or to count will interrupt the run of abnormal EEG activity.

About 30 percent of children with absence attacks will, in addition, display symmetrical or asymmetrical myoclonic jerks without loss of consciousness, and about 50 percent will also at some time have major generalized (tonic-clonic) convulsions. As described further on, a common variety of myoclonic seizures occurs in late childhood and adolescence (juvenile myoclonic epilepsy).

In sharp contrast to the aforementioned epilepsies is a form that has its onset between 2 and 6 years of age and is characterized by atonic, or astatic, seizures (i.e., falling attacks), often succeeded by various combinations of minor motor, tonic-clonic, and partial seizures and by intellectual impairment, in association with a distinctive, slow (1- to 2-Hz) spike-and-wave EEG pattern. This is the Lennox-Gastaut syndrome. Often it is preceded in earlier life by infantile spasms, a characteristic EEG pattern (“hypsarrhythmia”), and an arrest in mental development, a triad sometimes referred to as the West syndrome (see further on). The early onset of atonic seizures with abrupt falls, injuries, and associated abnormalities nearly always has a grave implication—namely, the presence of serious neurologic disorders. The underlying condition is often an encephalitic illness or a degenerative disease such as juvenile myoclonic epilepsy, in contrast to the foregoing idiopathic types. The Lennox-Gastaut syndrome may persist into adult life and is one of the most difficult forms of epilepsy to treat.

The notion that absence, myoclonic, and atonic seizures constitute a petit mal triad, as originally proposed by Lennox, has been generally abandoned. Akinia (motorlessness) is not unique to any seizure type. The typical absence, with or without myoclonic jerks, rarely causes the patient to fall and should be considered a separate entity because of its relative benignity.

Myoclonus and Myoclonic Seizures

The phenomenon of myoclonus has already been discussed in Chapter 6, where the relationship to seizures was indicated. Characterized by a brusque, brief, muscular contraction, some myoclonic jerks are so small as to involve only one muscle or part of a muscle; others are so large as to implicate a limb on one or both sides of the body or the entire trunk musculature. Many are brief, lasting 50 to 100 ms. They may occur intermittently and unpredictably or present as a single jerk or a brief salvo.

As mentioned earlier, several small, rhythmic myoclonic jerks occur with varying frequency as part of absence seizures and as isolated events in patients with generalized clonic-tonic-clonic or tonic-clonic seizures. As a rule, these types of myoclonus are quite benign and respond well to medication. In contrast, disseminated myoclonus (polymyoclonus), having its onset in childhood, raises the suspicion of acute viral encephalitis, the myoclonus-oppositional-ataxia syndrome of Kinsbourne, lithium or other drug toxicity, or, if lasting a few weeks, subacute sclerosing panencephalitis. Chronic progressive polymyoclonus with dementia characterizes the group of juvenile lipidosis, Laforty-type familial myoclonic epilepsy, certain mitochondrial disorders, or other chronic familial degenerative diseases of undefined type (paramyoclonus multiplex of Friedrich, dysynnergia cerebellaris myoclonica of Ramsay Hunt). In middle and late adult years, disseminated myoclonus joined with dementia usually indicates the presence of so-called Creutzfeldt-Jakob disease (page 814) and sometimes of Alzheimer disease. Myoclonus may be the main manifestation of juvenile myoclonic epilepsy, as discussed below. Uremia, at any age, gives rise to myoclonus, twitching, and sometimes to seizures. The large number of diseases causative of seizure disorders are discussed in Chapter 33, Chapter 37, and Chapter 39.

Juvenile Myoclonic Epilepsy This is probably the most common form of idiopathic generalized epilepsy. It begins in adolescence, typically about age 15. The patient comes to attention because of a generalized seizure, often upon awakening; less often, for morning myoclonic jerks that involve the entire body, or for absence seizures. The family reports that the patient has occasional myoclonic jerks of the arm and upper trunk that become prominent with fatigue, during early stages of sleep, or after alcohol ingestion. A few patients in our experience have had only the myoclonic phenomena and rare absence seizures that went unnoticed for years. The EEG characteristically shows bursts of 4- to 6-Hz irregular polyspike-and-wave activity. A linkage has been established to chromosome 6 in some cases of this illness and in some other forms of juvenile-onset epilepsy, but no mendelian pattern of inheritance has been established. The disorder does not impair intelligence and tends not to be progressive, but a proclivity to infrequent seizures usually persists throughout life. Valproic acid and other drugs are very effective in eliminating the seizures and myoclonus.

PARTIAL, OR FOCAL, SEIZURES

As indicated earlier, the International Classification divides all seizures into two types—generalized (described above), in which the clinical and EEG manifestations indicate bilateral and diffuse cerebral cortical involvement from the onset, and focal of partial (more recently termed localization-related) in which the seizure is the product of a focal lesion or EEG abnormality in some part of the cerebral cortex (or perhaps in a deep nuclear structure). As noted, partial seizures vary with the locale of the lesion and are conventionally divided into two groups, simple and complex, depending on whether consciousness is retained or impaired. Simple partial seizures most often arise from foci in the sensorimotor cortex. Complex partial seizures most often have their focus in the temporal lobe on one side or the other. Localization of the offending lesions and the types of seizures to which they give rise are listed in Table 16.2. These relationships are so helpful in diagnosis that they should be known to all neurologists.
Frontal Lobe Partial Seizures (Focal Motor and Jacksonian Seizures)

Focal or partial motor seizures are attributable to a discharging lesion of the opposite frontal lobe. The most common type, attributable to a focus in the supplementary motor area, takes the form of a turning movement of the head and eyes to the side opposite the irritative focus, associated with a tonic contraction of the trunk and limbs on that side. This may constitute the entire seizure, or it may be followed by focal and then generalized clonic movements; generalization of the seizure may occur just before or simultaneously with loss of consciousness. On the other hand, a lesion in one frontal lobe may give rise to a major generalized convulsion without an initial turning of the head and eyes. It has been postulated that in both types of seizure, the one with and the one without turning movements, there is an immediate spread of the discharge from the frontal lobe to integrating centers in the thalamic or high midbrain reticular formation, accounting for the loss of consciousness.

Seizures that begin with forceful, sustained deviation of the head and eyes, and sometimes of the entire body, are referred to as verballike or verballike. Since the turning movements are usually to the side opposite the irritative focus (sometimes to the same side), conterversive and ipsiversive respectively would be preferable terms. Nonforceful, unsustained, or seemingly random lateral head movements during the ictus do not have localizing value. The same is true for the head and eye turning that occurs at the end of the generalized tonic-clonic phase of a seizure (Fig. 22-1). Conterversive deviation of only the head and eyes can be induced most consistently by electrical stimulation of the superoposterior frontal region (area 6), just anterior to area 6 (see Fig. 22-1). Less consistently, the same movements can be obtained by stimulating the more anterior portions of the frontal cortex, the posterior part of the superior frontal gyrus (the supplementary motor area), and the temporal or occipital cortex—presumably through propagation of the ictal discharge to the frontal conterversive area. In seizures of temporal lobe origin, early in the seizure, there may be head turning ipsilaterally followed by forceful, conterversive head (and body) turning. These head and body movements, if they occur, are preceded by quiet staring and automatons.

The Jacksonian motor seizure begins with a tonic contraction of the fingers of one hand, the face on one side, or the muscles of one foot. This transforms into clonic movements in these parts in a fashion analogous to that in a generalized clonic-tonic-clonic convolution. Sometimes a series of clonic movements of increasing frequency build up to a tonic contraction. The movements may remain localized or spread (“march”) from the part first affected to other muscles on the same side of the body. In the latter, or “classic,” Jacksonian form, which is relatively uncommon, the seizure spreads from the hand, up the arm, to the face, and down the leg; or, if the first movement is in the foot, the seizure marches up the leg, down the arm, and to the face, usually in a matter of 20 to 30 s. Interestingly, spontaneously occurring focal motor seizures, e.g., those beginning in the toes or fingers, may sometimes be arrested (inhibited) by applying a ligature above the affected part or, in the case of focal sensory seizures, by applying a vigorous sensory stimulus ahead of the advancing sensory aura. Rarely, the first muscular contraction is in the abdomen, thorax, or neck. In some cases, the one-sided seizure activity is followed by turning of the head and eyes to the convulsing side, occasionally to the opposite side, and then by a generalized seizure with loss of consciousness. Consciousness is not lost if the sensorimotor symptoms remain confined to one side.

The high incidence of onset of focal motor epilepsy in the face, hands, and toes is probably related to the disproportionately large cortical representation of these parts. The disease process or focus of excitation is usually in or near the rolandic cortex, i.e., area 4 of Brodmann (Fig. 3-3 and Fig. 22-1); in some cases, and especially if there is a sensory accompaniment, it has been found in the postrolandic convolution. Lesions confined to the motor cortex are reported to assume the form of clonic contractions, and those confined to the premotor cortex (area 6), tonic contractions of the contralateral arm, face, neck, or all of one side of the body. Tonic elevation and extension of the contralateral arm (“fencer’s posture”) and choreoathetotic and dystonic postures have been associated with high medial frontal lesions (area 8 and supplementary motor cortex), as have complex, bizarre, and flailing movements of a contralateral limb. Perspiration and piloerection occur occasionally in parts of the body involved in a focal motor seizure, suggesting that these autonomic functions have a cortical representation in or adjacent to the rolandic area. Focal motor and Jacksonian seizures have essentially the same localizing significance.

Seizure discharges arising from the cortical language areas may give rise to a brief aphasic disturbance (ictal aphasia) or, more frequently, to vocal arrest. Ictal aphasia is usually succeeded by other focal or generalized seizure activity but may occur in isolation, without loss of consciousness, in which case it can later be described by the patient. Postictal aphasia is more common and has much the same localizing value. Vocalization at the onset of a seizure has no such significance. These disturbances should be distinguished from the stereotyped repetition of words or phrases or the garbled speech that characterizes some cases of complex partial seizures or the postictal confusional state.

As pointed out by Manford and colleagues, relatively few focal seizures can be localized precisely from clinical data alone. However, when combined with scalp and intracranial EEG recording and MRI, the data are reasonably accurate.

Somatosensory, Visual, and Other Types of Sensory Seizures

Somatosensory seizures, either focal or “marching” to other parts of the body on one side, are nearly always indicative of a focus in or near the postrolandic convolution of the opposite cerebral hemisphere. Penfield and Kristiansen found the seizure focus in the postcentral or precentral convolution in 49 of 55 such cases. The sensory disorder is usually described as numbness, tingling, or a “pins-and-needles” feeling and occasionally as a sensation of crawling (formication), electricity, or movement of the part. Pain and thermal sensations may occur but are exceedingly rare. In the majority of cases, the onset of the sensory seizure is in the lips, fingers, or toes, and the spread to adjacent parts of the body follows a pattern determined by sensory arrangements in the postcentral (postrolandic) convolution of the opposite hemisphere. If the sensory symptoms are localized to the head, the focus is in or adjacent to the lowest part of the convolution, near the Sylvian fissure; if the symptoms are in the leg or foot, the upper part of the convolution, near the superior sagittal sinus or on the medial surface of the hemisphere, is involved.

Visual seizures are relatively rare but also have localizing significance. Lesions in or near the striate cortex of the occipital lobe usually produce elemental visual sensations of darkness or sparks and flashes of light, which may be stationary or moving and colorless or colored. According to Gowers, red is the most frequently reported color, followed by blue, green, and yellow. These images may be referred to the visual field on the side opposite the lesion or may appear straight ahead. If they occur on one side of the visual field, patients usually report that only one eye is affected (the one opposite the lesion), probably because most persons are aware of only the temporal half of a homonymous field defect. Curiously, a seizure arising in one occipital lobe may cause momentary blindness in both fields. It has been noted that lesions on the lateral surface of the occipital lobe (Brodmann areas 18 and 19) are likely to cause a sensation of twinkling or pulsating lights. More complex or formed visual hallucinations are usually due to a focus in the posterior part of the temporal lobe, near its junction with the occipital lobe, and may be associated with auditory hallucinations. The localizing value of visual auras has been confirmed recently by Bien and colleagues in a group of 20 surgically treated patients with intractable seizures. They found that elementary visual hallucinations and visual loss were typical of occipital lobe epilepsy but could also occur with seizures foc1 in the anteromedial temporal and occipitotemporal regions.

Auditory hallucinations are infrequent as an initial manifestation of a seizure. Occasionally a patient with a focus in one superior temporal convolution will report a buzzing or roaring in the ears. A human voice, sometimes repeating unrecognized words, has been noted a few times with lesions in the more posterior part of one temporal lobe.

Vertiginous sensations of a type suggesting a vestibular origin may be the first symptom of a seizure. The lesion is usually localized to the superoposterior temporal region or the junction between parietal and temporal lobes. In one of the cases reported by Penfield and Jasper, a sensation of vertigo was evoked by stimulating the cortex at the junction of the parietal and occipital lobes. Occasionally, with a temporal focus, the vertigo is followed by an auditory sensation. Giddiness, or
light-headedness, is a frequent prelude to a seizure, but this symptom has so many different connotations that it is of little diagnostic value.

Olfactory hallucinations are often associated with disease of the inferior and medial parts of the temporal lobe, usually in the region of the parahippocampal convolution or the uncus (hence Jackson's term *uncinate seizures*, pages 242 and 481). Usually the perceived odor is externalized, i.e., projected to someplace in the environment, and is described as disagreeable or foul, though otherwise unidentifiable. Olfactory hallucinations have also been recorded in proven cases of temporal lobe disease (see page 245) and with lesions of the insula and parietal operculum; salivation and a sensation of thirst may be associated. Electrical stimulation in the depths of the sylvian fissure, extending into the insular region, has produced peculiar sensations of taste.

Vague and often indefinable visceral sensations arising in the thorax, epigastrium, and abdomen are among the most frequent of auras, as already indicated. Most often they have a temporal lobe origin although in several such cases the seizure discharge has been localized to the upper bank of the sylvian fissure; in a few others, the focus was located in the upper or middle frontal gyrus or in the medial frontal area near the cingulate gyrus. Palpitation and acceleration of the pulse at the beginning of the attack have also been related to a temporal lobe focus.

**Complex Partial Seizures (Psychomotor Seizures, Temporal Lobe Seizures)**

These differ from the major generalized and absence seizures discussed above in that (1) the aura (i.e., the initial event in the seizure) may be either a focal seizure of simple type or a hallucination or perceptual illusion, indicating (usually) a temporal lobe origin, and (2) instead of a complete loss of control of thought and action, there is a period of altered behavior and consciousness, for which the patient is later found to be amnesic.

Although it is difficult to enumerate all the psychic experiences that may occur during complex partial seizures, they may be categorized into a somewhat arbitrary hierarchy of illusions, hallucinations, dyscognitive states, and affective experiences. Sensory illusions, or distortions of ongoing perceptions, are the most common. Objects or persons in the environment may shrink or recede into the distance, or, less frequently, they may enlarge (micropsia and macropsia). Tilting of the visual environment has been reported. Hallucinations are most often visual or auditory, consisting of formed or unformed visual images, sounds, and voices; less frequently, they may be olfactory (usually unpleasant, unidentifiable sensations of smell), gustatory, or vertiginous. The term *dyscognitive state* refers to feelings of increased reality or familiarity (déjà vu) or to strangeness or unfamiliarity (jamais vu) or a stated depersonalization. Fragments of certain old memories or scenes may insert themselves into the patient's mind and recur with striking clarity, or there may be an abrupt interruption of memory. (See Gloor for a more detailed description of the experiential phenomena of temporal lobe epilepsy.) Episodic and abdominal sensations have been alluded to above.

Emotional experiences, while less common, may be dramatic—sadness, loneliness, anger, happiness, and sexual excitement have all been recorded. Fear and anxiety are the most common affective experiences, while occasionally the patient describes a feeling of rage or intense anger as part of a complex partial seizure. Ictal fear may have no apparent connection to objective experience and is generally not related to the situation in which the patient finds himself during the seizure.

Each of these subjective psychic experiences may constitute the entire seizure (simple partial seizure), or some combination may occur and proceed to a period of unresponsiveness. The motor components of the seizure occur during the latter phase and take the form of automatism (sl, as lip smacking, chewing or swallowing movements, salivation, fumbling of the hands, or shuffling of the feet). The patient may walk around in a daze or act inappropriately (undressing in public, speaking incoherently, etc.). Certain complex acts that were initiated before the loss of consciousness—such as walking, chewing food, turning the pages of a book, or even driving—may continue. However, when a specific question or command is given, the patient is obviously out of contact with his surroundings. There may be no response at all, or the patient may look toward the examiner in a perplexed way or utter a few stereotyped phrases. In a very small number of patients with temporal lobe seizures (7 of 123 patients studied by Ebener et al), some degree of responsiveness (to simple questions and motor commands) was preserved in the presence of prominent automatism such as lip smacking and swallowing. Interestingly, in this small group of partially responsive patients, the seizures lateralized to the right temporal lobe.

The patient, in his confused and irritable state, may resist or strike out at the examiner. The *violence and aggression* that are said to characterize patients with temporal lobe seizures usually take this form of nondirected oppositional resistance in response to restraint during the period of automatic behavior (so-called because the patient presumably acts like an automaton) or, more often, in the postictal period. Unprovoked assault or outbreaks of intense rage or blind fury are very unusual; rather, the outburst is often associated with such outbursts in only 16 of 696 patients (2.4 percent) with temporal lobe epilepsy. Peri iced once commented that he had never observed a rage state as a result of temporal lobe stimulation. It is exceedingly unlikely that an organized violent act requiring several sequential steps in its performance, such as obtaining a gun and using it, could represent a temporal lobe seizure.

Rarely, laughter (gelastic epilepsy) may be the most striking feature of an automatism. (A particular combination of gelastic seizures and precocious puberty is due to a hamartoma of the hypothalamus.) Or the patient may walk repetitively in small circles (voluntary epilepsia), run (epilepsia proscura), or simply wander aimlessly, either as an ictal or postictal phenomenon (piorrhea). These forms of seizure are actually more common with frontal lobe than with temporal lobe. Dystonic posturing of the arm and leg contralateral to the seizure focus is found to be a frequent accompaniment if sought—again, the origin is more often in the frontal than in the temporal lobes localizing particularly to the supplementary motor area. After the attack, the patient usually has no memory or only fragments of recall for what was said or done. Any type of complex partial seizure may proceed to other forms of secondary generalized seizures. The tendency to generalization holds true for all types of partial or focal epilepsy.

The patient with temporal lobe seizures may exhibit only one of the foregoing manifestations of seizure activity or various combinations of them. In a series of 414 patients studied by Lennox, 43 percent displayed some of the motor changes; 32 percent, automatic behavior; and 25 percent, alterations in psychic function. Because of the frequent concurrence of these symptom complexes, he referred to them as the psychomotor triad. Probably the clinical pattern varies with the precise location of the lesion and the direction and extent of spread of the electrical discharge. Because of their focal origin and complex symptomatology, all these types of seizures are subsumed under the title of *complex partial seizures*. This term is preferable to *temporal lobe seizures*, since typical complex partial seizures sometimes arise from a focus in the medial-oral part of the frontal lobe, and the seizure discharge in such cases can be limited to the frontal lobe. Also, seizures originating in the parietal or occipital lobes may be manifested as complex partial seizures because of seizure spread into the temporal lobes. Often the brief ictal aura is not reflected in cortical epileptic activity and therefore may be missed by routine EEG recordings.

Complex partial seizures are not peculiar to any period of life but show an increased incidence in adolescence and the adult years. In the series of Ounsted and coworkers, about one-third of such cases could be traced to the occurrence of severe febrile convulsions in early life (see further on). As a corollary, about 5 percent of all their patients with febrile seizures continued to have seizures during adolescence and adult life; in the latter group there were many in whom the seizures were of the temporal lobe type. Also, in Falconer's series of temporal lobectomies for intractable epilepsy, there were many patients who had previously had this type of aura. In their series, about one-third of such cases could be traced to the occurrence of severe febrile convulsions in early life (see further on). As a corollary, about 5 percent of all their patients with febrile seizures continued to have seizures during adolescence and adult life; in the latter group there were many in whom the seizures were of the temporal lobe type. T2-weighted image showing signal change in the hippocampi. (Courtesy of Dr. Peter William)
Complex partial seizures are notably retained more than an hour or two, although postictal confusion and amnesia may persist for a considerably longer time. Some complex partial seizures consist only of a momentary change in facial expression and a blank spell, resembling an absence. Almost always, however, the former are characterized by distinct ictal and postictal phases, whereas patients with absence attacks usually have an instantaneous return of full consciousness following the ictus.

Postictal behavior after partial complex seizures is often accompanied by widespread slowing in the EEG. With seizures of left-sided origin there is likely to be global and nonfluent aphasia. Prolonged disorientation for time and place suggests a right-sided source. Automatisms in the postictal period have no lateralizing connotation (Devinsky et al.). However, postictal posturing and paresis of an arm (Todd's paralysis) or an aphasic difficulty are helpful in determining the side of the lesion (Caviness). Also, postictal nosal wiping, is carried out by the hand ipsilateral to the seizure focus in 75 percent of patients, according to Leutzmeyer and colleagues, but the authors are in no position to confirm this.

Amnestic Seizures Rarely, brief, recurrent attacks of transient amnesia are the only manifestations of temporal lobe epilepsy, although it is unclear whether the amnesia in such patients represents an ictal or postictal phenomenon. These attacks of pure amnesia have been referred to as transient epileptic amnesia, or TEA (Palmini et al.; Zeman et al.). If the patient functions at a fairly high level during the attack, as may happen, there is some resemblance to transient global amnesia (page 457). However, the brevity and frequency of the TEA spells, their tendency to occur on awakening, the impaired performance on complex cognitive tasks, and, of course, a history of epilepsy and associated seizure discharges in the EEG help to make the distinction.

Behavioral and Psychiatric Disorders Some comments are in order concerning the issues of personality, behavioral, and psychiatric disorders in patients with complex partial seizures. Data as to prevalence and diagnostic criteria have been derived mainly from studies of selected groups of patients attending university hospital and other specialty clinics that tend to treat the most difficult and complicated cases. In one such study (Victoroff), about one-third of the patients had a history of major depressive illness and an equal number had symptoms of anxiety disorder; psychotic symptoms were found in 10 percent. Similar figures, also from a university-based epilepsy center, have been reported by Blumer et al. It must be emphasized that these remarkable rates of psychiatric morbidity do not reflect the prevalence in the entire population of epileptics.

The postictal state in patients with temporal lobe epilepsy sometimes takes the form of a protracted paranoid-delusional state. Indeed, some patients lapse into a paranoid-delusional or amnestic psychosis lasting for days or weeks. The EEG during this period may show no seizure discharge, though this does not exclude repeated or sustained seizure activity in the amygdala and other deep temporal lobe structures. This disorder, virtually indistinguishable from schizophrenia, may also persist into the postictal period. Again, the differential diagnosis is uncertain. An excess of psychosis has been reported only in studies emanating from specialized centers; epidemiologic studies provide only limited evidence of an excess of psychosis in the overall population of epileptics (see Trimble and Schmitz and the review by Trimble for a critical discussion of this subject).

Epileptic Personality Disorder It has long been observed that some patients with temporal lobe seizures also exhibit a number of abnormalities of behavior and personality during the interictal period. Often they are slow and rigid in their thinking, verbos, circumstantial and tedious in conversation, inclined to mysticism, and preoccupied with rather naive religious and philosophical ideas. Also they are often subject to outbreaks of bad temper and aggressiveness. Obsessionalism, humorless sobriety, emotionalism (mood swings, sadness and anger) and a tendency to paranoia are often frequently described traits. Diminished sexual interest and potency in men and menstrual problems in women, not readily attributable to anticonvulsant drugs, are common among patients with complex partial seizures of temporal lobe origin. Geschwind proposed that a triad of behavioral abnormalities—hyposexuality, hypergraphia and hyperreligiosity—constitute a characteristic syndrome in such patients.

Bear and Fedio have suggested that certain of these traits (obsessionalism, elation, sadness, and emotionality) are more common with right temporal lesions and that anger, paranoia, and cosmologic or religious conceptualizing are more characteristic of left temporal lesions. However, Rodin and Schmitz, who administered the Gibbs and Gibbs test to patients with both primary generalized and temporal lobe epilepsy, found no features that would distinguish patients with right-sided temporal foci from those with left-sided foci. Moreover, they found no behavioral changes that would distinguish patients with temporal lobe epilepsy from other groups of epileptics. The problem of personality disturbances in epilepsy remains to be clarified (see review by Trimble).

SPECIAL EPILEPTIC SYNDROMES

There remain to be considered several epileptic syndromes and other seizure states that cannot be readily classified with the usual types of generalized or partial seizures. These special types are described below.

Benign Childhood Epilepsy with Centrtemporal Spikes (Rolandic Epilepsy, Sylvian Epilepsy) or with Occipital Spikes

This type of focal motor epilepsy is unique among the partial epilepsies of childhood in that it tends to be a self-limited disorder, transmitted in families as an autosomal dominant trait. The convulsive disorder begins between 5 and 9 years of age and usually announces itself by a nocturnal tonic-clonic seizure with focal onset. Thereafter, the seizures take the form of clonic contractions of one side of the face, less often of one arm or leg, and the interictal EEG shows high-voltage spikes in the contralateral lower Rolandic or centroparietal area. The seizures are readily controlled by a single anticonvulsant drug and gradually disappear during adolescence. The relation of this syndrome to acquired aphasia with convulsive disorder in children, described by Landau and Kleffner, is unsettled.

A similar type of epilepsy, usually benign in the sense that there is no intellectual deterioration and a cessation of seizures in adolescence, has been associated with spike activity over the occipital lobes. In both of these types of childhood epilepsy, the observation that spikes are greatly accentuated by sleep is a useful diagnostic aid.

Infantile Spasms (West Syndrome) This is the term applied to a particular form of epilepsy of infancy and early childhood. West, in the mid-nineteenth century, described the condition in his son in exquisite detail. This seizure disorder, which in most cases appears during the first year of life, is characterized by recurrent, gross flexion movements of the trunk and limbs and, less frequently, by extension movements (hence the alternative terms infantile spasms or salsam or jackknife seizures). Most but not all patients with this disorder show severe EEG abnormalities, consisting of continuous multifocal spikes and slow waves of large amplitude. However, this pattern, referred to originally by Gibbs and Gibbs as hypsarrhythmia (“mountainous” dysrhythmia), is not specific for infantile spasms, being frequently associated with other developmental or acquired abnormalities of the brain. As the child matures, the seizures diminish and usually disappear by the fourth to fifth year. If MRI and CT scans are more or less normal, the usual pathologic findings according to Jellinger are cortical dysgenoses. Both the seizures and the EEG abnormalities may respond dramatically to treatment with adrenocorticotropic hormone (ACTH), corticosteroids, or the benzodiazepine drugs, of which clonazepam is probably the most widely used. However, most patients, even those who were apparently normal when the seizures appeared, are left mentally impaired. Infantile spasms may also be part of the Lennox-Gastaut syndrome, a seizure disorder of early childhood of grave prognosis (see page 335).

Febrile Seizures

The well-known febrile seizure, peculiar to infants and children between 6 months and 5 years of age (peak incidence 9 to 20 months) and with a strong tendency to be inherited, is generally regarded as a benign condition. Usually it takes the form of a single, generalized motor seizure occurring as the temperature rises or remains elevated. In the common form, the seizure lasts less than a few minutes; if the time an EEG can be obtained, there is usually no abnormality. Recovery is complete. Except for a presumed genetic relationship with benign epilepsy of childhood (Luders et al.), which in itself is transient in nature, these patients’ risk of developing epilepsy in later life is only slightly greater than that of the general population.

This benign type of febrile seizure should not be confused with a second and more serious type of illness in which an acute encephalitic or encephalopathic state presents as a febrile illness with focal or prolonged seizures, generalized or focal EEG abnormalities, and repeated episodes of febrile convulsions with the same or different illnesses (complicated febrile seizures). These seizures may recur not only with infections but also at other times. When patients with both types are lumped together under the rubric of febrile convulsions, it is not surprising that a high percentage are complicated by atypical petit mal, atonic, and astatic spells followed by tonic seizures, mental retardation, and partial complex epilepsy. Falconer, who studied psychomotor seizures in adults, noted retrospectively a high incidence of
“fibrile seizures” during the infancy and childhood of his subjects. The present authors believe that he was referring to complicated fibrile seizures, i.e., fever and convulsions with structural brain disease, which should be kept separate from the common benign fibrile seizures. In a later study of 67 patients with proven medial temporal lobe epilepsy (French et al.), 70 percent had a history of complicated fibrile seizures during the first 5 years of life, although many did not develop temporal lobe epilepsy until their teens. Bacterial meningitis was another important risk factor; head and birth trauma were less common factors. All of the patients had complex partial seizures and half of them, in addition, had secondarily generalized tonic-clonic seizures.

Epidemiologic studies have substantiated this clinical point of view. Annegers and colleagues observed a cohort of 687 children for an average of 18 years after their initial fever convulsion. Overall, these children had a fivefold excess of unprovoked seizures in later life. Among the children with simple fever convulsions, the risk was only 2.4 percent. By contrast, children with what Annegers et al. called complex febrile convulsions (focal, prolonged, or repeated episodes of fibrile seizures) had a greatly increased risk—8, 17, or 49 percent, depending on the association of one, two, or three of the complex features.

Reflex Epilepsy

For a long time it has been known that seizures could be evoked in certain epileptic individuals by a discrete physiologic or psychologic stimulus. The term reflex epilepsy is reserved for this small subgroup. Forster has classified these seizures in accordance with their evocative stimuli into five types: (1) visual—flickering light, visual patterns, and specific colors; (2) auditory—sudden unexpected noise (startle), specific sounds, musical themes, and voices; (3) somato-sensorv—either a brisk unexpected tap or sudden movement after sitting or lying still, or a prolonged tactile or thermal stimulus to a certain part of the body; (4) writing or reading of words or numbers; and (5) eating.

Visually induced seizures are by far the most common type of reflex epilepsy. The seizures are generalized and are most often triggered by the photic stimulation of television or an EEG examination or by the photic or pattern stimulation of video games. In other types of reflex epilepsy, the evoked seizure may be focal (beginning often in the part of the body that was stimulated) or generalized and may take the form of one or a series of myoclonic jerks or of an absence or tonic-clonic seizure. Seizures induced by reading, voices, or eating are most often of the complex partial type; seizures induced by music are usually myoclonic. A few such instances of reflex epilepsy have been due to focal cerebral disease, particularly occipital lesions.

Clonazepam, valproate, carbamazepine, and phenytoin are all effective in controlling individual instances of reflex epilepsy. Some patients learn to avert the seizure by understanding a mental task, e.g., thinking about some distracting subject, counting, etc., or by initiating some type of physical activity. Forster has demonstrated that in certain types of reflex epilepsy, the repeated presentation of the noxious stimulus may eventually render the stimulus innocuous. This technique requires a great deal of time and assiduous reinforcement, which limits its therapeutic value.

Epilepsia Partialis Continua

This is another special type of focal motor epilepsy characterized by persistent rhythmic clonic movements of one muscle group—usually of the face, arm, or leg—which are repeated at fairly regular intervals every few seconds and continue for hours, days, weeks, or months without spreading to other parts of the body. The term “partial” is, in effect, applied to the entire body. The distal musculature is involved first, and especially the flexors of the hand and fingers, are affected more frequently than the proximal ones. In the face, the recurrent contractions involve either the corner of the mouth, or one or both eyelids. Occasionally, isolated muscles of the neck or trunk are affected on one side. The clonic spasms may be accentuated by active or passive movement of the involved muscles and may be reduced in severity but not abolished during sleep.

First described by Kozhevnikov in patients with Russian spring-summer encephalitis, these partial seizures may be induced by a variety of acute or chronic cerebral lesions. In some cases the underlying disease is not apparent and the clonic movements are mistaken for some type of slow tremor or extrapyramidal movement disorder. Most patients with epilepsy partialis continua show focal EEG abnormalities, either repetitive slow-wave abnormalities or sharp waves or spikes over the central areas of the contralateral hemisphere. In some cases, the spike activity can be related more precisely in location and time to the clonic movements (Thomas et al.). In the series of cases collected by Obeso and colleagues, there were various combinations of epilepsy partialis continua and cutaneous reflex myoclonus (cortical myoclonus occurring only in response to a variety of afferent stimuli); these investigators view epilepsy partialis continua as part of a spectrum of motor disorders that also includes stimulus-sensitive myoclonus, focal motor seizures, and grand mal seizures. As would be expected, a wide range of causative lesions has been implicated—developmental anomalies, encephalitis, demyelinative diseases, brain tumors, and degenerative diseases. In our experience, epilepsy partialis continua has been particularly common in patients with Rasmussen’s encephalitis (page 352). As a rule, this type of seizure activity responds poorly or not at all to anticonvulsant medications.

Whether cortical mechanisms or subcortical ones are responsible for epilepsy partialis continua is an unresolved question. The electrophysiological evidence adduced by Thomas and colleagues favors a cortical origin. The pathologic evidence is less definite. In each of eight cases in which the brain was examined postmortem, they found some involvement of deeper structures on the same side as the cortical lesion, on the opposite side, or on both sides.

Hysterical Seizures

These seizures, also referred to as “psychogenic” seizures, are nonepileptic in nature—i.e., they are not caused by an abnormal neuronal discharge. They are mentioned here because they are frequently mistaken for epileptic seizures treated with anticonvulsant drugs, to which they are characteristically unresponsive. Such seizures are most often a symptom of hysteria in the female (“Briquet disease”) or of compensation neurosis and malingering in males and females, in which case they are referred to as “exaggerated seizures” or “‘seizures sometimes exhibit hysterical seizures as well, and distinguishing the two may be difficult. However, in most cases the clonic seizures are sufficient to identify it as such: completely asynchronous thrashing of the limbs and repeated side-to-side movements of the head; striking out at a person restraining the patient; hand-biting, kicking, trembling, and quivering; pelvic thrusting and opisthotonic arching postures; and screaming or talking during the ictus. In general, pseudoseizures tend to occur in the presence of other people, to be precipitated by emotional factors, and to be prolonged for many minutes or hours; with few exceptions, tongue-biting, incontinence, hurtful falls, and quivering; pelvic thrusting and opisthotonic arching postures; and screaming or talking during the ictus. In general, pseudoseizures tend to occur in the presence of other people, to be precipitated by emotional factors, and to be prolonged for many minutes or hours; with few exceptions, tongue-biting, incontinence, hurtful falls, and postictal confusion are lacking. No single one of these features is determinative, however.

Prolonged fugue states usually have proved to be manifestations of hysteria or a psychopathy even in a known epileptic. The serum creatine kinase and prolactin levels are normal after hysterical seizures; this may be helpful in distinguishing them from genuine convulsions. Where doubt remains, a recording of the ictal or postictal EEG or the combined video and EEG recording of an attack will settle the issue. This subject is discussed further in Chap. 56.

THE NATURE OF THE DISCHARGING LESION

Physiologically, the epileptic seizure has been defined as a sudden alteration of central nervous system (CNS) function resulting from a paroxysmal high-frequency or synchronous low-frequency, high-voltage electrical discharge. This discharge arises from an assemblage of excitable neurons in any part of the cerebral cortex and possibly in secondarily involved subcortical structures as well. Of course, there need not be a visible lesion. Under the proper circumstances, a seizure discharge can be initiated in an entirely normal cerebral cortex, as when the cortex is activated by ingestion or injection of drugs, by withdrawal from alcohol or other sedative drugs, or by repeated stimulation with subconvulsive electrical pulses (“kindling phenomenon”).

Just why the neurons in or near a focal cortical lesion discharge abnormally is not fundamentally understood. Some of the electrical properties of a cortical epileptogenic focus suggest that its neurons have been deafferented. Such neurons are known to be hyperexcitable, and they may remain so chronically, in a state of partial denervation, thereby the neurons surrounding the epileptogenic focus are hyperpolarized from the beginning and are mainly GABAergic, thereby inhibiting the neurons within the focus.
Seizure spread probably depends on any factor or agent that activates neurons in the focus or inhibits those surrounding it. The precise mechanisms that govern the transition from a circumscribed interictal discharge to a widespread seizure state are not understood.

Biochemical studies of neurons from a seizure focus have not clarified the problem. Levels of extracellular K are found to be elevated in glial scars near epileptic foci, and high intracellular Na and Ca. These ions are known to be sensitive to hypoxia and to be lower in binding.

Epileptic foci are known to be sensitive to acetylcholine and to be slower in binding and removing it than is normal cerebral cortex. A deficiency of the inhibitory neurotransmitter GABA, increased glycine, decreased taurine, and either decreased or increased glutamic acid have been variously reported in excised human epileptogenic tissue, but whether these changes are the cause or result of seizure activity has not been determined. The interpretation of reported abnormalities of GABA, biogenic amines, and acetylcholine in the cerebrospinal fluid (CSF) of epileptic patients poses similar difficulties.

Concurrent EEG recordings from an epileptogenic cortical focus and subcortical, thalamic, and brainstem centers in the animal model have enabled investigators to construct a sequence of electrical and clinical events that characterize an evolving focal seizure. Firing of the involved neurons in the cortical focus is reflected in the EEG as a series of periodic spike discharges, which increase progressively in amplitude and frequency. Once the intensity of the seizure discharge exceeds a certain point, it overcomes the inhibitory influence of surrounding neurons and spreads to neighboring cortical regions via short corticocortical synaptic connections. If the abnormal discharge remains confined to the cortical focus and the immediate surrounding cortex, there are probably no clinical symptoms or signs of seizure, and the EEG abnormality that persists during the interseizure period reflects this restricted type of abnormal cortical activity.

If unchecked, cortical excitation spreads to the adjacent cortex and to the contralateral cortex via interhemispheric pathways and also to anatomically and functionally related pathways in subcortical nuclei (particularly the basal ganglionic, thalamic, and brainstem reticular nuclei). It is then that the first clinical manifestations of the seizure begin, the initial signs and symptoms depending upon the portion of the brain from which the seizure originates. The excitation activity from the subcortical nuclei is fed back to the original focus and to the other parts of the forebrain, a mechanism that serves to amplify their excitatory activity and to give rise to the characteristic high-voltage polyspike discharge in the EEG. There is propagation down to spinal neurons as well, via corticospinal and reticulospinal pathways, yielding a generalized tonic-clonic convolution.

The spread of excitation to the subcortical, thalamic, and brainstem centers are thought to correspond to the tonic phase of the seizure and loss of consciousness, as well as to the signs of autonomic nervous system overactivity (salivation, mydriasis, tachycardia, increase in blood pressure). Vital functions may be arrested, but usually only for a few seconds. In rare instances, however, death may occur owing to a sustained cessation of respiration, a derangement of cardiac action, or some unknown cause. The development of unconsciousness and the generalized tonic contraction of muscles is reflected in the EEG by a diffuse high-voltage discharge pattern appearing simultaneously over the entire cortex.

Soon after the spread of excitation, a diencephalocortical inhibition begins and intermittently interrupts the seizure discharging, changing it from the persistent discharge of the tonic phase to the intermittent bursts of the clonic phase. Electrically, a transition occurs from a continuous polyspike to a spike-and-wave pattern. The intermittent clonic bursts becomes less and less frequent and finally cease altogether, leaving in their wake an "exhaustion" of the neurons of the epileptogenic focus, an increased permeability of the blood-brain barrier. An overshoot of these inhibitory mechanisms is thought to be the basis of Todd's postepileptic paralysis (and of postictal stupor, senility, loss of memory, aphasia, hemiopia, headache, diffuse slow waves in the EEG) and regional edema in T2-weighted MR images. Plum and associates have observed a two- to threefold increase in glucose utilization during seizure discharges, and the paralysis that follows might be due to neuronal depletion of glucose and increase in lactic acid. However, inhibition of epileptogenic neurons may occur in the absence of neuronal exhaustion. The exact patterns played by each of these factors in the paroxysmal pattern of function is not settled.

Bilaterally synchronous 3-per-second high-voltage spike-and-wave discharges and seizures resembling absence attacks have been produced in animals by a number of experimental procedures. The spike-and-wave complex, which represents brief excitation followed by slow-wave inhibition, is the type of EEG pattern that characterizes the tonic (inhibitory) phase of the focal motor or grand mal seizure. By contrast, this strong element of inhibition is present diffusely throughout an "absence" attack, a feature that perhaps accounts for the failure of excitation to spread to lower brainstem and spinal structures (tonic-clonic movements do not occur). However, the absence seizure can also at times activate the mechanism for rhythmic myoclonus, probably at an upper brainstem level.

Current physiologic data indicate that the characteristic EEG patterns of both generalized forms of epilepsy (i.e., tonic or tonic-clonic and absence) are generated in the neocortex and are enhanced by the synchronizing influences of subcortical structures. In both instances, the generalization of the clinical and electrical manifestations depends upon a activation of a deep, centrally located physiologic mechanism which, for reasons outlined in Chapter 17, includes the midbrain reticular formation and its diencephalic extension, the intralaminar and nonspecific thalamic projection systems (originally referred to by Penfield as the "centrencephalon"). There is no evidence, however, that seizure activity originates in these deep activating structures, for which reason the term centrencephalic epilepsy has been replaced by corticoreticular epilepsy.

Complex partial seizures are almost always of temporal origin, arising in foci in the medial temporal lobe, amygdaloid nuclei, and hippocampus. Only rarely do they originate in the neocortex, and propagate to the amygdaloid nuclei, hippocampus, and posteroi Inferior part of the frontal lobe. Electrical stimulation in these areas reproduces feelings of depersonalization, emotionality, and automatic behavior, the characteristic features of psychomotor epilepsy. The automatic behavior appears to be a direct effect of the temporal discharge in some instances and a postexcitatory or inhibitory effect in others. Loss of memory for the events of the episodes may be due to the paralytic effect of the discharge on neurons of the hippocampus.

Of theoretical importance is the observation that a seizure focus, if active for a time, may sometimes establish, via commissural connections, a persistent secondary focus in the corresponding cortical area of the opposite hemisphere (mirror focus). The nature of this phenomenon is obscure; it may be similar to the "kindling" phenomenon mentioned earlier in animals, where a repeated nonconvulsive stimulation induces a permanent epileptic focus. No morphologic change is visible in the mirror focus, at least by light microscopy. The mirror focus may be a source of confusion in trying to identify the side of the primary lesion by EEG, but there is little evidence that it can produce chronic seizures in humans. Similarly, there are no firm data supporting a role for kindling in the diagnosis and management of patients with epilepsy (Goldstein et al.).

Severe seizures may be accompanied by a systemic lactic acidosis with a fall in arterial pH, reduction in arterial oxygen saturation, and rise in Pco2. These effects are secondary to the respiratory arrest and excessive muscular activity. If prolonged, they may cause hypoxic-ischemic damage to remote areas in the cerebrum, basal ganglia, and cerebellum. In paralyzed and artificially ventilated subjects receiving electroconvulsive therapy, these changes are less marked and the oxygen tension in cerebral venous blood may actually rise. Heart rate, blood pressure, and particularly CSF pressure rise briskly during the seizure. According to Plum and colleagues, the rise in blood pressure evoked by the seizure usually causes a sufficient increase in cerebral blood flow to meet the increased metabolic needs of the brain.

The Electroencephalogram in Epilepsy

The EEG provides confirmation of Hughlings Jackson's concept of epilepsy—that it represents a recurrent, sudden, excessive discharge of cortical neurons. The EEG is undoubtedly the most sensitive, indeed indispensable, tool for the diagnosis of epilepsy, but, like other laboratory tests, it must be used in conjunction with clinical data. In patients with idiopathic generalized seizures and in a high proportion of their relatives, interictal spike-and-wave abnormalities, without any clinical seizure activity, are common. Possibly if the EEG is repeated several times. Conversely, a proportion of epileptic patients have a perfectly normal interictal EEG. Occasionally, using standard methods of scalp recording, the EEG may even be normal during a simple or complex partial seizure. Furthermore, a small number of healthy persons (approximately 2 to 3 percent) show paroxysmal EEG abnormalities; some of them have a family history of epilepsy (particularly of absence seizures) and may themselves later develop seizures.

EEG abnormalities that characterize a spreading epileptogenic focus and generalization of seizure activity, both the grand mal and absence types, have been described in the preceding section and are illustrated in Chapter 2. At first there was thought to be a characteristic EEG picture for seizures, but further studies have not confirmed this, many patterns being possible. One consistent observation, however, has been that the region of earliest spike activity corresponds best to the epileptogenic focus. This rule guides epilepsy surgery. The postseizure, or postictal, state following generalized seizures also has its EEG correlate, taking the form of random generalized slow waves. Following partial, or focal, seizures, the EEG shows focal slowing. With clinical recovery, the EEG returns to normal or to the preseizure state. A single EEG tracing obtained during the interictal state is abnormal to some degree in 30 to 50 percent of epileptic patients; this figure rises to 60 to 70 percent if patients are subjected to three or more studies utilizing standard activating measures (hyperventilation, photic stimulation, and sleep; see Chapter 2). With structural lesions, focal slow and sharp activity, which is not clearly epileptiform, may be the only clue to a seizure focus.
A higher yield of abnormalities and a more precise definition of seizure types can be obtained by the use of several special EEG procedures. Overnight EEG recording are particularly helpful because focal abnormalities, particularly in the temporal lobes, are most prominent in stage II sleep. Sphenoidal leads have been used to detect interomodal temporal seizure activity, but they are uncomfortable and probably add no more information than can be obtained by the placement of additional subtemporal scalp electrodes. In our experience, nasopharyngeal electrode recordings are too contaminated by artifact to be clinically useful. Activating procedures such as hyperventilation, photic stroboscopic stimulation, and sleep increase the yield of EEG recordings, as detailed in Chap. 2.

Several long-term monitoring procedures are now in common use and are of particular value in the investigation of patients with surgically removable epileptogenic foci. The most common of these makes use of telemetry systems, in which the patient is attached to the EEG machine by cable or radio transmitter without unduly limiting his freedom of movement. The telemetry system is joined to an audiovisual recording system, making it possible to record seizure phenomena (even at night, under dim infrared light) and to synchronize them with the EEG abnormalities. An alternative is the use of a small cassette recorder that is attached to a miniature EEG machine worn by the patient at home and at work. The patient is instructed to push a button if he experiences an “event,” which can later be correlated with EEG activity. The role of intensive neurodiagnostic monitoring in the investigation and treatment of seizures is described in detail in the monographs of Engel and of Niedermeyer.

The EEG changes in epilepsy are discussed further in Chap. 2.

Other Laboratory Abnormalities Associated with Seizures

MRI is the most important diagnostic tool for the detection of structural abnormalities underlying epilepsy. Medial temporal sclerosis, glial scars, porencephalohypertropias, and other disorders of neuronal migration can be clearly visualized. After a seizure, particularly one with a focal component, MRI sometimes discloses subtle focal cortical swelling, or, if an agent is administered, an ill-defined cortical blush may be visible on CT or MRI. There is a rough relationship between the duration of seizure activity and the intensity and size of these cortical changes. Likewise, angiography performed soon after a seizure may show a focal area of enhanced flow. This phenomenon was often a source of confusion when radionucleate scans were routinely performed for the evaluation of new seizures—focal increased uptake being mistaken for a tumor or stroke. All of these imaging abnormalities are thought to reflect transient disruption of the blood-brain barrier, and they rarely persist for more than a day or two. Less well understood is the occasional finding on MRI of increased T-2 signal (probably due to hypoxia) in the hippocampi after a prolonged seizure or status epilepticus.

The CSF is known to contain a small number of white blood cells (rarely up to 50/mm³, but more often in the range of 10/mm³) in about 15 percent of patients after a seizure. A slight increase in protein is also possible. Like the imaging abnormalities just mentioned, these findings may lead to spurious conclusions about the presence of an intracranial infection, particularly if polymorphonuclear leukocytes predominate. Nonetheless, a significant pleocytosis after a seizure should always be construed as a sign of inflammatory or infectious disease.

Systemic acidosis is a common result of convulsive seizures, and it is not unusual for the serum pH to reach levels near 7.0 if taken immediately after a seizure. Almost all convulsions produce a rise in serum creatine kinase activity, a finding that could be used more frequently in emergency departments to assist in distinguishing seizures from fainting. Of course, extensive muscle injury from a fall or prolonged compression during a period of unconsciousness can produce the same abnormality.

Concentrations of serum procalcitonin, like those of other hypothalamic hormones, rise after all types of generalized seizures, including complex partial seizures, but not in absence or myoclonic types. An elevation may help differentiate a hysterical seizure from a genuine one; however, serum procalcitonin may also be slightly elevated after a syncope episode. Elevations persist for 10 to 20 min after the seizure. Detection is facilitated by collecting capillary blood from the finger on filter paper for accurate measurement. There is also a postictal rise in ACTH and serum cortisol, but these changes have a longer latency and briefer duration. If changes in these hormonal levels are used as diagnostic tests, one must have information about normal baseline levels, diurnal variations, and the effects of concurrent medications. Changes in body temperature, sometimes even preceding a seizure, may reflect hypothalamic changes but are far less consistent and therefore difficult to use in clinical practice.

Pathology of Epilepsy

In most autopsied cases of primary generalized epilepsy of the grand mal and absence types, the brains have been said to be grossly and microscopically normal. However, it is unlikely that the brains in these cases were examined completely—at least there is not a single case that has been subjected to whole-brain serial sectioning in a search for disorders of neural migration and old scars. Not surprisingly, there are also no visible lesions in the seizure states complicating drug intoxication and withdrawal, and transient hyper- and hyponatremia, and hyper- and hypoglycemia, which presumably represent derangements at the cellular level.

In contrast, most of the so-called secondary epilepsies have definable lesions. These include zones of neuronal loss and gliosis (scars) or other signs of tissue loss such as a porencephaly, dysgenetic cortex, heterotopias, hamartomas, vascular malformations, and tumors. The frequency of these lesions is not fully known. Certainly the focal epilepsies have the highest incidence of structural abnormalities, although in certain cases no morphologic change is visible. In several series of cases of temporal lobe excisions, such as that of Falconer, a specific pattern of neuronal loss with gliosis (sclerosis) in the hippocampal and amygdaloid region was found in the majority, and this abnormality is being increasingly recognized with MRI, as noted below. Vascular malformations, hamartomas, and low-grade astrocytomas were less frequent; in a small number, no abnormalities could be found.

The widespread use of CT and MRI has offered an important surrogate approach to the pathologic study of epilepsy. More than 20 years ago, Gastaut and Gastaut reported that in primary grand mal and absence epilepsies, a CT abnormality was found in approximately 10 percent of cases, whereas in the Lennox-Gastaut syndrome, the West syndrome, and partial complex epilepsies it was found in 52, 77, and 63 percent, respectively. Atrophy, calcification, and malformations were the most frequent changes. MRI and particularly the FLAIR images have proved to be a particularly sensitive means of detecting epileptogenic lesions of the medial-basal portion of the temporal lobes (mesial temporal sclerosis; Fig. 16-1) and cortical heterotopias and other developmental abnormalities that give rise to seizures. Repeatedly, patients are observed in whom MRI disclosed a cortical or subcortical developmental malformation or another surgically treatable lesion of the temporal lobe, even after CT scanning had failed to do so. More subtle epileptogenic foci (areas of hypometabolism or hyperfusion) may be demonstrated by position emission tomography (PET) or interictal single photon emission computed tomography (SPECT). Ictal SPECT, which shows hyperperfusion of the seizure focus, is a more demanding but also more sensitive and specific procedure.

With reference to the focal epilepsies, it has not been possible to determine which component of the lesion is responsible for the seizures. Gliosis, fibrosis, vascularization, and meningeal and cerebrovascular cicatrices have all been incriminated, but they are found in non epileptic foci as well. The Schiebels’ Golgi studies of neurons from epileptic foci in the temporal lobe showed distortions of dendrites, loss of dendritic spines, and disorientation of neurons near the scars, but these findings have dubious status since they were not usually compared with similar non epileptic lesions. Moreover, changes such as these have proved to be nonspecific and artifactual. Once a glotic focus of whatever cause, bordered by groups of discharging neurons, becomes epileptogenic, it may remain so throughout the patient’s lifetime. Nevertheless, with the passage of years, seizures cease in as many as half of childhood epilepsies.

The most common histologic finding in the brains of epileptics is a bilateral loss of neurons in the CA1 segment (Sommer sector) of the pyramidal cell layer of the hippocampus, extending into contiguous segments of the pyramidal layer and the underlying dentate gyrus. It is still undecided whether this neuronal loss is primary or secondary and, if the latter, whether it was incurred at birth (as alluded to above) or happened later as the consequence of seizures. The cessation of seizures in many patients following surgical resection of the medial temporal lobe favors the first interpretation.

Role of Heredity

Most primary epilepsies are thought to have a genetic basis and—as in many other idiopathic diseases, such as diabetes and atherosclerosis—a complex or polygenic inheritance is common. That a genetic factor is operative in primary generalized tonic-clonic seizures is suggested by the finding of a familial incidence in 5 to 10 percent of such patients and, in particular families, the inheritance of a generalized seizure disorder through specific chromosomal regions (e.g., Xq). The importance of genetic factors in the primary (idiopathic) epilepsies is also underscored by evidence from twin studies; in six major studies, the overall concordance rate was 60 percent for monozygotic twins and 13 percent for dizygotic pairs.

In only a few of the idiopathic seizure disorders is a simple (mendelian) pattern of inheritance recognized. The idiopathic epileptic syndromes of proven inherited type...
are benign neonatal familial convulsions, inherited as an autosomal dominant trait (Lepetit et al), a similar disorder of infantile onset, and the benign myoclonic epilepsy of childhood (autosomal recessive). Another group displays mendelian inheritance, but these are symptomatic epilepsies in which the primary condition is a generalized myoclonic disorder (Lafora disease, Unverricht-Lundborg disease, neuronal ceroid lipofuscinosis and so-called Northern epilepsy syndrome, see page 109). Inherited diseases such as tuberous sclerosis could be added to this group.

A more complex genetic element is clearly discerned in several classic childhood types—absence epilepsy with 3-per-second spike-and-wave discharges and benign epilepsy of childhood with centrotemporal spikes—both of which are transmitted as incompletely penetrant autosomal dominant traits or perhaps in a more complicated manner. Interest has been aroused by the finding that the aberrant genes in the first of these conditions code for abnormal neuronal potassium channels that interfere with cellular repolarization. Certain other primary generalized epilepsies that begin in later childhood are inherited as well; the gene predisposing to juvenile myoclonic epilepsy has been mapped to chromosome 6p and in some cases to 15q (Delgado-Escueta et al). Undoubtedly inherited is the tendency to develop simple febrile convulsions, although it is not clear whether the mode of inheritance is polygenic or autosomal dominant with incomplete penetrance; perhaps either type may explain the occurrence in individual families.

In the partial, or focal, epilepsies (which is the form that seizures take in two-thirds of adults and almost half of the children with epilepsy), the role of heredity is not nearly so clear. However, numerous studies have shown a greater-than-expected incidence of seizures, EEG abnormalities, or both among first-degree relatives of patients with partial epilepsy. Among the familial cortical epilepsies, both a teleologic and a functional type has been identified. In a hyperkinetic fashion or as autosomal dominant traits. In the frontal lobe type, not only the chromosome but the gene defect (a mutant neuronal acetylcholine receptor) has been identified. An autosomal dominant familial partial epilepsy with frontal or temporal foci has also been described. The genetics of epilepsy has been reviewed in detail by Anderson and Hauser and by Andermann and by Berkovic.

CLINICAL APPROACH TO THE EPILEPSIES

A physician faced with a patient who seeks advice about an episodic disorder of nervous function must determine, first, whether the episode in question is indeed a seizure; if so, he must determine its pattern and other characteristics; and, finally, he must undertake a search for its cause.

In the diagnosis of epilepsy, history is the key; in most cases the physical examination is relatively unrevealing. A number of laboratory studies should routinely be included in the initial diagnostic workup—CBC, blood chemistries, liver and thyroid function tests, EEG, and most importantly an imaging study of the brain, preferably MRI. CT scanning may be the only feasible study in an emergency or for very young children. Some patients may later need protracted video/EEG monitoring, either in the hospital or with portable equipment at home. Other forms of testing—e.g., cardiac stress tests, Holter monitors, tilt-table testing, long-term patient activated cardiac monitors, and sleep studies—are sometimes indicated in order to exclude some of the disorders listed below.

The conditions most likely to simulate a seizure are syncope and transient ischemic attacks, but also to be considered are migraine, unexplained falls (drop attacks), sleepwalking and rapid-eye-movement (REM) sleep behavior disorder, panic attacks, hypoglycemia, cataplexy, paroxysmal ataxia and choreoathetosis, recurrent transient global amnesia, and the hysterical pseudoseizures discussed above. Often, in emergency departments, it is difficult to differentiate the postictal effects of an unwitnessed seizure from mild confusion following cerebral concussion or a brief loss of consciousness with subarachnoid hemorrhage.

The clinical differences between a seizure and a syncope attack are considered in Chapter 18. It must be emphasized that no single criterion stands inviolate. The authors have erred in mistaking akinetic seizures for simple faints and vasovagal and cardiac faints for seizures. If blood is obtained soon after an episode, elevations in creatine kinase and prolactin may be helpful in the diagnosis of a convulsive seizure. Postictal confusion, incontinence, and a bitten tongue bespeak seizure rather than syncope. Absence attacks may be difficult to identify because of their brevity. Helpful maneuvers are to have the patient hyperventilate in order to elicit an attack or to count aloud for 5 min. Those with frequent absence attacks will pause or skip one or two numbers. The diagnosis of complex partial seizures is the most difficult. These attacks are so variable and so often induce disturbances of behavior and psychic function (rather than obvious interruptions of consciousness—that they may be mistaken for temper tantrums, hysteria, sociopathic behavior, or acute psychosis. The careful questioning of witnesses of an attack is essential. Verbalizations that cannot be remembered, walking aimlessly, or inappropriate actions and social behavior are characteristic. As stated above, we have placed emphasis on amnesia for the events of at least part of the seizure as a crucial criterion for the diagnosis of temporal lobe epilepsy. In all obscure forms of epilepsy, prolonged EEG and video monitoring may prove diagnostic. A mild complex partial seizure, consisting of a brief loss of consciousness and lip smacking, may be mistaken for an absence unless it is kept in mind that the former (but not the latter) is commonly followed by a period of confusion and dysphasia when the language areas are involved.

Epilepsy complicated by states of constitutional mental dullness and confusion poses special problems in diagnosis. Most epileptic patients seen in a general hospital or in office practice show no evidence of mental retardation, regardless of the type of seizure. Undoubtedly, seizures are more common in the mentally retarded, but recurrent seizures in themselves seldom cause intellectual deterioration (Ellenberg et al); when this does happen, one should suspect an underlying degenerative or hereditary metabolic disease. An exception to this statement is the patient with frequent and uncontrolled subclinical seizures (nonconvulsive status) who is drugged or in a postseizure psychotic state. Hospital admission and a systematic study of the seizure state and drug levels is necessary in the analysis of this problem.

Migraine should not be mistaken for a seizure, for reasons discussed on page 187. One feature of the focal neurologic disorder of classic migraine is particularly helpful—namely, the pace of the sequence of cerebral malfunction, over a period of minutes rather than seconds, as in partial epilepsy. Even this criterion may fail occasionally, especially if both migraine and partial seizures are joined, e.g., as expressions of a vascular malformation of the brain.

Useful in the identification of a transient ischemic attack (TIA) and its separation from partial epilepsy is the patient’s age, evidence of disease of the heart or carotid arteries, and the lack of disorder of consciousness or amnesia. Again, if the ischemic attack is marked by an evolution of symptoms, they tend to develop more slowly than those of a seizure, and by their nature TIA tend to produce a focal loss of function, while seizures generally cause limb movements and positive sensory phenomena. However, a type of “limb-shaking” TIA and seizures during basilar artery occlusion may be nearly impossible to distinguish from epilepsy.

Drop attacks (falling to the ground without loss of consciousness) remain an enigma (page 399). In most cases, we have failed to substantiate their association with circulatory disturbances of the vertebobasilar system, and seldom have we observed them to be an expression of atomic or myoclonic epilepsy, but such an occurrence has been reported with the Lennox-Gastaut syndrome. In some instances they represent unexpected falls, especially in stout older women who are sedentary.

Regarding the distinction of narcolepsy, paroxysmal ataxia or choreoathetosis, transient global amnesia, hysterical fugues, panic attacks, and REM sleep behavior disorder from seizures, it is sufficient to be aware of the diagnostic criteria for each of these conditions.

The Probable Causes of Seizure(s) at Different Age Periods (See Table 16-3)

Table 16-3 Causes of recurrent seizures in different age groups

Having concluded that the neurologic disturbance under consideration is one of seizure, the next question is whether it should be subjected to treatment with
Neonatal Seizures The neonatologist is often confronted by a baby who begins to convulse in the first days of postnatal life. In most instances, the seizures are fragmentary—an abrupt movement or posturing of a limb, stiffening of the body, rolling up of the eyes, a pause in respirations, lip smacking, chewing, or bicycling movements of the legs. Even the experienced observer may have difficulty at times in distinguishing seizure activity from the normal movements of the neonate. If manifest seizures are frequent, respiratory support may be needed. The seizures correlate with focal or multifocal cortical discharges. Presumably, the immaturity of the cerebrum prevents the development of a fully organized seizure pattern. The EEG is helpful in diagnosis. Periods of EEG suppression may alternate with sharp or slow waves, or there may be discontinuous theta activity. However, electrical seizure activity may be unattended by clinical manifestations. Acardi finds an early onset of myoclonic jerks, either fragmentary or massive, with an EEG showing alternation of suppression and complex bursts of activity to be particularly ominous. An electroencephalographic diagnosis of neonatal seizures evolving later into infantile spasms and Lennox-Gastaut syndrome and leaving in its wake severe brain damage was described by Ohhtahara. Most of the reported patients later were mentally retarded (Brett).

Neonatal seizures occurring within 24 to 48 h of a difficult birth are usually indicative of severe cerebral damage, usually anoxic either antenatal or parturitional. Such infants die early, and about half of the survivors are seriously handicapped. Seizures having their onset several days or weeks after birth are more often an expression of acquired or hereditary metabolic disease. Hypoglycemia is the most frequent cause; hypocalcemia with tetany has become infrequent. A hereditary form of pyridoxine deficiency is a rare cause, sometimes also inducing seizures in utero and characteristically responding promptly to massive doses (100 mg) of vitamin B6 given intravenously. Biotinidase deficiency is another rare but correctable cause. Nonketotic hyperglycemia, maple syrup urine disease, and other metabolic disorders may lead to seizures in the first week or two of life and are expressive of a more diffuse encephalopathy.

Benign neonatal seizures have also been identified. Plouin has described a form of benign neonatal clonic convulsions beginning on days 2 and 3, up to day 7, without specific EEG changes. They then remit. The inheritance is autosomal dominant. In nonfamilial cases with onset on days 4 to 6, the partial seizures may increase to status epilepticus. The EEG consists of discontinuous theta activity. In both these groups, the outlook for normal development is good and seizures seldom recur later in life. There are also benign forms of myoclonic seizures without EEG abnormality in this age period. Some occur only with slow-wave sleep. They disappear after a few months and require no treatment. A form of benign nocturnal myoclonus in the neonate has also been documented.

Infantile Seizures (Occurring in the First Months, Up to 2 Years) Neonatal seizures may continue into the infantile period, or seizures may begin in an infant who seemed to be normal up to the time of the first convulsive attack. The most characteristic pattern at this age is the massive myoclonic jerk of head and arms leading to flexion or, less often, to extension of the body (infantile spasms, salaam spasms). The latter form, known as the West syndrome and described earlier, is the most threatening. We have observed the same seizure pattern in infants with tuberous sclerosis (diagnosed in infancy by dermal white spots), phenylketonuria, Sturge-Webner angiomatosis, and other diseases beginning in this age period. West syndrome is probably a metabolic encephalopathy of unknown type or, in some cases, a cortical dysgenesis (Jellinger) and is identified by an EEG picture of large bilateral slow waves and multifocal spikes (hypomyelination). Again, there is a benign form of infantile myoclonic epilepsy in which repetitive myoclonic jerking occurs in otherwise normal infants and whose EEG shows only spike waves in early sleep.

However, when the myoclonus begins in infancy with fever and unilateral or bilateral clonic seizures or with partial seizures that are followed by focal neurologic abnormalities, there is a likelihood of developmental delay. The latter types are sometimes referred to as febrile seizures, but, as indicated above, they must be distinguished from the benign familial febrile seizure syndrome. Infantile spasms cease by the fifth year and are replaced by partial and generalized grand mal seizures.

Seizures Presenting in Early Childhood (Onset during the First 5 to 6 Years) At this age, the first burst of seizures may take the form of status epilepticus and, if not successfully controlled, may end fatally. Or the convulsive state may present around the age of 4 years as a focal myoclonus with or without atactic seizures, atypical absence, or generalized tonic-clonic seizures. The EEG, repeated if initially normal, is most helpful in diagnosis; it reveals a paroxysmal 2- to 2.5-second spike-and-wave pattern on a background of predominant 4- to 7-Hz slow waves. This syndrome is difficult to separate from the Lennox-Gastaut syndrome. It proves difficult to treat and is likely to be associated with developmental retardation. The MRI may be helpful in identifying a birth injury or cortical dysgenesis.

In contrast, the more typical absence, with its regularly recurring 3-second spike-and-wave EEG abnormality, also begins in this age period (rarely before 4 years) and carries a good prognosis. This seizure disorder responds well to medications, as indicated further on. Its features are fully described on page 334.

A number of partial epilepsies may appear for the first time during this age period and carry a good prognosis, i.e., the neurologic and intellectual capacities remain relatively unimpaired and seizures may cease in adolescence. These disorders begin between 3 and 13 years of age, and there is often a familial predisposition. Most are marked by distinctive focal spike activity that is greatly accentuated by sleep (see above, in reference to benign childhood epilepsy with centrotemporal or occipital spikes). In one form, unilateral tonic or clonic contractions of the face and limbs recur repetitively with or without paresthesias; anarthria follows the seizure. There are central and temporal spikes in the EEG interictally. The focus may involve an occipital lobe with EEG spiking on eye closing, according to Gastaut. An atonic or aphasic type of seizure described by Landau and Kleffner is characterized by children who have marked or generalized motor seizures and multifocal spike or spike-and-wave discharges in the EEG. Tumor and arteriovenous malformation are rare causes in this age group.

Rasmussen encephalitis In other rare cases, a lesion, usually identified at operation, takes the form of a chronic focal encephalitis. In 1958, Rasmussen described the clinical syndrome from whom the clinical problem consisted of intractable focal epilepsy in association with a progressive hemiparesis. Biopsies of the cerebral cortex disclosed a mild meningeal infiltration of inflammatory cells and an encephalitic process marked by neuronal destruction, neuronophagia, some degree of tissue necrosis, and perivascular cuffing. Many additional cases were soon uncovered, and by 1991, in a publication devoted to this subject (edited by Andermann), Rasmussen was able to report on the natural history of 48 personally observed patients.

The expanded view of the syndrome has added several interesting features. All the patients were children aged 3 to 15 years, more girls than boys. Half of them had epilepsy partials continua. The progression of the disease led to hemiplegia or other deficits and brain atrophy in most cases. The CSF has shown pleocytosis and a mild meningeal reaction. In both these groups, the outlook for normal development is good and seizures are marked by distinctive focal spike activity that is greatly accentuated by sleep (see above, in reference to benign childhood epilepsy with centrotemporal or occipital spikes). In one form, unilateral tonic or clonic contractions of the face and limbs recur repetitively with or without paresthesias; anarthria follows the seizure. There are central and temporal spikes in the EEG interictally. The focus may involve an occipital lobe with EEG spiking on eye closing, according to Gastaut. An atonic or aphasic type of seizure described by Landau and Kleffner is characterized by children who have marked or generalized motor seizures and multifocal spike or spike-and-wave discharges in the EEG. Tumor and arteriovenous malformation are rare causes in this age group.

Seizures in Later Childhood and Adolescence These represent the most common epileptic problem in general practice. Here, we face two different issues: one relates to the nature and management of the first seizure in an otherwise normal person and the other to the management of a patient who has had one or more seizures at some time in the past. With respect to the first, a search for a cause by CT, MRI, CSF examination, and EEG rarely discloses a tumor or a vascular malformation and the epilepsy is classed as idiopathic. The type of seizure that first brings the child or adolescent to medical attention is most likely to be a generalized tonic-clonic convulsion and often marks the beginning of a juvenile myoclonic epilepsy, as described on page 335. In the second type of case, in which there had been some type of seizure at an earlier period, one should suspect a developmental disorder, parturitional hypoxic-ischemic encephalopathy (birth injury), or one of the hereditary metabolic diseases.

Several groups of patients fall between these two distinct types. Development may have been slightly delayed, but reportedly no seizures had occurred earlier in life. Closer investigation may disclose absence seizures, not always recognized as such by parents or teachers, and a typical absence EEG which points more directly to a genetic factor and to a more favorable prognosis.

When the seizures are an expression of a long-standing epileptic focus or foci that had been associated with mental backwardness, scholastic failure, and
inadequacy of social adjustment, the problem is much more difficult and demanding. Poor compliance with therapy, muddled thinking, and bizarre ideation on the part of the patient and unintelligent parents may pose problems as difficult as the seizures themselves. Some patients of this latter group will eventually fall into the category of epilepsy with complex partial seizures. In adulthood, the seizures may continue to interfere with work, marriage, and family relationships. In the interictal periods, the patients may exhibit bursts of bad temper, and they commonly have wide mood swings of sadness and anger or elation. As indicated earlier, paranoid ideation or a frank hallucinatory-delusional psychosis sometimes appears and lasts for weeks after a single seizure, without any specific EEG changes.

In the large group with intractable seizures in early life, many of which are indiscriminately called febrile seizures, nearly half end up in the group identified as temporal lobe epilepsies. Huttonlocher and Haje, in a follow-up study of 145 infants and children with intractable epilepsy, found that the majority had borderline or subnormal intelligence. This group stands in contrast to the group of otherwise normal adolescents with a first seizure, whose scholastic progress and social and emotional adjustment are little affected.

Finally, a first generalized seizure may bring to attention an adolescent who is abusing alcohol or another drug. Usually it is difficult from the clinical information alone to determine the type and quantity of the drug(s) and the setting in which the seizure occurred—whether in relation to overdose or withdrawal. While steps must be taken to exclude an infection of the nervous system, vascular occlusion, or trauma, the more important issue is generally not the seizure but the addiction and its control.

Regarding treatment, opinion is divided on whether treatment is required for the older child or adolescent who comes to medical attention because of a first seizure. When a large number of such cases have been left untreated, such as in the series reported by Hesdorfer and colleagues, the risk of another seizure over 10 years was 13 percent even if the first episode was status epilepticus, in which case the risk was 41 percent. Age, sex, and the circumstances of the seizure (withdrawal from drugs or alcohol, myoclonic episodes, family history, etc.) all figured into the risk.

Seizures with Onset in Adult Life, Secondary to Medical Disease Several primary diseases of the brain often announce themselves by an acute convulsive state, particularly primary and metastatic brain tumors; these are discussed further on in the section on seizures of late adult life. Here we focus on generalized medical disorders as causes of single and repeated seizures.

Withdrawal Seizures The possibility of abstinence seizures in patients who had chronically abused alcohol, barbiturates, or benzodiazepine sedative drugs must always be considered when seizures occur for the first time in alcoholics (or even in adolescence). Suspicion of this mechanism is raised by the stigmata of alcohol abuse or a history of prolonged nervousness and depression requiring sedation. Also, sleep disturbance, tremulousness, disorientation, illusions, and hallucinations are often associated with the convulsive phase of the illness. Seizures in this setting may occur singly, but more often they occur in a brief flurry, the entire convulsive period lasting for several hours and rarely for a day or longer, during which time the patient may be unduly sensitive to photic stimulation. Alcohol and other drug-related seizures are discussed in more detail on pages 1241 and 1261.

Infections An outburst of seizures is also a prominent feature of all varieties of bacterial meningitis, more so in children than in adults. Fever, headache, and stiff neck usually provide the clues to diagnosis, and lumbar puncture yields the salient data. Myoclonic jerking and seizures appear early in acute herpes simplex encephalitis and other forms of viral, treponemal, and parasitic encephalitis including those derived from HIV infection, both direct and indirectly, through toxoplasmosis and brain lymphoma, in subacute sclerosing panencephalitis, and in lipid storage diseases. In tropical countries, coccidioides and tuberculous granulomas of the brain are common causes of epilepsy. Seizure(s) without fever or stiff neck may be the initial manifestation of syphilitic meningitis.

Endogenous Metabolic Encephalopathies Uremia is a condition with a strong convulsive tendency. Of interest is the relation of seizures to the development of anuric renal failure, generally from acute tubular necrosis but occasionally due to glomerular disease. Uremia may be tolerated for several days, without the appearance of neurologic signs, and then there is an abrupt onset of twitching, trembling, myoclonic jerks, and generalized motor seizures. Tetany may be added. The motor display, one of the most dramatic in medicine, lasts several days until the patient sinks into terminal coma or recovers, depending on the outcome of the renal disease and its treatment by dialysis. When this twitch-convulsive syndrome accompanies lupus erythematosus, seizures of undetermined cause, or generalized neoplasia, one can nearly always be sure that it has its basis in renal failure.

Other acute metabolic illnesses and electrolytic disorders complicated by generalized and multifocal motor seizures are hyponatremia and its opposite, a hypernatremic hyperosmolar state, thyrotoxic storm, hypoglycemia, hyperglycemia, hyponormagnesemia, and hypocalcemia. In all these cases rapidly evolving electrolyte abnormalities are more likely to cause seizures than those occurring gradually. For this reason it is not possible to assign absolute levels of electrolyte, BUN, or glucose concentrations above or below which seizures are likely to occur. Lead (in children) and mercury (in children and adults) are the most frequent of the metallic poisons that cause convulsions.

In most cases of seizures due to metabolic and withdrawal states, treatment with anticonvulsants is not necessary as long as the underlying disturbance is rectified. Indeed, anticonvulsants are often ineffective if the metabolic disorder persists.

Generalized seizures, with or without twitching, may occur in the advanced stages of many other illnesses, such as hypertensive encephalopathy, sepsis—especially gram-negative sepsis with shock—hepatic stupor, and intractable congestive heart failure. Usually, seizures in these circumstances can be traced to an associated metabolic abnormality and are revealed by studies of the blood.

Medications A large number of medications can cause seizures, usually when toxic blood levels are attained. The antibiotic imipenem and excessive doses of other penicillins may cause seizures, particularly if renal failure leads to their accumulation. Cefampime, a fourth generation cephalosporin, widely used for the treatment of gram-negative sepsis, can result in status epilepticus, especially if given in excessive dosages (Dole et al). The tricyclic antidepressants, bupropion (Wellbutrin), and lithium may cause seizures, particularly in the presence of a structural brain lesion. Lidocaine and aminophylline are known to induce a single electrical convulsion. Sedatives, hypnotics, anesthetic agents, and muscle relaxants are also epileptogenic. Cocaine, peyote, and other hallucinogens can induce seizures in certain individuals, with a high dose or in combination with other drugs.

Global Arrest of Circulation and Cerebrovascular Diseases Cardiac arrest, suffocation or respiratory failure, CO poisoning, or other causes of hypoxic encephalopathy tend to induce diffuse myoclonic jerking and generalized seizures as cardiac function is resumed. The myoclonic-convulsive phase of this condition may last only a few hours or days, in association with coma, stupor, and confusion; or it may persist indefinitely as an intention myoclonus-convulsive state.

Convulsive seizures are relatively uncommon occurrences in the evolving phases of an arterial stroke. Only exceptionally will acute embolic infarction of the brain cause a focal fit at its onset, though embolic infarcts involving the cortex later become epileptoigenic in almost 25 percent of cases. Similarly, thrombotic infarcts are almost never of sudden onset. On the other hand, cortical venous thrombosis with ischemia and infarction is highly epileptogenic, but fortunately rare. The same is true for hypertensive encephalopathy. The rupture of a saccular aneurysm is sometimes marked by one or two generalized convulsions. Subcortical cerebral hemorrhages occasionally become sources of recurrent focal seizures.

Seizures in Pregnancy Here one contends with two types of problem: one, the woman with epilepsy who becomes pregnant; the other, the woman who has her first seizure during pregnancy. In respect to the first group, about half of the epileptic women who become pregnant have no change in seizure frequency or severity; in about 25 percent, the frequency increases; and in an equal number, it lessens. In a large cohort of such women, there was a slight increase in the number of stillbirths and neonatal deaths, but in the expected incidence of mental retardation and nonfebrile seizures in the offspring. Parturition itself was unaffected except that in those taking phenytoin, bleeding was slightly increased (but easily controlled with vitamin K). Plasma levels of most anticonvulsant drugs, both free and protein-bound fractions, fall slightly, particularly in those who are taking the drugs are cleared more rapidly from the blood. The conventional drugs (phenytoin, carbamazepine, phenobarbital, valproate) are all appropriate in pregnancy. The main practical issue is the potential teratogenicity of anticonvulsant drugs. The most common recorded teratogenic effects have been cleft lip and cleft palate, but a subtle facial dysmorphism ("fetal anticonvulsant syndrome"), similar to the fetal alcohol syndrome, has also been described. In general the risk of congenital defects is low—2 to 3 percent in the overall population of pregnant women—which increases to 4 to 5 percent in women taking anticonvulsant drugs during pregnancy. This risk is shared more or less equally by all the major anticonvulsants (lamotrigine and several other new drugs may not carry the risk).

The newer anticonvulsant agents should probably be avoided until greater experience has been obtained. The risk of neural tube defects (possibly increased by
anticonvulsants and greatest with valproate) can be reduced by giving folate before pregnancy has begun. Also, these risks are greater in women taking more than one anticonvulsant, so that monotherapy is a desirable goal. And since it is essential to prevent convulsions in the pregnant epileptic, anticonvulsant medication should not be discontinued or arbitrarily reduced, particularly if there have been convulsions in the recent past.

The conventional anticonvulsants also seem to be safe for the baby during breast-feeding in that only small amounts are excrated in lactated milk. For example, carbamazepine in human milk is found to be 40 percent of the mother's serum concentration, and this results in a neonatal blood level that is below the conventionally detectable amount. Phenyltoin is excrated at 15 percent of maternal serum concentration, and valproate, being highly protein-bound, is virtually absent in breast milk. No adverse effects have been attributed to these small amounts of drug.

Eclampsia during the last trimester of pregnancy may announce itself by hypertension and convulsions; the latter are generalized and occur in a cluster. The standard practice is to induce labor or perform cesarean section and manage the seizures as one would manage those of hypertensive encephalopathy (of which this is one type). The administration of magnesium sulfate continues to be the favored treatment for the prevention of eclamptic seizures; two randomized trials have re-established its value in preventing seizures in pre-eclamptic women (Lucas et al and in avoiding a second convolution once one had occurred (Eclampsia Trial Collaborative Group). Magnesium sulfate, 10 g intramuscularly, followed by 5 g every 4 h, proved comparable to standard doses of phenytoin as prophylaxis for seizures. Our colleagues use a regimen of 4 g intravenously over 5 to 10 min followed by a maintenance dose of 5 g every 4 h intramuscularly or 1 to 2 g per hour intravenously. Whether magnesium is as effective in the management of active convulsions of toxemia remains uncertain. In nontoxic gestational epilepsy, about 25 percent of patients are found to have some disease (neoplastic, vascular, or traumatic) that will persist after the pregnancy is terminated.

Focal or Generalized Seizures in Late Adult Life

Hauser and Kurland have reported a marked increase in the incidence of seizures as the population ages—from 11.9 per 100,000 in the 40- to 60-year age group to 82 per 100,000 in those 60 years of age or older. A person in the latter age group who begins to have seizures of either partial or generalized type is always to be suspected of harboring a primary or secondary tumor or an infant that had not declared itself clinically. This is a matter usually settled by the neurologic examination and by CT scans or MRI. Tumor, either primary or secondary, will be found to account for about half the cases of seizures occurring for the first time in late adult life. In our clinical material, almost 25 percent of patients with infarction involving the cerebral cortex later developed recurrent partial or generalized seizures. According to Sung and Chu, previous infarcts are by far the most common lesions underlying status epilepticus in late adult life. Cortical and subcortical encephalomalacia, the result of previous traumatic convulsions, are another important cause of seizures, particularly among alcoholics; the lesions are revealed by brain imaging and are typically located in the anterior frontal and temporal lobes. Brain abscess and other inflammatory and infectious illnesses are less common except in tropical regions. Seizures as a result of Alzheimer and other degenerative diseases are decidedly rare.

In the not infrequent cases of an adult with a first seizure that remains unexplained after thorough evaluation, it has been our practice to administer an anticonvulsant and to reevaluate the situation in a matter of 6 to 12 months, with the goal of eventually discontinuing medication. Sometimes, a second MRI and EEG are performed to exclude focal abnormalities that were not appreciated during the initial evaluation, but usually these studies are again unrevealing. This approach has been prompted by data such as those of Houser and colleagues, who found that about one-third of patients with a single unprovoked seizure will have another seizure within 5 years; the risk is even greater if there is a history of seizures in a sibling, a complex febrile convulsion in childhood, or a spike-and-wave abnormality in the EEG. Moreover, the risk of recurrence is greatest in the first 24 months. In patients with two or three unexplained seizures, three-quarters have further seizures in the subsequent 4 years.

TREATMENT

The treatment of epilepsy of all types can be divided into four parts: the use of antiepileptic drugs, the surgical excision of epileptic foci and other surgical measures, the removal of causative and precipitating factors, and the regulation of physical and mental activity.

The Use of Antiepileptic Drugs—General Principles

The use of antiepileptic drugs is the most important facet of treatment. In approximately 70 percent of all patients with epilepsy, the seizures are controlled completely or almost completely by the use of antiepileptic drugs; in an additional 20 to 25 percent, the attacks are significantly reduced in frequency and severity. The most commonly used drugs are listed in Table 16-4, along with their dosages, effective blood levels, and serum half-lives. Because of the long half-lives of phenytoin, phenobarbital, and ethosuximide, these drugs need be taken only once daily, preferably at bedtime. Valproate and carbamazepine have shorter half-lives, and their administration should be spaced during the day. It is also useful to be familiar with the serum protein-binding characteristics of antiepileptic drugs and the interactions among these drugs, and between antiepileptic and other drugs.

</table>

Certain drugs are more effective in one type of seizure than in another, and it is necessary to use the proper drugs in optimum dosages for the different types of seizures. Initially, only one drug should be used and the dosage increased until sustained therapeutic levels have been assured. If seizures are not controlled by the first drug, a different drug should be tried, but frequent shifting of drugs is not advisable; each should be given an adequate trial before another is substituted. In changing medication, the dosage of the new drug should be increased gradually to an optimum level while the dosage of the old drug is gradually decreased; the sudden withdrawal of a drug may lead to an increase in seizure frequency or status epilepticus, even though a new drug is substituted. If seizures are still not controlled, a second drug can then be added. Seldom if ever are more than two drugs necessary; the physician should make an effort to succeed with one drug and with no more than two, given in adequate dosage. Once an anticonvulsant or a combination of anticonvulsants is found to be effective, their use in most cases should be maintained for a period of years.

The therapeutic dose for any given patient must be determined, to some extent, by trial and error and by measurement of serum levels, as described below. Not uncommonly a drug is discarded as being ineffective, when a slight increase in dosage would have led to disappearance of the attacks. It is, however, also an error to administer a drug to the point where the patient is so dull and stupefied that the toxic effects are more incapacitating than the seizures. It is highly doubtful that prolonged administration of anticonvulsant medication is a factor in the development of the mental deterioration that occurs in a small percentage of patients with convulsive seizures. In fact, improvement in mentation sometimes occurs following control of the seizures by the proper dosage of appropriate antiepileptic drugs.

The management of seizures with drugs is greatly facilitated by having the patient chart his daily medication and the number, time, and circumstances of seizures. Some patients find it helpful to use a dispenser that is filled on Sunday, for example, with sufficient medication to last the week. This indicates to the patient whether a drug has been missed and whether the supply of medications is running low.

The proper use of anticonvulsant drugs is considerably enhanced by the measurement of their serum levels. The concentrations of almost all the commonly used drugs can be measured on a single specimen by immunosassay or by the older gas-liquid chromatography method. These measurements are helpful in regulating dosage, detecting irregular drug intake, identifying the toxic agent in patients taking more than one drug, and assuring patient compliance. Blood for serum levels is
The effective serum levels for each of the commonly used anticonvulsant drugs are indicated in Table 16.4. The upper and lower levels of the "therapeutic range" are not to be regarded as immutable limits within which the serum values must fit. In some patients, seizures are controlled at serum levels below the therapeutic range; in others, the seizures continue despite serum values within this range. In the latter patients, seizures are sometimes controlled by raising levels above the therapeutic range but not to the point of producing clinical toxicity. In general, higher serum concentrations of drugs are necessary for the control of simple or complex partial seizures than for the control of tonic-clonic seizures alone (Schmidt et al). It is to be noted that the blood level is not a precise measure of the amount of drug entering the brain, because—in the case of the most widely used anticonvulsants—the larger proportion of drug is bound to albumin and does not penetrate nervous tissue. Laboratory measurements of the serum concentration, however, detect only the protein-bound fraction. In patients who are malnourished or chronically ill or who have a constitutional reduction in proteins, this may lead to intoxication at low total serum levels. Certain anticonvulsants also have active metabolites that may produce toxic effects at serum levels not measured by conventional used to determine the toxicities of antiepileptic drugs. This is particularly true for the epoxide of carbamazepine. The situation may be further complicated by interactions between one anticonvulsant and the metabolites of another, as, for example, the inhibition of epoxide hydrolyase by valproic acid, leading to toxicity through the buildup of carbamazepine epoxide. In circumstances of unexplained toxicity in the face of conventionally obtained serum levels that are normal, it is therefore important to measure the levels of free drug and the concentration of active metabolites by chromatographic techniques.

Finally, the pharmacokinetics of each drug play a role in toxicity and the serum level that is achieved with each alteration in the dose. This is particularly true of phenytoin, which is excreted nonlinearly once serum concentrations reach 10 µg/mL, as the result of saturation of liver enzymatic capacity. For this reason, the typical increase in dose from 300 to 400 mg daily often results in a disproportionate elevation of the serum level and toxic side effects. These elevations are also accompanied by a prolongation of the serum half-life, which increases the time to reach a steady-state phenytoin concentration after dosage adjustments. Similarly, carbamazepine is known to induce its own metabolism, so that doses adequate to control seizures at the outset of therapy are no longer effective several weeks later.

Always to be considered in the use of an antiepileptic drug, as already mentioned, is its interactions with other drugs. Many such interactions have been demonstrated, but only a few are of clinical significance, requiring adjustment of drug dosages (Kutt). Important drugs in this respect are chloramphenicol, which causes the accumulation of phenytoin and phenobarbital, and erythromycin, which causes the accumulation of carbamazepine. Antacids reduce the blood phenytoin concentration, whereas cimetidine does the opposite. Salicylates may reduce the plasma levels of anticonvulsant drugs. Among anticonvulsant drugs, valproate often leads to accumulation of phenytoin and of phenobarbital by displacing them from serum proteins; equally important, warfarin levels are decreased by the addition of phenobarbital or carbamazepine and may be increased by phenytoin. Enzyme-inducing drugs such as phenytoin, carbamazepine, and barbiturates can greatly increase the chance of breakthrough menstrual bleeding in women taking oral contraceptives, and adjustments in the amount of estradiol must be made.

Hepatic failure can seriously affect antiepileptic anticonvulsant drug concentrations, since most of these drugs are metabolized in the liver. Serum levels must be checked frequently, and if there is hypoprothrombinemia, it is advisable to obtain free drug levels for reasons just mentioned. Renal failure has only an indirect effect on the pharmacokinetics of the commonly used anticonvulsants, but some newer agents, such as vigabatrin and gabapentin, are renally excreted. The main renal effects have to do with alterations in protein binding that are induced by uremia. In end-stage renal failure, serum levels are not an accurate guide to therapy, and the goal should be to attain free phenytoin protein concentrations of 1 to 2 µg/mL. In addition, uremia causes the accumulation of phenytoin metabolites, which are measured with the parent drug in blood and urine samples, and thus total blood levels are not a true reflection of total drug effect. For this reason, estimation of decreased protein binding; in this situation it is also necessary to track free (unbound) phenytoin levels. Dialysis does remove phenobarbital and ethosuximide, and dosage may need to be increased. Decreased phenytoin levels are also known to occur during viral illnesses, and supplementary doses are occasionally necessary.

Once an effective anticonvulsant regimen has been established, it must usually be continued for many years. Because of the long-term toxic effects of such a regimen, many neurologists choose not to institute anticonvulsant therapy after the occurrence of a single generalized seizure in an otherwise normal child or adult (normal EEG and MRI; no family history of seizures). Our more conservative approach of administering an anticonvulsant for 6 to 12 months and then re-evaluating the patient has already been mentioned.

Discontinuing Anticonvulsants Withdrawal of anticonvulsant drugs may be undertaken in patients who have been free of seizures for a prolonged period. There are few firm rules to guide the physician in this decision. A safe plan, applicable to most forms of epilepsy, is to obtain an EEG whenever withdrawal of medication is contemplated; if the EEG is abnormal, it is generally better to continue treatment. A prospective study by Callaghan and colleagues has shown that in patients who had been seizure-free during 2 years of treatment with a single drug, one-third relapsed after discontinuation of the drug, and this relapse rate was much the same in adults and children and whether the drug was reduced over a period of weeks or months. The relapse rate was less in patients with absence and generalized-onset seizures than in those with complex partial seizures and secondary generalization. Other authors have suggested that a longer seizure-free period is associated with a lesser rate of relapse (see reviews of Todt and of Pedley and comments above, under "Focal or Generalized Seizures in Late Adult Life"). Patients with juvenile myoclonic epilepsy, even those with long seizure-free periods, should probably continue with medication lifelong. The appropriate duration of treatment for postinfection epilepsy has not been studied and most neurologists continue to use one drug indefinitely. Interestingly, epilepsy caused by military brain wounds tends to be reduced in frequency or to disappear in 20 to 30 years, no longer requiring treatment.

The Use of Specific Drugs in Treatment of Seizures

Phenytoin, carbamazepine, and valproate are more or less equally effective in the treatment of both generalized and partial seizures (see Table 16.4 for typical initial dosages). Valproate is probably less effective in the treatment of complex partial seizures. The first two of these drugs putatively act by blocking sodium channels, thus preventing abnormal neuronal firing and seizure spread.

Since carbamazepine has somewhat fewer side effects it is preferred as the initial drug by many neurologists, but phenytoin and valproate have very similar therapeutic and side-effect profiles. Carbamazepine and valproate are probably preferable to phenytoin for epileptic children because they do not cause facial features and do not produce gynaecomastia or breast enlargement. In many cases, phenytoin or carbamazepine alone will control the seizures. If not, the use of valproate (which facilitates GABA activity) alone or the combined use of phenytoin and carbamazepine is sometimes effective. In addition, the other valproate to carbamazepine may prove effective.

Rash, fever, lymphadenopathy, eosinophilia and other blood dyscrasias, and polyarteritis are manifestations of an idiosyncratic "phenytoin hypersensitivity"; their occurrence calls for discontinuation of the medication. Overdose with phenytoin causes ataxia, diplopia, and stupor. The prolonged use of phenytoin often leads to hirsutism (mainly in young girls), hyperophy of gums, and coarsening of facial features in children. Chronic phenytoin intoxication may rarely be associated with peripheral neuropathy and probably with a form of cerebellar degeneration (Lindvall and Nilsson). An antifolate effect on blood and interference with vitamin K metabolism has also been reported. The pregnant woman taking phenytoin should be given vitamin K before delivery and the newborn infant should receive vitamin K (Fig. 16.7). Phenothiazines, chlorpromazine, procainamide, and other drugs that are known to affect liver function (e.g., disulfiram, chlorprothixene, or cyclophosphamide, and the use of either phenobarbital or phenytoin is not advisable in patients receiving warfarin (Coumadin) because of the undesirable interactions already described.

Carbamazepine causes many of the same side effects as phenytoin, but to a slightly lesser degree. Leukopenia is common and rare instances of pancytopenia, hyponatremia, and diabetes insipidus have been reported as idiosyncratic reactions. It is essential, therefore, that a complete blood count be done before treatment is instituted, and that the white cell count be checked regularly. A newly introduced analogue of carbamazepine oxcarbazepine is said to have fewer side effects than the parent drug, but its long-term therapeutic effects still have to be established.

Valproate is occasionally hepatotoxic, an adverse effect that is usually (but not invariably) limited to children 2 years of age and younger. The use of valproate with hepatic enzyme–inducing drugs increases the risk of liver toxicity. However, mild elevations of serum ammonia and mild impairments of liver function tests in an adult do not require discontinuation of treatment.

Phenobarbital, which was introduced as an antiepileptic drug in 1912, is still highly effective, but because of its toxic effects—drowsiness and mental dullness, restlessness, and staggering—is seldom used as a first-line drug. The adverse effects of primidone are much the same. Both drugs may provoke behavioral problems in retarded children. It is still used to advantage as an adjunctive anticonvulsant.

A newer drug, the folate antagonist lamotrigine, closely resembles phenytoin in its antisiezure activity and toxicity and is thought to have less risk of teratogenic
effects. It is effective as a first-line drug for generalized and focal seizures.Felbamate, a drug similar to mepropamate, has shown promise as an adjunctive form of treatment of generalized seizures, complex partial seizures, and Lennox-Gastaut syndrome, but its use has been limited because of the rare occurrence of bone marrow suppression and liver failure. Two other new drugs, gabapentin and vigabatrin, were synthesized specifically to enhance the intrinsic inhibitory system of GABA in the brain. Gabapentin is chemically similar to GABA, but actually its anticonvulsant mechanism is not known. It is moderately effective in partial and secondary generalized seizures and has the advantage of not being metabolized by the liver. Vigabatrin and the related drugs, probabole and tiaigabine are inhibitors of GABA transaminase and are effective in the treatment of partial seizures and, to a lesser extent, primary generalized seizures. Neither is bound to plasma protein, and they have few toxic effects and no known adverse drug interactions. Topiramate, another new antiepileptic agent, has much the same mode of action and degree of effectiveness as gabapentin. It may cause serious dermatologic side effects, especially if used with valproate and appears to induce renal stones in 1.5 percent of patients. Ethosuximide (Zarontin) and valproate are equally effective for the treatment of absence seizures, the latter one being used mainly in children more than 4 years of age. It is good practice, in order to avoid excessive sleepiness, to begin with a single dose of 250 mg of ethosuximide per day and to increase it every week until the optimum therapeutic effect is achieved. Methsuximide (Celonitin) is useful in individual cases where ethosuximide and valproate have failed. In patients with benign absence attacks that attacks with photosensitivity, myoclonus, and clonic-tonic-clonic seizures (including juvenile myoclonic epilepsy), valproate is the drug of choice. Valproate is particularly useful in patients who have both absence and grand mal attacks, since the use of this drug alone often permits the control of both types of seizure. The concurrent use of valproate and clonazepam has been known to produce absence status.

Treatment of the special types of convulsions in the neonatal period and in infancy and childhood is discussed by Fenichel and by Volpe. In general, phenobarbital is preferred for seizure control in infancy.

Probably the form of epilepsy that is most difficult to treat is the Lennox-Gastaut syndrome. Some of these patients have as many as 50 or more seizures per day, and every combination of anticonvulsant medications may have no effect. Valproic acid (900 to 2400 mg/day) will reduce the frequency of spells in approximately half the cases. The newer drugs—lamotrigine, topiramate, vigabatrine—are each beneficial in about 25 percent of cases. Clonazepam also has had limited success.

Seizure states in which myoclonus is a major element (absence, juvenile myoclonic, and certain cases of tonic-clonic epilepsy) respond particularly well to valproate. Even the myoclonus of certain progressive diseases, such as the Unverricht-Lundborg syndrome, may be suppressed by this drug. Methsuximide is preferred by some physicians as a first-line drug because it is considered the most effective. Postanoxic intention myoclonus (page 110) can be suppressed to some extent by clonazepam and by Valproate, combined with other drugs.

Restricted forms of myoclonus or polymyoclonus, discussed in Chap. 6, may respond to special drugs in restricted combinations.

**Status Epilepticus**

Recurrent generalized convulsions at a frequency that prevents the regaining of consciousness in the interval between seizures (grand mal status) constitute the most serious therapeutic problem (an overall mortality of 20 to 30 percent, according to Towne and colleagues, but probably lower in recent years). Most patients who die of epilepsy do so because of uncontrolled seizures of this type, complicated by the effects of the underlying illness or an injury sustained as a result of a seizure. Rising temperature, acidosis, hypotension, and renal failure from myoglobinuria is a sequence of life-threatening events that may be encountered in cases of status epilepticus. Prolonged convulsive status (for longer than 30 min) also carries a risk of serious neurologic sequelae ("epileptic encephalopathy"). The MRI frequently shows signal abnormalities in the hippocampi, most often reversible, but we have had several patients who came awake and were left in a permanent amnesic state. From time to time a case of neurogenic pulmonary edema is encountered during or just after the convulsions.

The many regimens that have been proposed for the treatment of status attest to the fact that no one of them is altogether satisfactory and none is clearly superior (Treiman et al). The present authors have had the most success with the following program: when the patient is first seen, an initial assessment of cardiorespiratory function is made and an oral airway has been established. A large-bore intravenous line is inserted; blood is drawn for glucose, blood urea nitrogen, electrolytes, and a metabolic and drug screen, and a normal saline infusion is begun. Diazepam is given intravenously at a rate of about 2 mg/min until the seizures stop or a total of 20 mg has been given. Lorazepam may be administered, being marginally more effective than diazepam because of its putative longer duration of action in the central nervous system. Lorazepam 0.1 mg/kg is given by intravenous push at a rate not to exceed 2 mg/min.

Immediately thereafter a loading dose (15 to 18 mg/kg) of phenytoin is administered by vein at a rate of less than 50 mg/min. Faster administration risks hypotension and heart block; it is therefore recommended that the blood pressure and electrocardiogram be monitored during the infusion. Phenytoin must be given through a freely running line with normal saline (it precipitates in other fluids) and should not be injected intramuscularly. A large study by Treiman and colleagues has demonstrated the superiority of using lorazepam instead of phenytoin as the first drug to control status, but this is not surprising considering the longer latency of action of phenytoin. Nonetheless, it is a long-acting anticonvulsant such as phenytoin may be administered immediately after diazepam has controlled the initial seizures. An alternative is the water-soluble drug fosphenytoin, which is administered in the same doses as phenytoin but can be given at twice the maximum rate. Moreover, it can be given intramuscularly in cases where venous access is difficult. Because of the delay in the hepatic conversion of fosphenytoin to active phenytoin, the latency of clinical effect is the same for both drugs.

In an epileptic patient known to be taking anticonvulsants chronically, but in whom the serum level of drug is unknown, it is probably best to administer the full recommended dose of phenytoin or fosphenytoin. If the serum phenytoin can be established at a level above 10 µg/mL, a lower loading dose can be given. If seizures continue, an additional 5 mg/kg is indicated. If this fails to suppress the seizures and status has persisted for 20 to 30 min, an endotracheal tube should be inserted and O3 administered.

Several regimens have been suggested if status persists after these efforts. The conventional and still dependable one is infusion of phenobarbital at a rate of 100 mg/min until the seizures stop or to a total dose of 20 mg/kg. In our experience, a long subsequent period of stupor must be anticipated, but some epileptologists still prefer this as the initial treatment. Alternatively, at this stage, we prefer the approach of Kumar and Bleck, using high doses of midazolam (0.2 mg/kg loading dose followed by an infusion of 0.1 to 0.4 mg/kg/h as determined by clinical and EEG monitoring). If status continues, the dose can be raised as blood pressure permits. We have had to occasion to use in excess of 20 mg/kg because of a diminishing effect over days. This regimen of midazolam and phenytoin may be maintained for days without major ill effect in previously healthy patients. Propofol given in a bolus of 2 mg/kg and then as an intravenous drip of 2 to 8 mg/h is an alternative to midazolam, but after 24 h the drug behaves like a high dose of barbiturate and there may be difficulty due to hypotension.

If none of these measures controls the seizures, all medication except phenytoin should be discontinued and a more aggressive approach taken to subdue all brain electrical activity. The preferred medications for this purpose have been pentobarbital and propofol, which, despite their poor record as anticonvulsants, are easier to use than the alternative inhalational anesthetic agents. An initial intravenous dose of 5 mg/kg pentobarbital or 2 mg/kg propofol is given slowly to induce an EEG burst-suppression pattern, which is then maintained by the administration of 0.5 to 2 mg/kg/h pentobarbital or 10 mg/kg/h of propofol. Every 12 to 24 h, the rate of infusion is slowed to determine whether the seizures have stopped. The experience of Lowenstein and colleagues, like our own, is that the majority of instances of status epilepticus that cannot be controlled with the standard anticonvulsants and midazolam will respond to high doses of barbiturates (or propofol) but that the infusions cause hypotension and cannot be carried out for long periods.

Should the seizures continue either clinically or electrographically despite all these medications, one is justified in the assumption that the convulsive tendency is so strong that it cannot be checked by reasonable quantities of anticonvulsants. A few patients in this predicament have survived and awakened, even at times with minimal neurologic damage. Isoflurane (Forane) has been used in these circumstances with good effect, but continuous administration of such inhalational agents is impractical in most critical care units. Halothane has been ineffective as an anticonvulsant, but either, also impractical, had in the past been effective in some cases. In these patients with intractable status, one usually depends entirely on phenytoin, 0.5 g, and phenobarbital, 0.4 g/day (smaller doses in infants and children, as shown in Table 16-4), and on measures that safeguard the patient’s vital functions.

A word must be added concerning neuromuscular paralysis and continuous EEG monitoring in status epilepticus. With failure of aggressive anticonvulsant and anesthetic treatment, there may be a temptation to paralyze all muscular activity, something easily accomplished with drugs such as pancuronium, while neglecting the underlying seizures. The use of neuromuscular blocking drugs without a concomitant attempt to suppress seizure activity is a mistake. If such measures are undertaken and the paralysis continued for more than several hours, continuous or frequent intermittent EEG monitoring is virtually obligatory, and it is also helpful in the early stages of status epilepticus in adjusting the doses of anticonvulsants that are required to suppress the seizures.
In the related but less serious condition of acute repetitive seizures, a diazepam gel, which is well absorbed if given rectally, is available and has been found useful in institutional and home care of epileptics, although it is quite expensive. A similar effect has been attained by the nasal or buccal (transmucosal) administration of midazolam, which is quickly absorbed from these sites (5 mg/mL, 0.2 mg/kg nasally; 2 ml to 10 mg buccally). These approaches have found their main use in children with frequent seizures who live in supervised environments where a nurse or parent can administer the medication.

Petit mal status should be managed by intravenous lorazepam, valproic acid, or both, followed by ethosuximide. Nonconvulsive status is treated along the lines of grand mal status, usually stopping short of using anesthetic agents.

**Surgical Treatment of Epilepsy**

The surgical excision of epileptic foci in simple and complex partial epilepsies that have not responded to intensive and prolonged medical therapy is being used with increasing effectiveness in a large number of specialized epilepsy centers. At these centers, it has been estimated that approximately 25 percent of all patients with epilepsy are candidates for surgical therapy and more than half of these may benefit from surgery. To locate the discharging focus requires a careful analysis of clinical and EEG findings, often including those obtained by long-term video/EEG monitoring and sometimes intracranial EEG recording by means of intraparenchymal depth electrodes, subdural strip electrodes, and subdural grids. The most favorable candidates for surgery are those with complex partial seizures and a unilateral temporal lobe focus, in whom rates of cure and significant improvement approach 90 percent. Outside of the temporal lobe, complete seizure-free states are attained in about 50 percent. Only about 10 percent of patients obtain no improvement at all and less than 5 percent are worse.

Other surgical procedures of value in selected cases are section of the corpus callosum and hemispherectomy. The most encouraging results with callosotomy have been obtained in the control of partial and secondarily generalized seizures, particularly when atomic drop attacks are the most disabling seizure type. Removal of all of the cortex of one hemisphere, in addition to the amygdala and hippocampus, may be of value in young children and also in some adults with severe cerebral disease of that hemisphere and intractable unilateral motor seizures and hemiplegia. Rasmussen encephalitis, Sturge-Weber disease, and large porencephalic cysts at times fall into this category. Surgical or endovascular reduction of arteriovenous malformations generally reduce the frequency of associated seizures, but the results in this regard are somewhat unpredictable (see Chap. 34).

**Regulation of Physical and Mental Activity**

The most important factors in seizure breakthrough, next to the abandonment of medication, are loss of sleep and abuse of alcohol or other drugs. The need for moderation in the use of alcohol must be stressed, as well as the need to maintain regular hours of sleep.

A moderate amount of physical exercise is desirable. With proper safeguards, even potentially more dangerous sports, such as swimming, may be permitted. However, a person with incompletely controlled epilepsy should not be allowed to drive an automobile, operate unguarded machinery, climb ladders, or take tub baths behind locked doors; such a person should swim only in the company of a good swimmer and wear a life preserver when boating.

Psychosocial difficulties must be identified and addressed early. Simple advice and reassurance will frequently help to prevent or overcome the feelings of inferiority and self-consciousness of many epileptic patients. Patients and their families may benefit from more extensive counseling and proper family attitudes should be cultivated. Over solicitousness and overprotection should be discouraged. It is important that the patient be allowed to live as normal a life as possible Every effort should be made to keep children in school, and adults should be encouraged to work. Once seizures have ceased under medical control for a period varying from 6 months to a year, driving an automobile is allowed in most western countries. Many communities have vocational rehabilitation centers and special social agencies for epileptics, and advantage should be taken of such facilities.

**Other Therapeutic Measures**

**Ketogenic Diet** Since the 1920s interest in this form of seizure control has vacillated, being revived periodically in centers caring for many children with intractable epilepsy. Despite the absence of controlled studies showing its efficacy or a reasonable hypothesis for its mechanism, several trials in the first half of the century and again more recently have demonstrated a reduction in seizures in half of the patients, including handicapped children with severe and sometimes intractable fits. The regimen is initiated by starvation for a day or so to so as to induce ketosis followed by a diet in which 80 to 90 percent of the calories are derived from fat (Vining). The difficulties in making such a diet palatable leads to its abandonment by about one-third of children and their families.

**Vagal Nerve Stimulation** This experimental technique has found favor in cases of intractable partial and secondarily generalizing seizures. A pacemaker-like device is implanted in the anterior chest wall and stimulating electrodes are connected to the vagus at the left carotid bifurcation. The procedure is well tolerated except for hoarseness in some cases. Several trials have demonstrated an average of one-quarter or greater reduction in seizure frequency among patients who were resistant to all manner of anticonvulsant drugs (Wild). The mechanism by which vagal stimulation produces its effects is unclear, and its role in the management of seizures is still being defined. Cerebellar stimulation has also been used in the control of seizures, with no clear evidence of success.

**CHAPTER REFERENCES**

In hospital neurology, the clinical analysis of unresponsive and comatose patients becomes a practical necessity. There is always an urgency about such medical problems—a need to determine the underlying disease process and the direction in which it is evolving and to protect the brain against more serious or irreversible damage. When called upon, the physician must therefore be prepared to implement a rapid, systematic investigation of the comatose patient; the need for prompt therapeutic and diagnostic action allows no time for deliberate, leisurely investigation.

Some idea of the dimensions of this category of neurologic disease can be obtained from published statistics. Many years ago, in two large municipal hospitals, it was estimated that 3 percent of all admissions to the emergency wards were for diseases that had caused coma. Alcoholism, cerebral trauma, and cerebrovascular diseases were the most common causes, accounting for 82 percent of the comatose patients admitted to the Boston City Hospital in past years (Solomon and Aring). Epilepsy, drug intoxication, diabetes, and severe infections were the other major causes for admission. Recent figures from municipal hospitals are much the same, emphasizing that the common conditions underlying coma are relatively invariant in general medical practice. In university hospitals, which tend to attract more obscure cases, the statistics may be somewhat different. For example, in the series of Plum and Posner (Table 17-1), only one-quarter proved to have cerebrovascular disease, and only in 6 percent was coma the consequence of trauma. Indeed, all “mass lesions,”—such as tumors, abscesses, hemorrhages, and infarcts—were made up less than one-third of the coma-producing diseases. A majority were the result of exogenous (drug overdose) and endogenous (metabolic) intoxications and hypoxia. Subarachnoid hemorrhage, meningitis, and encephalitis made up another 5 percent of the total. Thus the order is reversed, but still intoxication, stroke, and cranial trauma stand as the “big three” of coma-producing conditions. Equally common in some series, albeit obvious and usually transient, is coma that follows seizures and resuscitation from cardiac arrest.

The terms consciousness, confusion, stupor, unconsciousness, and coma have been endowed with so many different meanings that it is almost impossible to avoid ambiguity in their usage. They are not strictly medical terms but literary, philosophic, and psychologic ones as well. The words consciousness is the most difficult of all. William James once remarked that everyone knows what consciousness is until he attempts to define it. To the psychologist, consciousness denotes a state of continuous awareness of one’s self and environment. Knowledge of self includes all “feelings, attitudes and emotions, impulses, volitions, and the active or striving aspects of conduct,” in short, an awareness of all one’s own mental functions, particularly of the cognitive processes, and their relation to past memories and experience. These can be judged only by the patient’s verbal account of his introspections and, indirectly, by his actions. Physicians, being more practical and objective for the most part, give greater credence to the patient’s behavior and reactions to overt stimuli than to what the patient says. For this reason they usually give the term consciousness its commonest and simplest operational meaning—namely, the state of the patient’s awareness of self and environment and his responsiveness to external stimulation and inner need. This narrow definition has another advantage in that unconsciousness has the opposite meaning—a state of unawareness of self and environment or a suspension of those mental activities by which people are made aware of themselves and their environment, coupled with a diminished responsiveness to environmental stimuli. Some authors make a distinction between the level of consciousness—meaning the state of arousal or the degree of variation from normal alertness as judged by the appearance of facial muscles, fixity of gaze, and body posture—and the content of consciousness, i.e., the quality and coherence of thought and behavior. For medical purposes, the loss of normal arousal is by far the more important and dramatic aspect of disorders consciousness and the one identified by laypersons and physicians as being the central issue in coma. To add to the ambiguity, psychoanalysts have given the word unconscious a still different meaning; for them it is a repository of impulses and memories of previous experiences that cannot immediately be recalled to the conscious mind.

Much more could be said about the history of our ideas concerning consciousness and the theoretic problems with regard to its definition, but this would serve no practical purpose. The interested reader is referred to the discussions of consciousness by Young and by Plum and Posner listed in the references.

Description of States of Normal and Impaired Consciousness

The following definitions, though probably not acceptable to all psychologists, are of service to clinicians and will provide the student and practitioner with a convenient terminology for describing the states of awareness and responsiveness of their patients.

**Normal Consciousness** This is the condition of the normal person when awake. In this state the individual is fully responsive to stimuli and indicates by his behavior and speech the same awareness of self and environment as that of the examiner. This normal state may fluctuate during the day from one of keen alertness or deep concentration with a marked contraction of the field of attention to one of mild general inattentiveness. From this state, the normal individual can be brought immediately to a state of full alertness and function.

**Confusion** In this condition the patient does not take into account all elements of his immediate environment. This state always implies a degree of imperceptiveness and distractibility, referred to traditionally as “clouding of the sensorium.” The term confusion lacks precision, but in general it denotes an inability to think with customary speed and clarity, usually marked by some degree of inattentiveness and disorientation. Here the difficulty is to define thinking, a term that refers variably to problem-solving or to coherence of ideas and formation of memories. Confusion results most often from a process that influences the brain globally, such as a toxic or metabolic disturbance or a dementia. Any condition that causes drowsiness or stupor, including the natural state that comes from sleep deprivation, results in some
Additional terms that have been used to describe this syndrome of preserved autonomic and respiratory function without cognition include the terminal phase of progressive degenerative processes such as Alzheimer disease and of Creutzfeldt-Jakob disease. The profound and widespread dysfunction of changes are in the thalamic and subthalamic nuclei, as in the celebrated Quinlan case (closed head trauma, widespread laminar necrosis of the cortex after cardiac arrest, and thalamic necrosis from a number of causes. Occasionally, the most prominent reflexes are preserved in varying degree, and muscle tone in the limbs may be increased. Respiration may be slow or rapid, periodic, or deranged in other ways (see further on). In still lighter stages, sometimes referred to by the ambiguous term semicoma, most of the above reflexes can be elicited, and the plantar reflexes may be either flexor or extensor (Babinski sign). Moreover, vigorous stimulation of the patient or distention of the bladder may cause a stirring or moaning and a quickening of respiration. These physical signs vary somewhat depending on the cause of coma. For example, patients with alcoholic coma may be afebrile and unresponsive to noxious stimuli, even when respiration and other vital functions are not threatened. The depth of coma and stupor, when compared in serial examinations, is most useful in assessing the direction in which the disease is evolving.

**Drowsiness and Stupor** In these states, mental, speech, and physical activity are reduced. Drowsiness denotes an inability to sustain a wakeful state without the application of external stimuli. Inattentiveness and mild confusion are the rule, both improving with arousal. The lids droop without closing completely; there may be some opening of the eyes, and the jaw and limb muscles are relaxed. This state is indistinguishable from light sleep, with slow arousal elicited by speaking to the patient or applying a tactile stimulus.

Stupor describes a patient who can be roused only by vigorous and repeated stimuli, at which time he opens his eyes, looks at the examiner, and does not appear to be oriented. Even spoken commands are ignored or answered with absent or slurred speech. Reflexes are absent or only mildly increased. Sleepless and drowsy patients are in stupor and they do not shift position as frequently as patients who are only drowsy. When left unstimulated, they quickly drift back into a sleep-like state. The eyes move outward and upward, a feature that is shared with sleep (see further on). Tendon and plantar reflexes and breathing pattern may or may not be altered, depending on how the underlying disease has affected the nervous system. In psychiatry, the term stupor has been used in a second sense—to denote an uncommon condition in which the perception of sensory stimuli is presumably normal but activity is suspended or marked by negativism (catatonic stupor).

**Coma** The patient who appears to be asleep and is at the same time incapable of being aroused by external stimuli or inner need is in a state of coma. There are variations in the degree coma in its deepest form is characterized by complete absence of eye opening, pupillary, pharyngeal, tendon, and plantar reflexes are in abeyance, and tone in the limb muscles is diminished. With lesser degrees of coma, pupillary reactions, reflex ocular movements, and corneal and other brainstem reflexes are preserved in varying degree, and muscle tone in the limbs may be increased. Respiration may be slow or rapid, periodic, or altered in other ways (see further on). In still lighter stages, sometimes referred to by the ambiguous term semicoma, most of the above reflexes can be elicited, and the plantar reflexes may be either flexor or extensor (Babinski sign). Moreover, vigorous stimulation of the patient or disturbance of the bladder may cause a stirring or moaning and a quickening of respiration. These physical signs vary somewhat depending on the cause of coma. For example, patients with alcoholic coma may be afebrile and unresponsive to noxious stimuli, even when respiration and other vital functions are not threatened. The depth of coma and stupor, when compared in serial examinations, is most useful in assessing the direction in which the disease is evolving.

**Coma**

Persons in sleep give little evidence of being aware of themselves or their environment; in this respect they are unconscious. Sleep shares a number of other features with the pathologic states of drowsiness, stupor, and coma. These include yawning, closure of the eyelids, cessation of blinking and spontaneous eye movements, and a decreased tendon and corneal reflexes. Tonic and clonic movements in sleep have a different meaning than movements in coma, where they represent absence of brainstem mediation. The appearance of fast sleep spindles is an important physiologic difference as well. Cerebral oxygen uptake does not decrease during sleep, as in coma, and the patient remains awake, does not speak, and shows no signs of awareness of the environment or inner need; responsiveness is limited to primitive reflex and postural movements of the limbs. In brief, in arousal is wakefulness and alternating arousal-nonarousal cycles may be established, but the patient remains neither aware nor purposeful behavior of any kind. This state is characterized by a number of specific clinical, neurologic, and neurophysiologic abnormalities, each of which points to the underlying lesion. The most prominent low-amplitude delta-frequency background activity, burst suppression, widespread alpha and theta activity, an alpha coma pattern, and sleep spindles have all been described in this state, as summarized by Hanssota (see Chap. 2). Moreover, the transition from coma to a state of partial awakenings is generally not marked by a change in the EEG pattern.

If lasting, the above described syndrome is most appropriately referred to as the *persistent vegetative state* or PVS (Jennett and Plum). This term has gained wide acceptance and applies to the clinical situation whatever the underlying cause. The most common pathologic bases of this state are diffuse cerebral injury due to closed head trauma; severe lobar necrosis, with or without neocortical necrosis from carotid or vertebral occlusion; hypoxic encephalopathy from birth asphyxia; and severe hypoxia, hypotension, or hypercarbia. The most prominent changes are in the thalamic and subthalamic nuclei, as in the celebrated Quinlan case (Kirnhey et al). It is noteworthy that a persistent vegetative state may also be the terminal phase of progressive degenerative processes such as Alzheimer disease and of Creutzfeldt-Jakob disease. The profound and widespread dysfunction of the cerebrum is reflected by extreme reductions in cerebral blood flow and metabolism noted by positron emission tomography (PET) and other techniques. On the basis of PET studies in a patient with carbon monoxide poisoning, Laures and colleagues observed that the main difference between the PVS and the recovered state was the presence of hypometabolism in the parietal lobe areas in the former. However, it is clear that the neuroanatomic basis of the vegetative state is far more complex.

Additional terms that have been used to describe this syndrome of preserved autonomic and respiratory function without cognition include apraxia syndrome and necrotic death. A recent position paper has codified the features of the persistent vegetative state and suggests dropping a number of related ambiguous terms, although some, such as akinetic mutism, discussed further on, have a more specific neurologic meaning and still find use (see Multi-Society Task Force on PVS).
It is difficult to predict which patients will fall permanently into the PVS category (see pages 1178 to 1179). Plum and Posner have reported that of 45 patients with signs of the vegetative state at 1 week, 13 awakened and 5 had satisfactory outcomes; after being vegetative for close to 2 weeks, only one recovered to a level of moderate disability. And after 2 weeks, the prognosis was uniformly poor. Larger studies by Hitpas and colleagues have given similar results. As a rough guide to prognosis, Plum and Posner have classified patients as: (a) Group patients: no signs of brainstem or cortical function, (b) Group patients: slight response (pupillary or reflex abnormalities); (c) Group patients: normal pupillary or reflex responses. The presence of sleep-wake cycles, blinks, or other voluntary movements may be diagnostic of a preserved brainstem system. The presence of sleep-wake cycles, blinks, or other voluntary movements may be diagnostic of a preserved brainstem system.

When the details of such cases become known, it is evident that recovery might reasonably have been expected. There are, however, numerous reported instances of partial recovery in patients—particularly children—after prolonged vegetative states for several weeks or, as Andrews describes, even several months after injury. Such observations cast doubt on unqualified claims of success with various therapies such as sensory stimulation. Nevertheless, the occurrence of rare instances of very late recovery in adults must be acknowledged [see Andrews; Hitpas et al.; and Rosenberg et al. (1977)].

The states of coma described above and the PVS cannot be clearly distinguished from a clinical state in which there is little or no disturbance of awareness (consciousness) but only an inability of the patient to respond adequately. The latter is referred to as the locked-in syndrome or the de-efferted state. The term pseudocoma is often used for this state. The patient is usually resistant to eye opening, and some patients display a wax-like flexibility of passive limb movement. The patient is usually of primary value in the diagnosis. Some centers utilize nuclide brain scanning or cerebral angiography to demonstrate an absence of blood flow to the brain, including spontaneous respiration; and (3) irreversibility of the state. To these is usually added evidence of catastrophic brain damage (trauma, cardiac arrest, profound hypothermia or intoxication with sedative-hypnotic drugs and immediately following cardiac arrest). For this reason, it has been recommended that the term be abandoned (Kennard and Illingworth), a more meaningful goal would be to insist on strict adherence to the clinical diagnostic criteria.

It is useful to maintain a critical view of news reports of remarkable recuperation from prolonged coma or the vegetative state. When the details of such cases become known, it is evident that recovery might reasonably have been expected. There are, however, numerous reported instances of partial recovery in patients—particularly children—after prolonged vegetative states for several weeks or, as Andrews describes, even several months after injury. outcome should be explained to the family and no intimation given that they have a role in deciding whether to remove the ventilator. The family’s desires regarding organ transplantation should be sought after adequate time has passed for them to absorb the shock of the circumstances. Neurologists must, of course, resist pressures from diverse sources that might lead them to the premature designation of a state of brain death. The clinical findings should show complete absence of brain function, not an approximation that might be reflected, for example, by slow or poorly reactive pupils, slight eye deviation with oculocephalotorsional flexion, posturing of the limbs, and the like. At the same time, it should be clarified that while brain death is an operational state that allows transplantation to proceed and mandates withdrawal of ventilation and blood pressure support, patients with overwhelming brain injuries need not fulfill these absolute criteria in order for medical support to be withdrawn.

A task force for the determination of brain death in children has recommended the adoption of essentially the same criteria as for adults. Because of the great difficulty in evaluating the status of nervous function in relation to perinatal insults, they have suggested that a diagnosis of brain death not be made before the seventh postnatal day and that the period of observation be extended to 48 h. As with adults, the possibility of reversible brain dysfunction from toxins, drugs, hypothermia, and hypotension must always be considered.

The Electroencephalogram and Disturbances of Consciousness

One of the most definitive confirmations of the fact that the states of impaired consciousness are expressions of neurophysiologic changes in the cerebral cortex is the altered EEG. Some alteration of brain waves occurs in all disturbances of consciousness except the milder degrees of confusion and in catatonia. These alterations usually consist of a disorganization of the EEG pattern, including disappearance of alpha rhythm and replacement by random slow waves of low to moderate voltage in the initial stages of confusion; a more regular pattern of slow, 2- to 3-second waves of high voltage in stupor; slow low-voltage waves or intermittent suppression of organized electrical activity in the deep coma of hypoxia and ischemia; and ultimately a complete absence of electrical activity in brain death.

In some deeply comatose patients, the EEG may transiently show diffuse and variable (8- to 12-Hz) activity, which may be mistaken for physiologic alpha rhythm. However, the former pattern (so-called alpha coma) is not limited to the posterior cerebral regions, is not monorhythmic like normal alpha activity, and displays no reactivity to sensory stimuli. This alpha-like activity pattern may be associated with pontine or diffuse cortical lesions and has a poor prognosis (Figs. 4 and 5; page 33). A rarer EEG abnormality is “spindle coma,” in which sleep spindles dominate the record (page 415).

The EEG accurately reflect the depth of certain metabolic comas, particularly those due to hepatic or renal failure. In these conditions the slow waves become higher in amplitude as coma deepens, ultimately assuming a high-voltage delta pattern and a triphasic configuration. There is also a general correspondence between the intensity of stimuli required to elicit motor activity and the degree of slowing of the background rhythm. Not all cerebral disorders that cause confusion, stupor, and coma have the same effects on the EEG. In cases of intoxication with sedatives, exemplified by barbiturates, fast activity initially replaces normal rhythms. Continuing sedation is accomodating during a mixed or a sharp or a sharpswave is a feature that is not unusual in the background EEG of the comatose patient. In general, the differences in EEG changes among metabolic derangements probably represent important biologic distinctions at the neuronal level that have not yet been elucidated (see also Chap. 2).

The Anatomy and Neurophysiology of Coma

Our current understanding of the anatomy and physiology of alertness comes largely from the elegant experiments of F. G. Bremer and of Magoun and Moruzzi in the 1940s. Observations in cats which had sectioned the brainstem between the pons and midbrain and at the level of the lower medulla, Bremer found that the rostral section caused a sleep-like state and “synchronized” EEG rhythms that were characteristic of sleep; animals with the lower section remained awake, with appropriate “desynchronized” EEG rhythms. He interpreted this mean that a constant stream of sensory stimuli, provided by trigeminal and other cranial sources, was required to maintain the awake state. Several years later, Morrison and Dempsey demonstrated a system of “nonspecific” projections from the thalamus to all cortical regions, independent of any specific sensory nucleus. A critical refinement of this concept resulted from the observation, by Moruzzi and Magoun, that electrical stimulation of the medial midbrain tegmentum and adjacent areas just above this level caused a lightly anesthetized animal to become suddenly alert and its EEG to change correspondingly, i.e., to become “desynchronized,” in a manner identical to normal arousal by sensory stimuli. The sites at which stimulation led to arousal consisted of a series of points extending from the non-specific medial thalamic nuclei down through the caudal midbrain. These points were situated along the loosely organized core of neurons that anatomists had referred to as the reticular system or formation. The anatomic studies of the Schiebes described widespread innervation of the reticular formation by multiple bifurcating and collateral axons of the ascending sensory systems, implying that this area was maintained in a tonically active state by ascending sensory stimulation. Because this region, especially the medial thalamus, projected widely to the cerebral hemispheres, there arose the concept of a reticular activating system (RAS) that maintained the alert state and the inactivation of which led to an unarousable state. In this way, despite a number of experimental inconsistencies (see Steriade) the paramedian upper brainstem tegmentum and lower diencephalon came to be conceived as the locus of the alerting system of the brain.

The anatomic boundaries of the high brainstem reticular activating system are somewhat indistinct. This system is interspersed throughout the paramedian regions of the upper (rostral) pontine and midbrain tegmentum; at the thalamic level, it includes the functionally related posterior paramedian, parafascicular, and medial portions of the centromedian and adjacent intralaminar nuclei. In the brainstem, nuclei of the reticular formation receive collaterals from the direct spinothalamic pathways and pontine and medullary reticular nuclei, or somatic afferents do to the thalamus. Reticular formation fibers also differ from the whole of the cerebral cortex. Thus, it would seem that sensory stimulation has a double effect—i.e., conveys information to the brain from somatic structures and the environment and also activates those parts of the nervous system on which the maintenance of consciousness depends. The cerebral cortex not only receives impulses from the ascending reticular activating system, but it also modulates this incoming information via corticothalamic connections to the reticular formation. Although the physiology of the reticular activating system is far more complicated than this simple formulation would suggest, it is nevertheless, as a working idea, retains a great deal of clinical credibility and makes some of the neuropathologic observations noted further on, under “Pathologic Anatomy of Coma,” more comprehensible.

Metabolic Mechanisms That Disturb Consciousness

In a number of disease processes that disturb consciousness there is direct interference with the metabolic activities of the nerve cells in the cerebral cortex and the central nuclei of the brain. Hypoxia, global ischemia, hypoglycemia, hyper- and hypo-osmolar states, acidosis, alkalosis, hypokalemia, hyperammonemia, hypercalcemia, hypercarbia, drug intoxication, and severe vitamin deficiencies are well-known examples (see Chap. 40 and Table 40-1). In general, the loss of consciousness in these conditions produces a depression in cerebral metabolism or blood flow. For example, in the case of global ischemia, an acute drop in cerebral blood flow (CBF) to 25 mL/min/100 g brain tissue from its normal 55 mL/min/100 g causes slowing of the EEG and syncope or impaired consciousness; a drop in CBF below 15 mL/min/100 g causes electrocerebral silence, coma, and cessation of most neuronal metabolic and synaptic functions. Lower levels are tolerated if blood flow (CBF) to 25 mL/min/100 g causes slowing of the EEG and syncope or impaired consciousness; a drop in CBF below 12 to 15 mL/min/100 g causes electrocerebral silence, coma, and cessation of most neuronal metabolic and synaptic functions. Lower levels are tolerated if...
little effect on consciousness until it spreads from one side of the brain (and body if there is a convulsion) to the other. Coma then ensues, presumably because the spread of the seizure discharge to deep central neural structures paralyzes their function. In other types of seizure, in which consciousness is interrupted from the very beginning, a diencephalic origin has been postulated (centrencephalic seizures of Penfield).

Concussion exemplifies another special pathophysiologic mechanism of coma. In “blunt” or closed head injury, it has been shown that at the moment of theconcussive injury there is an enormous increase in intracranial pressure, on the order of 200 to 700 lb/in

The variation set up in the skull and transmitted to the brain was for many years thought to be the basis of the abrupt paralysis of nervous function that characterizes concussive head injury. Instead it is more likely that the sudden swirling motion of the brain induced by the blow to the head, producing a rotation (torque) of the cerebral hemispheres around the axis of the upper brainstem, is the proximate cause of loss of consciousness. These same physical forces, when extreme, cause multiple shearing lesions or hemorrhages in the diencephalon and upper brainstem. The subject of concussion is discussed fully in

Yet another unique form of coma is that produced by inhalation anesthetics. Current theories attribute the effects of general anesthesia to changes in the physical chemistry of neuronal membranes and perhaps to consequent alterations in neurotransmitter function. Inhalation anesthetics are unusual among coma-producing drugs in respect to the sequence of inhibitory and excitatory effects that they produce at different concentrations. During anesthesia, sufficient inhibition of brainstem activity can be attained to eliminate the pupillary responses and the corneal reflex. Both return to normal by the time the patient is able to speak. Sustained clonus, exaggerated tendon reflexes, and Babinski signs are common. These findings have been studied systematically by Ropper and Kennedy. Pre-existing focal deficits from strokes often worsen transiently with the administration of anesthetics, as is true for other sedatives, metabolic encephalopathies, and hyperthermia.

Recurring Stupor and Coma Aside from repeated drug overdose, recurring episodes of stupor are usually due to the decompensation of an encephalopathy from an underlying biochemical derangement, hepatic failure being the most common. A similar condition of periodic hyperammonemnic coma in children and adults can come about from urea cycle enzyme defects, such as ornithine transcarbamylase deficiency. These are discussed in

Under the title of idiopathic recurring stupor, a rare condition has been described in adult men who displayed a prolonged state of deep sleepiness lasting from hours to days intermittently over a period of many years. Despite the impression of a sleep disorder related to narcolepsy, the electroencephalogram (EEG) showed widespread fast (betta) activity, and both the stupor and EEG changes were promptly reversed by flumazenil, a benzodiazepine receptor antagonist. During the bouts, a hundredfold increase of circulating endoperoxide-4, a naturally occurring diazepine agonist, was found in the serum and spinal fluid. Subsequently, the authors of the original reports (Lugaresi et al) found, by use of more advanced techniques, that intoxication with lorazepam may have accounted for at least some of the cases; the status of this entity is therefore unclear.

It is uncertain to us whether migraine can cause a similar syndrome, as suggested in the study of familial hemiplegic migraine by Fitzsimmons and Wolfenden. Basilar migraine may exceptionally cause transient stupor and coma. Catatonic stupor and Kleine–Levin syndrome also need to be considered.

Pathologic Anatomy of Coma

Coma-producing alterations in the brain are divided into two broad groups: The first is clearly morphologic, consisting either of discrete lesions in the upper brainstem and lower diencephalon (which may be primary or secondary to compression), or of more widespread changes throughout the hemispheres. The second is metabolic or submicroscopic, resulting in suppression of neuronal activity. The clinical examination in coma is designed to separate these various mechanisms and to gauge the depth of brain dysfunction.

The study of a large number of human cases in which coma preceded death by several days has disclosed three main types of lesion, each of which ultimately deranges the function of the reticular activating system directly or indirectly. In the first type, a readily discernible mass lesion—chiefly a tumor, abscess, meningitis, massive edematous infarct, or intracerebral, subarachnoid, subdural, or epidural hemorrhage—is demonstrable. Usually the lesion involves only a portion of the cortex and white matter, leaving much of the cerebrum intact but nonetheless it distorts deeper structures. In most instances, these mass lesions in or surrounding the hemispheres cause coma by a lateral displacement of deep central structures, sometimes, but not always, with herniation of the temporal lobe into the tentorial opening, resulting in compression, ischemia, and secondary hemorrhages in the midbrain and subthalamic region including the reticular activating system (see below and also Chap. 31). Likewise, a cerebellar lesion may secondarily compress the adjacent upper brainstem reticular region by displacing it forward and perhaps upward. A detailed clinical record will show the coma to have coincided with these displacements and herniations. The anatomical displacements caused by herniations are discussed in more detail below.

In a second type, less frequent than the first, the lesion is located in the thalamus or midbrain, in which case the reticular activating neurons are involved directly. This pathoatomic pattern characterizes brainstem stroke from basilar artery occlusion, and thalamic–upper brainstem hemorrhage.

In a third type, widespread bilateral damage to the cortex and white matter is found—the result of traumatic damage (contusions, diffuse axonal injury), bilateral infarcts or hemorrhages, viral encephalitis, meningitis, hypoxia, or ischemia, as occurs after cardiac arrest. The coma in these cases results either from interruption of corticopetal impulses or from generalized derangement of the reticular activating neurons, which prevents the normal activation of the upper reticular formation. Often the cerebral lesions are bilateral and extensive is consciousness markedly impaired. Thus, pathologic changes are compatible with physiologic deductions—that the state of prolonged coma correlates with lesions of all parts of the cortical-diencephalic system of neurons; but it is only in the upper brainstem that the coma-producing lesions may be small and discrete.

In yet another, larger group of cases, no lesion is visible to the naked eye. Sometimes no abnormality is divulged by any technique of pathology; the lesion, caused by a metabolic or toxic abnormality or a generalized electrical discharge (seizure), is presumably subcellular or molecular, or the visible microscopic lesions are too diffuse for clinicatomic correlation, as discussed below.

Pathoanatomy of Brain Displacement and Herniations

As was pointed out earlier, large, destructive, and space-consuming lesions of the cerebrum—such as hemorrhage, tumor, abscess, or infarction—impair consciousness in one of two ways. One is by direct extension of the lesion into the diencephalon and midbrain. The other, far more frequent, is by lateral and downward displacement of the subthalamic-upper brainstem structures with or without herniation of the medial part of the temporal lobe (uncus, hippocampus) through and below the opening in the tentorium. One consequence of lateral displacement is that the upper midbrain, particularly the cerebral peduncle, is compressed and ischemic. The resulting ischemia of the lateral edge of the peduncle is called Kernohan’s notch or, more properly, the Kernohan–Woltman phenomenon, causing a Babinski sign ipsilateral to the hemispheric lesion. The posterior cerebral artery is also compressed at the edge of the tentorium, leading to hemorrhagic infarction of the ipsilateral occipital lobe (see also page 682).

It follows from the foregoing discussion that unilateral destructive lesions of the hemispheres, such as infarcts or hemorrhages, do not cause coma unless they create some degree of mass effect, usually delayed in onset, which secondarily compresses the upper brainstem. There are exceptions in which patients with massive strokes affecting the territory of the internal carotid artery are drowsy from the onset, even before brain swelling occurs, but more often they are simply apathetic with a tendency to keep their eyes closed, a state that may be misinterpreted as stupor.

Plum and Posner, following earlier observations of McNealy and Plum, subdivided the brainstem displacements by supratentorial masses into two groups: one a central syndrome with downward displacement and bilateral compression of the upper brainstem and the other a unilateral displacement with medial temporal lobe and particularly uncal gyrus herniation into the tentorial opening. Both are types of transtentorial herniation. According to these authors, the central syndrome takes the form of a rostral-caudal deterioration of function: there is first confusion, apathy, and drowsiness and often Cheyne-Stokes respiration (CSR); then the pupils become small and react very little to light; “doll’s-head” (oculocerebral) eye movements are elicitable, as are deviations of the eyes in response to cold-water caloric testing (the compensatory fast component of the response is impaired or absent, however). Bilateral Babinski signs can be detected early; later, grasp reflexes and decorticate postures appear. These signs give way to a downward gradient of brainstem signs—coma, central hyperventilation, medium-sized fixed pupils, bilateral decerebrate postures, loss of oculovestibular (caloric) responses, slow, irregular breathing, and death.

The uncical syndrome, thought traditionally to be the result of herniation of the medial temporal lobe downward through the tentorial opening, differs mainly in that drowsiness in the early stages is accompanied or preceded by unilateral pupillary dilatation, most often on the side of a mass. These herniations between dural
Our own experience does not fully substantiate this distinction between the two syndromes, and seldom have we been able to follow such an orderly sequence of neural dysfunction from the diencephalic to the medullary level. With lateral shift and uncal herniation, one sometimes observes smallness of the pupils, rather than ipsilateral pupillary dilatation, as drowsiness develops. Or, infrequently, the contralateral pupil may dilate before the ipsilateral one. Nor is it clear that the dilatation of one pupil is always due to trapping or compression of the oculomotor nerve by the herniated uncus, as traditionally taught. More often the third nerve is stretched and angulated over the clivus or compressed under the descended posterior cerebral artery. Involvement of the third nerve nucleus or its fibers of exit may be responsible for the dilatation of the opposite pupil, the usual occurrence after the pupil on the side of the mass has become fixed. In a serial study of 12 patients with brain edema and lateral diencephalic-mesencephalic shifts due to hemispheric infarcts, 4 patients initially had no ipsilateral pupillary enlargement; in 1 patient, the pupillary enlargement was contralateral; in 3 patients, the pupils were symmetrical when drowsiness gave way to stupor or coma (Ropper and Shafran). Cyclic Cheyne-Stokes breathing was an early sign of deterioration. In one patient, the first motor sign was an ipsilateral deacrebrate rigidity rather than decorticate posture; most of the patients had bilateral Babinski signs by the time they became stuporous. Indeed, the appearance of a Babinski sign on the nonhemiparetic side has been one of the best sentinels of secondary brain tissue shift. These signs often progressed to deep coma and decerebration within hours and they fluctuated widely, worsening with waves of high intracranial pressure.

As the primary explanation for coma from a large mass in one hemisphere, we favor a mechanism of predominantly lateral displacement that causes compression of subthalamic and mesencephalic structures. This is often but not invariably associated with temporal lobe herniation. The resulting neural dysfunction of deep structures is probably due to ischemia. This view is supported by findings on CT scans and MRI, which have been used to study the earliest structural displacements in patients with acute hemispheric mass lesions. In our experience, the early disturbances of consciousness (drowsiness and stupor) are related to the degree of lateral displacement of high brainstem and subthalamic structures (judged by shifts in the position of the pineal body and, with less accuracy, the septum pellucidum), all occurring in the absence of transtentorial herniation which arises later. With acute masses, a 3- to 5-mm horizontal displacement of the pineal calcification is associated with drowsiness; 5 to 8 mm, with stupor; and greater than 8 or 9 mm, with coma (Ropper, 1986).

The location as well as the size of a mass determines the degree of brain distortion and displacement of crucial structures in the lower diencephalon and upper midbrain. Andrews and colleagues have pointed out that frontal and occipital hemorrhages are less likely to displace deep structures and to cause coma than are clots of equivalent size in the parietal or temporal lobes. Nor is it surprising that slowly enlarging masses such as brain tumors may sometimes cause massive shifts of brain tissue yet result in few clinical changes.

Downward movement of the upper brainstem occurs, but its role in the production of coma in comparison to horizontal shift is not entirely settled. In our view, the importance of direct downward displacement may be overestimated as the main pathoanatomic cause of coma. Although in some cases the predominant shift is downward and in others it is horizontal, horizontal displacement on MRI is usually disproportionate to vertical displacement, and the clinical state corresponds better with the degree of lateral shift. Others, notably Reich and colleagues, disagree with these observations and find the argument for vertical shift to be more compelling. It is noteworthy that the brainstem can usually tolerate, without inducing a change in consciousness, a large downward movement that occurs as part of the syndrome of low cerebrospinal fluid (CSF) pressure following lumbar puncture. This is not always the case, however, as in the patient reported by Pleasure and colleagues who became stuporous with low CSF pressure from a spinal leak and aroused when the pressure was normalized.

**CLINICAL APPROACH TO THE COMATOSE PATIENT**

It must be repeated that coma is always a symptomatic expression of an underlying disease. Sometimes the primary disorder is perfectly obvious, as with severe cranial trauma. All too often, however, the patient is brought to the hospital in a state of coma and little pertinent medical information is immediately available. The need for efficiency in reaching a diagnosis and providing appropriate acute care demands that the physician have a methodical approach that leaves none of the common and treatable causes of coma unexplored.

When the comatose patient is first seen, one must quickly make sure that the patient's airway is clear and the patient is not in shock; if trauma has occurred, one must check for bleeding from a wound or ruptured organ (e.g., spleen or liver). If hypotension is present, certain therapeutic measures—placement of a central venous line and administration of fluids and pressor agents, oxygen, blood, or glucose solutions (after blood is drawn for glucose determinations and thiamine is administered)—take precedence over diagnostic procedures. If respirations are shallow or labored or if there is emesis with a threat of aspiration, tracheal intubation and mechanical ventilation are required. An oropharyngeal airway is usually adequate in a comatose patient who is breathing normally. Deeply comatose patients with shallow respirations require endotracheal intubation. The patient with a head injury may also have suffered a fracture of the cervical vertebrae, in which case caution must be exercised in moving the head and neck, and in intubation, lest the spinal cord be inadvertently damaged.

There must then be an inquiry as to the previous health of the patient—whether there was a history of diabetes, a head injury, a convolution, alcohol or drug use, or a prior episode of coma or attempted suicide—and the circumstances in which the person was found. Persons who accompany the comatose patient to the hospital should be encouraged not to leave until they have been questioned.

From an initial survey, many of the common causes of coma—such as severe head injury, alcoholic or other forms of drug intoxication, and hypertensive brain hemorrhage—are readily recognized.

**General Examination**

Alterations in vital signs—temperature, pulse, respiratory rate, and blood pressure—are important aids in diagnosis. Fever is most often due to a systemic infection such as pneumonia or to bacterial meningitis or viral encephalitis. An excessively high body temperature (42 or 43°C) associated with dry skin should arouse suspicion of heat stroke or intoxication by a drug with anticholinergic activity. Fever should not be ascribed to a brain lesion that has disturbed the temperature-regulating center—so-called central fever, which is a very rare occurrence. Hypothermia is observed in patients with alcoholic or barbiturate intoxication, drowning, exposure to cold, peripheral circulatory failure, and myxedema.

Slow breathing points to opiate or barbiturate intoxication and occasionally to hypothyroidism, whereas deep, rapid breathing (Kussmaul respiration) should suggest the presence of pneumonia, diabetic or uremic acidosis, pulmonary edema, or the less common occurrence of an intracranial disease that causes central neurogenic hyperventilation. Diseases that elevate intracranial pressure or damage the brain often cause slow, irregular, or cyclic Cheyne-Stokes respiration (see further on). The various disordered patterns of breathing and their clinical significance are described further on and on page 579. Vomiting at the outset of sudden coma, particularly if combined with pronounced hypertension, is highly characteristic of cerebral hemorrhage or subarachnoid space. When occurring with coma of more gradual onset, it may signify drug or alcohol intoxication.

The pulse rate, if exceptionally slow, should suggest heart block from medications such as tricyclic antidepressants or anticoagulants, or—if combined with periodic breathing or Cheyne-Stokes respiration—an increase in intracranial pressure. Marked hypertension is observed in patients with cerebral hemorrhage and hypertensive encephalopathy and, at times, in those with greatly increased intracranial pressure. Hypotension is the usual finding in states of depressed consciousness due to...
diabetes, alcohol or barbiturate intoxication, internal hemorrhage, myocardial infarction, dissecting aortic aneurysm, septicemia, Addison disease, or massive brain trauma.

Inspection of the skin may yield valuable information. Cyanosis of the lips and nail beds signifies inadequate oxygenation. Cherry-red coloration is typical of carbon monoxide poisoning. Pernicious anemia (paradoxical flushing), or the nose, chest, or oral mucosae is common, but must not be confused with the rare situation in which hypercalcemia greatly increases the likelihood of cranial fracture and intracranial trauma. Telangiectases and hyperemia of the face and conjunctivae are the common stigma of alcoholism; mydriasis imparts a characteristic puffiness of the face, and hypotension, an equally characteristic sallow complexion. Marked pallor suggests internal hemorrhage. A maculohemorrhagic rash indicates the possibility of meningococcal infection, staphylococcal endocarditis, typhus, or Rocky Mountain spotted fever. Enlarged sweating suggests all types of myeloma and a history of diabetes, or uremia. Skin that is dry, shiny, or desquamating is typical of dehydration. Large blebs or ulcers, sometimes bloody, may form over pressure points if the patient has been motionless for a time; they are particularly characteristic of acute barbiturate, alcohol, or opiate intoxication. Thrombotic thrombocytopathy purpura, disseminated intravascular coagulation, and fat embolism may cause diffuse petechiae.

The odor of the breath may provide a clue to the etiology of coma. The odor of alcohol is easily recognized (except for vodka, which is odorless). The spoiled-fruit odor of diabetic coma, the uninfiltrated odor of urea, the musky fetor of hepatic coma, and the almond odor of cyanide poisoning are distinctive enough to be identified by physicians who possess a keen sense of smell.

Neurologic Examination of the Stuporous or Comatose Patient Although limited in many ways, the neurologic examination is of crucial importance. Simply watching the patient for a few moments often yields considerable information. The predominant postures of the limbs and body; the presence or absence of spontaneous movements on one side; the position and shape of the pupils; and the rate, depth, and rhythm of respiration should be noted. The state of responsiveness is estimated by noting the patient’s reaction to calling his name, to simple commands, or to noxious stimuli such as supraorbital or sternal pressure, pinching the side of the nose or inner parts of the arms or thighs, or applying pressure to the knuckles. By gradually increasing the strength of these stimuli, one can roughly estimate both the degree of unre sponsiveness and changes from hour to hour. Vomiting may persist in the stupor and is the first response to be lost as coma appears. Grimacing and deft avoidance movements of the stimulated parts are preserved in light coma; their presence substantiates the integrity of corticobulbar and corticospinal tracts. Yawning and spontaneous shifting of body positions indicate a minimal degree of unresponsiveness. The Glasgow Coma Scale, constructed originally as a quick and simple means of quantitating the responsiveness of patients with severe cerebral trauma, can be used in the grading of other acute coma-producing diseases (see Chap. 35).

It is usually possible to determine whether coma is associated with meningial irritation or with focal cerebral or brainstem disease. In all but the deepest stages of coma, meningial irritation—from either bacterial meningitis or subarachnoid hemorrhage—will cause resistance to passive flexion of the neck but not to extension, turning, or tilting of the head. It should be noted that in some patients the signs of meningial irritation do not develop for 12 to 24 h after the onset of subarachnoid hemorrhage, during which time CT scanning and lumbar puncture are the most reliable diagnostic measures. Resistance to movement of the neck in all directions may be part of generalized muscular rigidity (as in phenothiazine intoxication) or indicate disease of the cerebral spine. In the infant, bulging of the anterior fontanel is at times a more reliable sign of meningitis than stiff neck. A temporal lobe or cerebellar herniation or decerebrate rigidity may also limit passive flexion of the neck and be confused with meningial irritation.

A lesion in a cerebral hemisphere can usually be detected, even though the patient is comatose, by careful observation of the patient’s spontaneous movements, responses to stimulation, prevailing postures, respiratory rate and rhythm, and by examination of the cranial nerves. A hemiplegia is revealed by a lack of restless movements of the limbs and of aversive or protective movements in response to painful stimuli. The paralyzed limbs are usually slack; they tend to remain in passive positions and, if lifted from the bed, “fall flat.” The hemiplegic leg lies in a position of external rotation (this may also be due to a fractured femur), and the thigh may appear wider and flatter than the nonhemiplegic one. In expiration, the cheek and lips puff out on the paralyzed side. With hemispheric lesions, the eyes are often turned away from the paralyzed side (toward the lesion, as described below); the opposite may occur with brainstem lesions. In most cases, a hemiplegia and an accompanying Babinski sign are indicative of a contralateral hemispheric lesion; but with lateral mass effect and compression of the opposite cerebral peduncle against the tentorium, extensor rigidity, a Babinski sign, and weakness of arm and leg may also occur ipsilateral to the lesion (Kernohan-Woltman sign). A moan or grimace may be provoked by painfull stimuli on one side but not on the other, reflecting the presence of a hemianesthesia; also during grimacing, facial weakness may be noted.

Of the various indicators of brainstem function, the most useful are pupillary size and reactivity, ocular movements, oculovestibular reflexes, and, to a lesser extent, the pattern of breathing. These functions, like consciousness itself, are to a large extent dependent on the integrity of structures in the midbrain and rostral pons.

The Pupillary Reactions These are of great diagnostic importance in the comatose patient. A uni laterally enlarged pupil (>5.5 mm diameter) is an early indicator of stretching or compression of the third nerve as a secondary effect of an ipsilateral hemispheric mass. First there is usually a loss of light reaction alone. With continued pressure, the pupil gradually becomes nonreactive to light and even to near stimulation. Anisocoria, the presence of two unequal pupils, may be part of a larger structural lesion affecting the oculomotor nuclei. With a brainstem lesion, the pupils are usually 4 to 6 mm in diameter, with one larger than the other (anisocoria). Both eyes are not equally reactive to light. Bilateral mydriasis and unreactive pupils are characteristic of a complete third nerve lesion. Increased light reaction, the rapid constriction of the pupil on a bright light, is another indication of a brainstem lesion. The dilated pupil is commonly associated with a midline shift, or with lesions in the tegmentum of the midbrain and rostral pons.

Pontine tegmental lesions cause extremely miotic pupils (<1 mm in diameter) with only a slight reaction to strong light; this is characteristic of the early phase of pontine hemorrhage. The ipsilateral pupillary dilatation from pinching the side of the neck (the ciliospinal reflex, page 296) is also lost in brainstem lesions. A Horner syndrome (miosis, ptosis, apparent enophthalmos, and reduced sweating) may be observed homolateral to a lesion of the brainstem or hypothalamus or as a sign of pontine hemorrhage. A maculohemorrhagic rash indicates the possibility of meningococcal infection, staphylococcal endocarditis, typhus, or Rocky Mountain spotted fever. Multiple bruises (particularly a bruise or boggy area in the scalp), bleeding, CSF leakage from an ear or the nose, or periorbital hemorrhage may provide a clue to the etiology of coma. The odor of alcohol is easily recognized (except for vodka, which is odorless). The spoiled-fruit

Movements of Eyes and Eyelids and Corneal Responses May be altered in a variety of ways. In light coma of metabolic origin, the eyes rotate conjugately from side to side in random fashion, sometimes resting briefly in an eccentric position. These movements disappear as coma deepens and the eyes then remain motionless in slightly exotropic positions.

A lateral and slight downward deviation of one eye suggests the presence of a third nerve palsy, and a medial deviation, a sixth nerve palsy. There may be a persistent conjugate deviation of the eyes to one side—away from the side of the lesion (the colliophthallic reflex, page 296) is also lost in brainstem lesions. A Homer syndrome (miosis, ploss, apparent enophthalmos, and reduced sweating) may be observed homolateral to a lesion of the brainstem or hypothalamus or as a sign of dissection of the internal carotid artery.

With coma due to drug intoxications and metabolic disorders, pupillary reactions are usually spared, but there are notable exceptions. Opiates cause pinpoint pupils with so little a constriction to light that it can be seen only with a magnifying glass. High-dose barbiturates may act similarly, but the pupillary diameter tends to be 1 mm or more. Poisoning with atropine or atropinic drugs, especially tricyclic antidepressants, is characterized by wide dilatation and flicky of pupils, which cannot be reversed by physostigmine. Hippus, or fluctuating pupillary size, is said by some observers to be characteristic of the metabolic encephalopathies.

Oculocephalic reflexes (doll’s-eye movements), are elicited by briskly turning or tilting the head. The response in coma consists of conjugate movement of the eyes in the opposite direction to the movement of the head and is not present in a comatose patient. With the eyes in the midline, there is a conjugate deviation of the eyes on each side of the head to positions of fixation (1:7). A large degree of unimped ed function of the oculomotor nerves and of the midbrain and pontine tegmental structures that integrate ocular movements, and (2) loss of the cortical inhibition that normally modifies these movements in check. The presence of unpaired reflex eye movements implies that coma is not due to a mass lesion causing secondary compression or one that directly destroys the upper midbrain. Instead, it must be the result of widespread cortical dysfunction. This occurs with cerebral anoxia or metabolic-toxic suppression of cortical function. It must be conceded, however, that although the failure to elicit eye movement implies brainstem secondary compression or one that directly destroys the upper midbrain. Instead, it must be the result of widespread cortical dysfunction such as occurs with cerebral anoxia or metabolic-toxic suppression of cortical function.
but the movement of the eye on the side of the mass is often impeded in adduction, as a result of a third nerve paresis.

Irrigation of each ear with 10 mL of cold water (or room-temperature water if the patient is not comatose) normally causes slow conjugate deviation of the eyes toward the irrigated ear, followed in a few seconds by compensatory nystagmus (fast component away from the stimulated side). This is the oculocephalic or calorice reflex. If the ears are irrigated simultaneously, the eyes are tonic or nystagmic. In comatose patients, the fast “corrective” phase of nystagmus is lost and the eyes are tonically deviated to the side irrigated with cold water or away from the side irrigated with warm water; this position may be held for 2 to 3 min. With brainstem lesions, these vestibulo-ocular reflexes are lost or disrupted.

If, on attempted lateral gaze, only one eye adducts and the other fails to adduct, one can conclude that the medial longitudinal fasciculus has been interrupted (on the side of adductor paralysis). An abducens palsies, pathologically anisocoria, is indicated by an esotropic resting position and a lack of outward deviation of one eye with the reflex maneuvers.

Reduction in frequency and eventual loss of spontaneous blinking, then loss of blink in response to touching the eyelashes, and finally a lack of response to corneal touch (aft erment–trigeminal nerve; eff erent limb–both facial nerves) is among the most dependable signs of deepening coma. A marked asymmetry in corneal responses indicates either an acute lesion of the opposite hemisphere or, less often, an ipsilateral lesion in the brainstem.

Spontaneous Limp Movements Restless movements of both arms and both legs and grasping and picking movements signify that the corticospinal tracts are more or less intact. Variable oppositional resistance to passive movement (paratonic rigidity), complex avoidance movements, and discrete protective movements have the same meaning: if these movements are bilateral, the coma is usually not profound. The occurrence of focal motor epilepsy usually indicates that the corresponding cortical area is affected. With mass lesions in the limbic system, e.g., production of a cerebral hemisphere, as occurs in hypertensive hemorrhage or internal carotid–middle cerebral artery occlusion, focal sei 2

ures may be seldom seen on the paralyzed side; seizure activity may be manifest solely in the ipsilateral limbs, the contralateral limbs being prevented from participating by the hemiplegia. Often, elaborate forms of semivoluntary movement are present on the “good side” in patients with extensive disease in one hemisphere, they probably represent some type of disequilibrium or disinhibition of cortical and subcortical movement patterns. Definite choreic, athetotic, or hemiballistic movements indicate a disorder of the basal ganglionic and subthalamic structures, just as they do in the alert patient.

Postural Changes in the Comatose Patient One of these abnormal postures is decerebrate rigidity, which in its fully developed form consists of opisthotonos, clenching of the jaws, and stiff extension of the limbs, with internal rotation of the arms and plantar flexion of the feet. This postural pattern was first described by Sherrington, who produced it in cats and monkeys by transecting the brainstem at the intercerebellar level. The decerebrate pattern was noted to be ipsilateral to a one-sided lesion, hence not due to involvement of the corticospinal tracts. Such a precise correlation is rarely possible in patients who develop this stereotyped extensor posturing in a variety of clinical settings—with midbrain compression due to a hemipidal mass; with cerebellar or other posterior fossa lesions; with certain mammillary bodies and pontine lesions; and profound insidious death with an acute lesion of one cerebral hemisphere may show a similar type of extensor posturing of the contralateral and sometimes ipsilateral limbs, and this may coexist with the ability to make purposeful movements of the same limbs. The extensor postures, unilateral or bilateral, may seemingly occur spontaneously, but more often they occur in response to manipulation of the limbs and all varieties of noxious stimuli. One characteristic is the extensor posturing of arm and leg on one side and flexion and abduction of the opposite arm. These reactions are analogous to the tonic reflexes described by Magnus in decerebrate animals.

In some patients with the foregoing postural changes the lesions are clearly in the cerebral white matter or basal ganglia, which is difficult to reconcile with the classic picture of decerebrate rigidity. The mechanism of decerebrate posturing presumably there is a functional derangement of structures in the midbrain in these cases due to brain swelling and distortion. Decerebrate posturing, either in experimental preparations or in humans, is usually not a persistent steady state but an intermittent and transient one. Hence the term decerebrate state is preferable to decerebrate rigidity, which implies a fixed, tonic extensor attitude (Feldman).

Decorticate rigidity, with arm or arms in flexion and adduction and leg(s) extended, signifies lesions at a higher level—in the cerebral white matter or internal capsule and thalamus. Bilateral decorticate rigidity is essentially a bilateral spastic hemiplegia. Diagonal postures, e.g., flexion of one arm and extension of the opposite arm and leg, usually indicate a supratentorial lesion. Forceful extensor postures of the arms and weak flexor responses of the legs are probably due to lesions at about the level of the vestibular nuclei. Lesions below this level lead to flaccidity and abolition of all postures and movements. The coma is then usually profound and often progresses to brain death.

Only in the most advanced degrees of intoxication and metabolic coma, as might occur with anoxic necrosis of neurons throughout the entire brain, are coughing, swallowing, hiccoughing, and spontaneous respiration all abolished. Further, the tendon and plantar reflexes may give little indication of what is happening. Tendon reflexes are usually preserved until the late stages of coma due to metabolic disturbances and intoxications. In coma due to a large cerebral infarct or hemorrhage, the tendon reflexes may be normal or only slightly reduced on the hemiplegic side and the plantar reflexes may be absent or extensor. Plantar flexor responses, exceeding extensor responses, signify either a return to normocay or, in the context of deepening coma, a transition to brain death.

Patterns of Breathing (see pages 579–580) A massive supratentorial lesion, bilateral deep-seated cerebral lesions, or metabolic disturbances of the brain give rise to a characteristic pattern of breathing, in which a period of waxing and waning hyperpnea regularly alternates with a shorter period of apnea (Cheyne-Stokes respiration). This type of breathing, first demonstrated by Nenon hoy Fe, remains characteristically disordered even in the decerebrate state, and is probably due to some intrinsic sympathetic instability, rather than to control from the respiratory center (hypoventilation drive). As a result of overbreathing, the blood CO₂ drops below the concentration required to stimulate the centers, and breathing gradually stops. Carbon dioxide then reaccumulates until it exceeds the respiratory threshold, and the cycle then repeats itself. Alternatively, CSR has been attributed to the stimulating effect of a low arterial P₅ on a depressed respiratory center. In either case, the presence of CSR signifies bilateral dysfunction of cerebral structures, usually those deep in the hemispheres or diencephalon, and is sensitive to the state of drowsiness or sleep. Coma with CSR is usually due to elevation of a severe metabolic derangement and occasionally to bilateral lesions, such as subdural hematomas. In itself, CSR is not a grave sign. It may occur during sleep in elderly individuals and can be a manifestation of cardiopulmonary disorders in awake patients. Only when it gives way to other abnormal respiratory patterns that involve the brainstem more directly is the patient in imminent danger.

A number of other abnormally breathing rhythms occur with brainstem lesions (reviewed in Chap. 26), but few are as specifically localizing as are abnormalities of the pupils and eye movements. The more conspicuous respiratory arhythmias are associated with brainstem lesions below the level of the reticular activating system and are therefore found in the late stages of brainstem compression or with large brainstem lesions such as infarction, primary hemorrhage, or infiltrating tumor.

Lesions of the lower midbrain–upper pontine tegmentum, either primary or secondary to a tentorial herniation, may give rise to central neurogenic hyperventilation (CNH). This disorder is characterized by an increase in the rate and depth of respiration to the extent that respiratory alkalosis results. CNH is thought to represent a release of the reflex mechanisms for respiratory control in the lower brainstem. It must be distinguished from hyperventilation caused by medical illnesses, particularly pneumonia and acidosis. Mild degrees of hyperventilation are common after a number of acute neurologic events, notably head injury. The neurologic basis of CNH is uncertain. It has been observed with tumors of the medulla, lower pons, and midbrain. However, Fisher, in a study of respiratory abnormalities in neurosurgical patients, found no consistent correlation between tachypnea and the site of the lesion. It is noteworthy that primary brain lymphoma and other mass lesions of the brainstem, e.g., flexion of one arm and extension of the opposite arm—just as they do in the alert patient. Severe metabolic derangement and occasionally to bilateral lesions, such as subdural hematomas. In itself, CSR is not a grave sign. It may occur during sleep in elderly individuals and can be a manifestation of cardiopulmonary disorders in awake patients. Only when it gives way to other abnormal respiratory patterns that involve the brainstem more directly is the patient in imminent danger.

A number of other abnormally breathing rhythms occur with brainstem lesions (reviewed in Chap. 26), but few are as specifically localizing as are abnormalities of the pupils and eye movements. The more conspicuous respiratory arhythmias are associated with brainstem lesions below the level of the reticular activating system and are therefore found in the late stages of brainstem compression or with large brainstem lesions such as infarction, primary hemorrhage, or infiltrating tumor.

Lesions of the lower midbrain–upper pontine tegmentum, either primary or secondary to a tentorial herniation, may give rise to central neurogenic hyperventilation (CNH). This disorder is characterized by an increase in the rate and depth of respiration to the extent that respiratory alkalosis results. CNH is thought to represent a release of the reflex mechanisms for respiratory control in the lower brainstem. It must be distinguished from hyperventilation caused by medical illnesses, particularly pneumonia and acidosis. Mild degrees of hyperventilation are common after a number of acute neurologic events, notably head injury. The neurologic basis of CNH is uncertain. It has been observed with tumors of the medulla, lower pons, and midbrain. However, North and Jenden, in a study of respiratory abnormalities in neurosurgical patients, found no consistent correlation between tachypnea and the site of the lesion. It is noteworthy that primary brain lymphoma without brainstem involvement has emerged as a common cause of CNH (Pauwet et al.).

Low pontine lesions, usually due to basilar artery occlusion, sometimes cause apneustic breathing (a pause of 2 to 3 s in full inspiration) or so-called short-cycle CSR, in which a few rapid deep breaths alternate with apneic cycles. With lesions of the dorsolateral part of the medulla, the rhythm of breathing is chaotic, being interrupted by periods of inspiration without appreciable expiration and each breath varying in rate and depth (Biot breathing). This has also been called “ataxia of breathing”—not an appropriate term. The latter progresses to intermittent prolonged inspiratory gasps and finally to apnea; in fact, respiratory arrest is the mode of death of most patients with serious central nervous system (CNS) disease.

Most probably all of these erratic breathing patterns are related in some manner; Webber and Speck have shown that apnea, Biot breathing, and gasping could be produced in the same animal with lesions in the dorsolateral pontine tegmentum by altering the depth of anesthesia. As has been pointed out by Fisher and by Plum and Posner, when certain supratentorial lesions progress to the point of terminal lobar and cerebral herniation, one may observe a succession of respiratory patterns (CSR-CNH-Biot breathing), indicating an extension of the functional disorder from upper to lower brainstem; but, again, such a sequence is seldom observed in clinical practice. Rapidly evolving lesions of the posterior fossa may cause acute apnea without any of the aforementioned abnormalities of breathing.

Signs of Increased Intracranial Pressure A history of headache before the onset of coma, recurrent vomiting, severe hypertension beyond the patient’s static level, and subhyaloid retinal hemorrhages are immediate clues to the presence of increased intracranial pressure, usually from one of the types of cerebral hemorrhage. Papilledema develops within 12 to 24 h in cases of brain trauma and hemorrhage, but if it is pronounced, it usually signifies brain tumor or abscess—i.e., a lesion of
longer duration. Increased intracranial pressure produces coma by impeding global cerebral blood flow; however, this occurs only at extremely high levels of pressure. High pressure within one compartment, produce shifts of central structures and a series of "false localizing" signs, due to lateral displacements and herniations, as previously discussed.

The syndrome of acute hydrocephalus, most often from subarachnoid hemorrhage or from rapid obstruction of the ventricular system by a tumor in the posterior fossa, induces a state of abulia (page 633), followed by stupor and then coma with bilateral Babinski signs, small pupils and increased tone in the legs, as well as the systemic features of raised intracranial pressure, noted above. This subject is discussed further in Chap. 30.

**Laboratory Procedures**

Unless the diagnosis is established at once by history and physical examination, it is necessary to carry out a number of laboratory procedures. In patients with evidence of a cerebral mass or acute hydrocephalus, as evidenced by signs of raised intracranial pressure or indications of brain displacements (asymmetry of limb movements, papillary enlargement), a CT scan or MRI should be obtained as a primary procedure. As discussed in Chap. 2, lumbar puncture, although carrying a certain small risk of promoting further herniation, is nevertheless necessary in some instances to exclude bacterial meningitis or encephalitis. If poisoning is suspected, aspiration and analysis of the gastric contents is sometimes helpful, but greater reliance should be placed on chromatographic analysis of the blood and urine. Accurate means are available for measuring the blood concentrations of phenytoin and other anticonvulsants, opiates, diazepines, barbiturates, alcohol, and a wide range of other toxic substances. A specimen of urine is obtained by catheter for determination of specific gravity and for glucose, acetone, and protein content. Proteinuria may also be found for 2 or 3 days after a subarachnoid hemorrhage or with fever. Urine of high specific gravity, glycosuria, and acetonuria occur almost invariably in diabetic coma; but transient glycosuria and hyperglycemia may result from a massive cerebral lesion. Blood counts should be obtained, and in malarial districts a blood smear is examined for parasites. Neutrophilic leukocytosis occurs in bacterial infections and also with brain hemorrhage and infarction, although the elevation of leukocytes in the latter conditions rarely exceeds 12,000/mm³. Venous blood should be examined for glucose, urea, carbon dioxide, bicarbonate, ammonium, sodium, potassium, chloride, calcium, and SGOT (serum glutamic oxaloacetic transaminase) and analysis of blood gases should be obtained in appropriate cases.

It should be kept in mind that disorders of water and sodium balance, reflected in hyper- or hyponatremia, may be the result of cerebral disease (excess ADH secretion, diabetes insipidus, atrial natriuretic factor release), as well as the cause of coma.

**Classification of Coma and Differential Diagnosis (Table 17-2)**

The demonstration of focal brain disease or of meningeal irritation with abnormalities of the CSF is of particular help in the differential diagnosis of coma and serves to divide the diseases that cause coma into three classes, as follows:

I. Diseases that cause no focal or lateralizing neurologic signs, usually with normal brainstem functions. CT scan and cellular content of the CSF are normal.

A. Intoxications: alcohol, barbiturates and other sedative drugs, opiates, etc. (Chap. 42 and Chap. 43).
B. Metabolic disturbances: anoxia, diabetic acidosis, uremia, hepatic failure, nonketotic hyperosmolar hyperglycemia, hypo- and hypernatremia, hypoglycemia, Addisonian crisis, profound nutritional deficiency, thyroid states (Chap. 40 and Chap. 41).
C. Severe systemic infections: pneumonia, peritonitis, typhoid fever, malaria, septicemia, Waterhouse-Friderichsen syndrome.
D. Circulatory collapse (shock) from any cause.
E. Postseizure states and convulsive and non-convulsive status epilepticus (Chap. 16).
F. Hypertensive encephalopathy and eclampsia (Chap. 34).
G. Hyperthermia and hypothermia.
H. Concussion (Chap. 35).
I. Acute hydrocephalus (Chap. 30).
J. Late stages of certain degenerative diseases and Creutzfeldt-Jakob disease.

II. Diseases that cause meningeal irritation with or without fever, and with an excess of WBCs or RBCs in the CSF, usually without focal or lateralizing cerebral or brainstem signs. CT scanning or MRI, (which preferably should precede lumbar puncture) may be normal or abnormal.

A. Subarachnoid hemorrhage from ruptured aneurysm, arteriovenous malformation, or following a seizure. In hypertensive encephalopathy, focal signs may reassert itself in the course of uremic or hepatic coma with hypotension, hypoglycemia, diabetic acidosis, or following a seizure. In hypertensive encephalopathy, focal signs may reassert itself in the course of uremic or hepatic coma with hypotension, hypoglycemia, diabetic acidosis, or following a seizure.
B. Acute bacterial meningitis (Chap. 32).
C. Some forms of viral encephalitis (Chap. 33).
D. Neoplastic and parasitic meningiides.

III. Diseases that cause focal brainstem or lateralizing cerebral signs, with or without changes in the CSF. CT scanning and MRI are usually abnormal.

A. Hemispheral hemorrhage or massive infarction (Chap. 34).
B. Brainstem infarction due to basilar artery thrombosis or embolism (Chap. 34).
C. Brain abscess, subdural empyema (Chap. 32).
D. Epidural and subdural hemorrhage and brain contusion (Chap. 35).
E. Brain tumor (Chap. 31).
F. Cerebellar and pontine hemorrhage.
G. Miscellaneous: cortical vein thrombosis, some forms of viral encephalitis (herpes), focal embolic infarction due to bacterial endocarditis, acute hemorrhagic leukoencephalitis, disseminated (postinfectious) encephalomyelitis, intravascular lymphoma, thrombotic thrombocytopenic purpura, diffuse fat embolism, and others.

Using the clinical criteria outlined above, one can usually ascertain whether a given case of coma falls into one of these three categories. Concerning the group without focal or lateralizing or meningeal signs (which includes most of the metabolic encephalopathies, intoxications, concussion, and postseizure states), it must be kept in mind that residual from previous neurologic disease may confuse the clinical picture. Thus, an earlier hemiparesis from vascular disease or trauma may reassert itself in the course of uremic or hepatic coma with hypotension, hypoglycemia, diabetic acidosis, or following a seizure. In hypertensive encephalopathy, focal signs may also be present. Occasionally, for no understandable reason, one leg may seem to move less, one plantar reflex may be extensor, or seizures may be predominantly or entirely unilateral in a metabolic coma, particularly in the hyperglycemic–hyperosmolar state. Babinski signs and extensor rigidity, conventionally considered to be indicators of structural disease, do occur in profound intoxications with a number of agents.

The diagnosis of concussion or of postictal coma depends on observation of the precipitating event or indirect evidence thereof. Often a convulsive seizure is marked by a bitten tongue, urinary incontinence, and an elevated CK-skeletal muscle fraction and may be followed by another seizure or burst of seizures. The presence of small conscious movements of a hand or foot or fluttering of the eyelids requires that an EEG be performed to determine whether status epilepticus is the cause of coma.
especially in known epileptics (Table 17-2).

With respect to the second group in the above classification, the signs of meningeal irritation (head retraction, stiffness of neck on forward bending, Kernig and Brudzinski signs) can usually be elicited in both bacterial meningitis and subarachnoid hemorrhage. However, in infants and in adults, if the coma is profound, stiff neck may be absent. In such cases the spinal fluid has to be examined in order to establish the diagnosis. In most cases of bacterial meningitis, the CSF pressure is not exceptionally high (usually less than 400 mmH$_2$O). However, in cases associated with brain swelling, the CSF pressure is greatly elevated; the pupils become fixed and dilated, and there may be signs of compression of the brainstem with arrest of respiration. Patients in coma from ruptured aneurysms also have high CSF pressure; the CSF is overtly bloody and the blood is invariably visible in the CT scan throughout the basal cisterns and ventricles if the bleeding has been severe enough to cause coma.

In the third group of patients, it is the facility of sensorimotor signs and the abnormal pupillary and ocular reflexes, postural states, and breathing patterns that provide the clues to serious structural lesions in the cerebral hemispheres and their effects upon segmental brainstem functions. As the brainstem effects become prominent, they may obscure earlier signs of cerebral disease.

It is worth emphasizing once more that hepatic, hypoglycemic, hyperglycemic, and hypoxic coma sometimes resemble coma due to brainstem lesions by causing asymmetrical motor signs, focal seizures, and decerebrate postures and that deep coma from drug intoxication may obliterate reflex eye movements. Also, certain structural lesions of the cerebral hemispheres are so diffuse as to produce a picture that simulates a metabolic disturbance: thrombotic thrombocytopenic purpura (TTP), fat embolism, and the late effects of global ischemia-anoxia are examples of such states. At other times they cause a diffuse encephalopathy with superimposed focal signs. Unilateral infarction due to anterior, middle, or posterior cerebral artery occlusion produces no more than drowsiness, as a rule; however, with massive unilateral infarction due to carotid artery occlusion, coma can occur if extensive brain edema and secondary tissue shift are associated. Edema of this degree seldom develops before 12 or 24 h. Rapidly evolving hydrocephalus causes smallness of the pupils, rapid respiration, extensor rigidity of the legs, Babinski signs, and sometimes a loss of eye movements.

Finally, it should be restated that diagnosis has as its prime purpose the direction of therapy. The treatable causes of coma are: drug and alcohol intoxications, shock due to infection, cardiac failure, or systemic bleeding, epidural and subdural hematomas, brain abscess, bacterial and fungal meningitis, diabetic acidosis or hyperosmolar state, hypoglycemia, hypo- or hypernatremia, hepatic coma, uremia, status epilepticus, and hypertensive encephalopathy. Also treatable to a varying degree are uremia; putaminal and cerebellar hemorrhages, which can sometimes be evacuated successfully; edema from massive stroke, which may be ameliorated by hemicraniectomy; and hydrocephalus from any cause, which may respond to ventricular drainage.

### Management of the Acutely Comatose Patient

Seriously impaired states of consciousness, regardless of their cause, are often fatal not only because they represent an advanced stage of many diseases but also because they add their own particular burdens to the primary disease. The physician's main objective, of course, is to find the cause of the coma and to treat it appropriately. It often happens, however, that the disease process is one for which there is no specific therapy; or, as in hypoxia or hypoglycemia, the acute, irreversible effects already have occurred before the patient comes to the attention of the physician. Again, the problem may be highly complex, for the disturbance may be attributable not to a single cause but to several factors acting in unison, no one of which could account for the total clinical picture. In lieu of specific therapy, supportive measures must be used; indeed, the patient's chances of surviving the original disease often depend on the effectiveness of these measures.

The successful management of the insensate patient requires the services of a well-coordinated team of nurses under the close guidance of a physician. Necessary treatment must be instituted immediately, even before all the diagnostic steps have been completed; diagnosis and treatment may have to proceed concurrently. The following is a brief outline of the principles involved in the treatment of such patients. The details of management of shock, fluid and electrolyte imbalance, and other complications that threaten the comatose patient (pneumonia, urinary tract infections, deep venous thrombosis, etc.) are found in Harrison's Principles of Internal Medicine.

1. The management of shock, if present, takes precedence over all other diagnostic and therapeutic measures.
2. Shallow and irregular respirations, stertorous breathing (indicating obstruction to inspiration), and cyanosis require the establishment of a clear airway and delivery of oxygen. The patient should initially be placed in a lateral position so that secretions and vomitus do not enter the tracheobronchial tree. Secretions should be removed by suctioning as soon as they accumulate; otherwise, they will lead to atelectasis and bronchopneumonia. Arterial blood gases should be measured and further observed by monitoring of oxygen saturation. A patient's inability to protect against aspiration and the presence of either hypoxia or hypoventilation dictates the use of endotracheal intubation and a positive-pressure respirator.
3. Concomitantly, an intravenous line is established and blood samples are drawn for determination of glucose, drugs, and electrolytes and for tests of liver and kidney function. Naloxone, 0.5 mg, should be given intravenously if a narcotic overdose is a possibility. Hypoglycemia that has produced stupor or coma demands the infusion of glucose, usually 25 to 50 mL of a 50% solution followed by a 5% infusion; this must be supplemented with thiamine. A urine sample is obtained for drug and glucose testing.
4. With the development of elevated intracranial pressure from a mass lesion, mannitol, 25 to 50 g in a 20% solution, should be given intravenously over 10 to 20 min and hyperventilation instituted if deterioration occurs, as judged by pupillary enlargement or deepening coma. Repeated CT scanning allows the physician to follow the size of the lesion and degree of localized edema and to detect displacements of cerebral tissue. With massive cerebral lesions, it may be appropriate to place a pressure-measuring device in the cranium of selected patients (see Chap. 35 for details of intracranial pressure monitoring and treatment).
5. A lumbar puncture should be performed if meningitis or subarachnoid hemorrhage is suspected, keeping in mind the risks of this procedure and the means of dealing with them. A CT scan may have disclosed a primary subarachnoid hemorrhage, in which case lumbar puncture is not necessary.
6. Convulsions should be controlled by measures outlined in Chap. 16.
7. As indicated above, gastric aspiration and lavage with normal saline may be diagnostically and therapeutically useful in some instances of coma due to drug ingestion. Salicylates, opioids, and antihistaminic drugs (tricyclic antidepressants, phenothiazines, scopolamine), all of which induce gastric atony, may be recovered many hours after ingestion. Caustic materials should not be lavaged because of the danger of gastrointestinal perforation. The administration of activated charcoal is indicated in certain drug poisonings. Measures to prevent gastric hemorrhage and excessive gastric acid secretion are usually advisable.
8. The temperature-regulating mechanisms may be disturbed, and extreme hypothermia, hyperthermia, or poikilothermia should be corrected. In severe hyperthermia, evaporative-cooling measures are indicated in addition to antipyretics.
9. The bladder should not be permitted to become distended; if the patient does not void, decompression should be carried out with an indwelling catheter. Needless to say, the patient should not be permitted to lie in a wet or soiled bed.
10. Diseases of the CNS may disrupt the control of water, glucose, and sodium. The unconscious patient can no longer adjust the intake of food and fluids by hunger and thirst. Both salt-losing and salt-retaining syndromes have been described with brain disease (see Chap. 27). Water intoxication and severe hyponatremia may of themselves prove damaging. If coma is prolonged, the insertion of a nasogastric tube will ease the problems of feeding the patient and maintaining fluid and electrolyte balance. It is quite acceptable to leave the tube in place for long periods. Otherwise, approximately 35 mL/kg of isotonic fluid should be administered per 24 h (5% dextrose in 0.45% saline with potassium supplementation unless there is brain edema, in which case the use of isotonic normal saline is indicated).
11. Aspiration pneumonia is avoided by prevention of vomiting (gastric tube and endotracheal intubation), proper positioning of the patient, and restriction of oral fluids. Should aspiration pneumonia occur, it requires treatment with appropriate antibiotics, and aggressive pulmonary physical therapy.
12. Leg vein thrombosis—a common occurrence in comatose and hemiplegic patients—often does not manifest itself by obvious clinical signs. An attempt may be made to prevent it by the subcutaneous administration of heparin, 5000 units q 12 h, and by the use of intermittent pneumatic compression boots.
13. If the patient is capable of moving, suitable restraints should be used to prevent falling out of bed and self-injury from convulsions.

14. Regular conjunctival lubrication and oral cleansing should be instituted.

**Prognosis of Coma (See also page 1179)**

As a general rule, recovery from coma of metabolic and toxic causes is far better than from anoxic coma, with head injury occupying an intermediate prognostic position. Most comatose stroke patients die. If there are no pupillary, corneal, or oculovestibular responses within several hours of the onset of coma, the chances of regaining independent function are practically nil (see Levy et al). Other signs that predict a poor outcome are absence of corneal reflexes and eye-opening responses and atonia of the limbs at 1 and 3 days after the onset of coma and absence of the cortical component of the somatosensory evoked responses on both sides. It is the unfortunate survivor from this latter group who may remain in a vegetative state for months or years, breathing without aid and with preserved hypothalamic-pituitary functions. The frequency of this persistent vegetative state after head injury and the negligible chances of improvement if the condition persists for several weeks have already been discussed (page 370).

MAGNUS R: Some results of studies in the physiology of posture. Lancet 2:531, 585, 1926.

The term syncope (Greek, syncope) literally means a “cessation,” a “cutting short” or “pause.” Medically, it refers to an episodic loss of consciousness and postural tone and an inability to stand, due to a diminished flow of blood to the brain. It is synonymous in everyday language with fainting. Feeling faint and a feeling of faintness are also commonly used terms to describe the sudden loss of strength and other symptoms that characterize the impending or incomplete fainting spell. This latter state is referred to as presyncope. Relatively abrupt onset, brief duration, and spontaneous and complete recovery not requiring specific resuscitative measures are other distinguishing features.

Faintness and syncope are among the most common of all medical phenomena. Practically every adult has experienced some presyncopal symptoms if not a fully developed syncope or attack or has observed such attacks in others. Description of these symptoms, as with other predominantly subjective states, is often ambiguous. The patient may refer to the experience as light-headedness, giddiness, dizziness, a “drunk feeling,” a weak spell, or, if consciousness was lost, a “blackout.” Careful questioning may be necessary to ascertain the exact meaning of these words. In many instances the nature of the symptoms is clarified by the fact that they include a sensation of faintness and then a momentary loss of consciousness, which is easily recognized as a faint, or syncope. This sequence also informs us that under certain conditions any difference between faintness and syncope is only one of degree. These symptoms must be clearly set apart from certain types of epilepsy, the other major cause of episodic unconsciousness, and disorders such as cataplexy, transient ischemic attacks, “drop attacks,” and vertigo, which are also characterized by episodic attacks of generalized weakness or inability to stand upright but not by a loss of consciousness.

CLINICAL FEATURES OF SYNCOPE

The clinical manifestations of fainting attacks vary to some extent, depending on their mechanisms and the settings in which they occur.

The commonest type of faint—namely, vasodepressor or vasovagal syncope, defined more precisely further on—confers more or less to the following pattern. The patient is usually in the upright position at the beginning of the attack, either sitting or standing. Certain subjective symptoms, the prodrome, mark the onset of the faint. The person feels queasy, is assailed by a sense of giddiness and dyspnea, may sway, and sometimes develops a headache. What is most noticeable at the beginning of the attack is pallor or an ash-gray color of the face; often the face and body become bathed in cold perspiration. Salivation, epigastric distress, nausea, and sometimes vomiting accompany these symptoms, and the patient tries to suppress them by yawning, sighing, or breathing deeply. Vision may dim or close in concentrically, the ears may ring, and it may be impossible to think clearly (“gray-out”).

The duration of the prodromal symptoms is variable, from a few minutes to only a few seconds, but it is doubtful that consciousness is ever abolished as abruptly as with a seizure. If, during the prodromal period, the person is able to lie down promptly, the attack can be averted before complete loss of consciousness occurs; otherwise, consciousness is lost and the patient falls to the ground. The more or less deliberate onset of this type of syncope enables patients to lie down or at least to protect themselves as they slump. A hurtful fall is exceptional in the young, though an elderly person may be injured.

The depth and duration of unconsciousness vary. Sometimes the person is not completely oblivious to his surroundings; he may still hear voices or see the blurred outlines of people. More often there is a complete lack of awareness and responsiveness. The patient lies motionless, with skeletal muscles fully relaxed. Sphincteric control is maintained in nearly all cases. The pupils are dilated. The pulse is thin and slow or cannot be felt; the systolic blood pressure is reduced (to 60 mmHg or less), and breathing is almost imperceptible. The depressed vital functions, striking facial pallor, and unconsciousness simulate death.

Once the patient is horizontal, the flow of blood to the brain is no longer hindered. The strength of the pulse soon improves and color begins to return to the face. Breathing becomes quicker and deeper. Then the eyelids flutter and consciousness is quickly regained. However, should unconsciousness persist for 15 to 20 s, convulsive movements may occur (convulsive syncope). These movements, which are often mistaken for a seizure, usually take the form of brief, mild, clonic jerks of the limbs and trunk and twitches of the face or a tonic extension of the trunk and clenching of the jaw. Occasionally the extensor rigidity and jerking flexor movements are more severe, but very rarely is there urinary incontinence or biting of the tongue, features that characterize a generalized tonic-clonic convolution.

From the moment that consciousness is regained, there is a correct perception of the environment. Confusion, headache, and drowsiness, the common sequelae of a convulsive seizure, do not follow a syncope attack. Nevertheless, the patient often feels weak and groggy after a vasodepressor faint and, by arising too soon, may precipitate another faint.

The clinical features of cardiac and carotid sinus syncope are much the same as those described above except that the onset of these forms of syncope may be absolutely abrupt, without any warning symptoms, and is much less dependent upon the patient being in an upright posture. The clinical particularities of these and other forms of syncope are described further on.

CAUSES OF EPISODIC FAINTNESS AND SYNCOPE

From a clinical and pathophysiologic perspective, syncope is essentially of three main types, each of which may lead to a temporary reduction in the flow of blood to the brain:

1. Sudden loss of vascular sympathetic tone (vasodepressor effect), often associated with excessive vagal effect and bradycardia (vasovagal effect) triggered by the centrally mediated inhibition of the normal tonic sympathetic influences. These are referred to as the neurogenic or neurocardiogenic syncope.

2. A failure of sympathetic innervation of blood vessels and of autonomically activated compensatory responses (reflex tachycardia and vasocostriction), which occurs with assumption of the upright body position and leads to pooling of blood in the lower parts of the body—causing orthostatic hypotension and syncope. Typically, in individuals with these first two forms of syncope, there is no evidence of underlying cardiac disease.

3. A diminished cardiac output due to disease of the heart itself (as in the Stokes-Adams attack); or to greatly reduced blood volume from dehydration or blood loss.

The three main types of syncope and several other types that cannot readily be included within these categories can be further subdivided as follows:

1. Neurogenic vasodepressor reactions
   A. Elicited by extrinsic signals to the medulla from baroreceptors
      1. Vasodepressor (vasovagal)
      2. Neurocardiogenic

Carotid sinus hypersensitivity
Vagoglossopharyngeal
Coupled with diminished venous return to the heart
1. Micturitional
2. Tussive
3. Valsalva, straining, breath holding, weight lifting
4. Postprandial
Intense psychic stimuli
1. Fear, anxiety (presyncope more common)
2. Sight of blood
3. Hysterical

II. Failure of sympathetic nervous system innervation (postural-orthostatic hypotension)
Peripheral nervous system autonomic failure
1. Diabetes
2. Paraplegia
3. Guillain-Barré syndrome
4. Amyloid neuropathy
5. Surgical sympathectomy
6. Antihypertensive medications and other blockers of vascular innervation

Central nervous system autonomic failure
1. Primary autonomic failure (idiopathic orthostatic hypotension)
2. Multiple system atrophy (parkinsonism, ataxia, orthostatic hypotension)
3. Spinal cord trauma, infarction, and necrosis
4. Centrally acting antihypertensive and other medications

III. Reduced cardiac output or inadequate intravascular volume (hypovolemia)
Reduced cardiac output
1. Cardiac arrhythmias
   a. Atrioventricular (AV) block (second and third degree) with Stokes-Adams attacks
   b. Ventricular asystole
   c. Sinus bradycardia, sinoatrial block, sinus arrest, sick-sinus syndrome
   d. Tachyarrhythmias
      a. Episodes of atrial fibrillation
      b. Supraventricular tachycardia (infrequently causes syncope)
2. Myocardial: infarction or severe congestive heart failure
3. Obstruction to left ventricular outflow: aortic stenosis, hypertrophic subaortic stenosis
4. Obstruction to pulmonary flow: pulmonic stenosis, tetralogy of Fallot, primary pulmonary hypertension, pulmonary embolism
5. Pericardial tamponade

Inadequate intravascular volume (hemorrhage); dehydration
A. Hypoxia
B. Anemia
C. Diminished CO₂ due to hyperventilation (faintness common, syncope rare)
D. Hypoglycemia (faintness frequent, syncope rare)
E. Anxiety (panic) attacks
F. Environmental overheating

This list of conditions causing faintness and syncope is deceptively long and involved. It will be recognized that the usual types are reducible to a few well-established mechanisms, all resulting in a temporary reduction of blood flow to the brain. In order not to obscure these mechanisms by too many details, only the varieties of fainting commonly encountered in clinical practice or those of particular neurologic interest are discussed below.

Neurogenic Syncope
This term refers to all forms of syncope that result directly from the vascular effects of neural signals coming from the central nervous system, primarily the nucleus tractus solitarius. A number of stimuli, mostly from the viscera but some of psychologic origin, are capable of eliciting this response, which consists of a reduction or loss of sympathetic vascular tone coupled with a heightened vagal activity. The nucleus tractus solitarius (NTS) in the medulla integrates these afferent stimuli and normal baroreceptor signals with the efferent sympathetic mechanisms that maintain vascular tone (see further on and Chap. 26). By the use of microneurography, Wallin and Sundlöf have demonstrated that sympathetic outflow in peripheral nerves is greatly increased just prior to syncope, but at the onset of fainting sympathetic activity ceases. This signifies that there is an initial attempt to compensate for falling blood pressure by enhanced sympathetic tone, following which there is a centrally mediated withdrawal of sympathetic activity that results in fainting

It has been suggested, on the basis of reasonable but not conclusive physiologic evidence, that the early sympathotonic attempt to maintain blood pressure leads to overly vigorous contractions of the cardiac chambers, and this, in turn, acts as the afferent stimulus for withdrawal of sympathetic tone (see "Neurocardiogenic Syncope," below). It is also possible that the initial adrenergic discharge that precedes syncope causes a vasodilation in muscular blood vessels and initiates hypotension. The vasodilating effects of nitric oxide on vascular endothelium and the greatly augmented levels of circulating acetylcholine in syncope have also been involved as factors in the vasodepressor phenomenon.

In essence all the following types of syncope are "vasovagal," meaning a combination of vasodepressor and vagal effects in varying proportions; the only differences are in the stimuli that elicit the response from the medulla.

Vasodepressor Syncope
This is the common faint, fully described above and seen mainly in young individuals. A familial proclivity is known (Mathias et al.). The evocative factors are usually strong emotion, physical injury—particularly to viscera (testicles, gut)—or other factors (see below). As described above, the vasodilatation of adrenergically innervated "resistance vessels" leads to a reduction in peripheral vascular resistance, but cardiac output fails to exhibit the compensatory rise that normally occurs in hypotension. Some physiologic studies suggest that the dilatation of intramuscular vessels, innervated by beta-adrenergic fibers, may be more important than dilatation of the splanchic ones. Skin vessels are constricted. Vagal stimulation may then occur (hence the term vasovagal), causing bradycardia and leading possibly to a slight further drop in blood pressure. Other vagal effects are perspiration, increased peristaltic activity, nausea, and salivation.

As already mentioned, bradycardia probably contributes little to the hypotension and syncope. The term vasovagal, used originally by Thomas Lewis to designate this type of faint, is therefore not entirely apt and should be avoided as a synonym for vasodepressor syncope. As Lewis himself pointed out, atropine, "while raising the pulse rate up to and beyond normal levels during the attack, leaves the blood pressure below normal and the patient still pale and not fully conscious."

In summary, the vasodepressor faint occurs (1) in normal health under the influence of strong emotion, particularly in some susceptible individuals (sight of blood or an accident) or in conditions that favor peripheral vasodilation, e.g., hot, crowded rooms ("heat syncope"), especially if the person is hungry or tired or has had a few alcoholic drinks, or (2) during a painful illness or after bodily injury (especially of the abdomen or genitalia), as a consequence of fright, pain, and other factors (where pain is involved, the vagal element tends to be more prominent in the genesis of the faint), and (3) during exercise in some sensitive persons (see further on).

Neurocardiogenic Syncope
This entity, a component or perhaps a subtype of vasodepressor syncope, has received attention as a cause of otherwise unexplained fainting in children and young adults. As alluded to above, it may be the final precipitant in the common vasodepressor faint, and the term is used synonymously with vasovagal or vasodepressor syncope by some authors (Kosinski et al.).

Obérg and Thoren were the first to observe that the left ventricle itself can be the source of neurally mediated syncope in much the same way as the carotid sinus,
when stimulated, produces vasodilation and bradycardia. During acute blood loss in cats, they noted a paradoxical bradycardia that was preceded by increased afferent activity in autonomic fibers arising from the ventricles of the heart, a reaction that could be eliminated by sectioning these nerves. This concept of the heart as the source of vasoreactive reflexes had been suggested earlier by Bezold as well as by Jarisch and Zoterman and came to be known as the “Bezold-Jarisch reflex.” The interposition wall of the left ventricle is the site of most of the subendocardial mechanoreceptors that are responsible for the afferent impulses.

In order for this mechanism to become active, very vigorous cardiac contractions must occur in the presence of deficient filling of the cardiac chambers (hence “neurocardiogenic”). In the simple faint, an initial burst of sympathetic activity is thought to precipitate these physiologic circumstances of excessive cardiac activity. Echocardiographic findings of a greatly diminished ventricular chamber size and vigorous contractions just prior to syncope support this notion (the “empty heart syndrome”). However, the ability to induce a similar neurally mediated syncope in cardiac transplantation patients, whose hearts are denervated, leads one to question this concept. Perhaps the remaining baroreceptors in the aorta are responsible in this instance.

According to Kaufmann, patients with a proclivity to primary neurocardiogenic syncope can be identified by the finding of delayed fainting when the patient is placed at a 60-degree upright position on a tilt table. After approximately 10 min of upright posture, the blood pressure drops below 100 mm Hg; soon thereafter patients complain of dizziness and sweating, and subsequently faint. In contrast, patients with primary sympathetic failure will faint soon after upward tilting. Half of patients with unexplained syncope display this delayed tilt-table reaction, but it is seen also in 5 percent of controls (see page 401). The value of isoproterenol as a cardiac stimulant and peripheral vasodilator to enhance the effect of upright posture and expose neurocardiogenic syncope during the tilt-testable contrast is controversial (see further on).

Exercise-Induced Syncope Aerobic exercise, particularly running, is known to induce fainting in some persons, a trait that may become apparent in late childhood or later and may be familial. There is nausea as well as other presyncopal symptoms, and the faint can be avoided by discontinuing exercise or not exceeding a threshold effort set by the patient himself. Such persons do not seem unduly sensitive to nonaerobic exercise and have no recognizable electrocardiographic (ECG) or structural heart problems. They have a predilection to faint with prolonged tilt-table testing and with isoproterenol infusion, suggesting an excessive muscular vasodilatory response, as described above with neurocardiogenic syncope. These patients may benefit from beta-adrenergic blocking drugs if given under careful supervision. As discussed further on, exercise can also precipitate syncope in patients with a number of underlying cardiac conditions (myocardial ischemia, prolonged–GT interval syndrome, aortic outflow obstruction, cardiomyopathy, structural chamber anomalies, exercise-induced ventricular tachycardia, and, less often, supraventricular tachycardias).

Athletes who faint unpredictably during exercise pose a particularly difficult problem. Obviously those found to have serious heart disease should give up competitive sports, but the majority have no demonstrable cardiac abnormality. Subjecting these patients to intense exercise and other testing sometimes fails to elicit the faints, but often the symptoms are reproduced by forced head-up tilt, again suggesting the possibility of neurocardiogenic syncope (see above). Standard pacemakers are not curative in these vasodepressor fants, since the main deficiency is in vascular resistance. Unless the results of tilt testing are unequivocal and reproducible, it is best to consider the more serious causes of exercise-induced syncope and to treat the patient appropriately.

Carotid Sinus Syncope The carotid sinus is normally sensitive to stretch and gives rise to sensory impulses carried via the nerve of Hering, a branch of the glossopharyngeal nerve, to the medulla. Massage of one of the carotid sinuses or of both of them alternately, particularly in elderly persons, causes (1) a reflex cardiac slowing (sinus bradycardia, sinus arrest, or even atrioventricular block)—the vagal type of response, or (2) a fall of arterial pressure without cardiac slowing—the vasodepressor type of response. Another (“central”) type of carotid sinus syncope was in the past ascribed to cerebral arterioconstriction but such an entity has never been validated.

Faintness or syncope due to carotid sinus sensitivity has reportedly been initiated by turning of the head to one side while wearing a tight collar or even by shaving over the region of the sinus. However, the absence of a history of such an association does not exclude the diagnosis. The attack nearly always occurs when the patient is upright, usually standing. The onset is sudden, with falling. Small convulsive movements occur quite frequently in both the vagal and vasodepressor types of carotid sinus syncope. The period of unconsciousness in carotid sinus syncope seldom lasts longer than 30 s, and the sensorium is immediately clear when consciousness is regained. The majority of the reported cases have involved men.

As intimated above, in a patient displaying faintness on massage of one carotid sinus, it is important to distinguish between the benign disorder (hypersensitivity of the carotid sinus) and a more serious condition—atheromatous narrowing of the basilar or opposite carotid artery (see Chap. 34). In testing for carotid sinus sensitivity in the latter circumstance, it is important to avoid compression of the carotid artery, which may major the vascular supply to both hemispheres; testing should be avoided altogether if a carotid bruit is heard in either vessel.

A number of other types of purely reflexive cardiac slowing can be traced to direct irritation of the vagus nerves (from esophageal diverticula, mediastinal tumors, gallbladder stones, carotid sinus disease, bronchospasm, and needling of body cavities). Here, the reflex bradycardia is more often of sinoaortial than atrioventricular type. Weiss and Ferris called such faints vagovalgal.

Gastaut and Fischer-Williams used the oculocardiac inhibitory reflex to study this form of syncope. They found that the heightened vagal discharge produced by compression of the eyeballs (orofovagal reflex) could produce brief periods of cardiac arrest and syncope. This effect was produced in 20 of 100 patients who had a history of syncope attacks, mainly of the vasodepressor type. These investigators found that after a 7- to 13-s period of cardiac arrest, there was a loss of consciousness, pallor, and muscle relaxation. Toward the end of this period, runs of bilaterally synchronous theta and delta waves appeared in the EEG, predominantly in the frontal lobes; in some patients there were one or more myoclonic jerks, synchronous with the slow waves. If the cardiac arrest persisted for 14 or 15 s, the EEG became flat. This period of electrical silence lasted for 10 to 20 s and was sometimes accompanied by a generalized tonic spasm with incontinence. Following the spasm, heartbeats and large-amplitude delta waves reappeared, and after another 20 to 30 s, the EEG reverted to normal. It is noteworthy that rhythmic clonic seizures or epileptiform EEG activity were not observed at any time during the periods of cardiac arrest, syncope, and tonic spasm.

Tumors or lymph node enlargements at the base of the skull or in the neck which impinge on the carotid artery, as well as post radiation fibrosis are capable of causing dramatic syncope attacks, sometimes preceded by unilateral head or neck pain. Often the episodes are unpredictable, but some patients find that turning the head stimulates an attack. The mechanism in our experience has been primarily a vasodepressor response; patients with prominent bradycardia have generally had tumors that impinged directly on the glossopharyngeal and vagus nerves (Frank et al; Macdonald et al). If the tumor can be safely removed from the carotid region, the syncope often abates; in many cases, however, intracranial section of the ninth and upper rootlets of the vagus nerves on the side of the mass is necessary. The syncope in Association with Glossopharyngeal Neuralgia Glossopharyngeal neuralgia (also referred to as vagoglossopharyngeal neuralgia) (page 1456) typically begins in the sixth decade with paroxysms of pain localized to the base of the tongue, pharynx or larynx, tonsillar area, or an ear. In only a small proportion of cases (estimated at 2 percent) are the paroxysms of pain complicated by syncope. Always, the sequence is pain, then bradycardia, and finally syncope. Presumably the pain provokes a massive volley of afferent impulses along the glossopharyngeal nerve, activating the medullary vasoconstrictor centers via collateral fibers from the spinal tract of the trigeminal nerve. An increase in parasympathetic (vagal) activity slows the heart. Wallin and colleagues have demonstrated that, in addition to bradycardia, there is an element of hypotension, due to inhibition of peripheral sympathetic activity. The effects of the bradycardia greatly exceed those of the vasodepressor hypotension, sometimes to the point of asystole, thus differing from the related condition of carotid sinus syncope and from most other types of syncope.

The medical treatment of this type of syncope parallels that of trigeminal neuralgia (which is associated in approximately 10 percent of cases, usually on the same side). Anticonvulsants and baclofen are helpful in some patients. Vascular decompression procedures involving small branches of the basilar artery that impinge on the ninth nerve are said to be useful, but such patients but have not been extensively studied. Conventional surgical treatment, which consists of sectioning the ninth cranial nerve and upper rootlets of the tenth, has proved to be effective.

The same mechanism is probably operative in so-called deglutitional syncope, in which consciousness is lost during or immediately after a forceful swallow. The administration of anticholinergic drugs (propantheline 15 mg tid) has abolished these attacks (Levin and Posner).

Micturition Syncope This condition is usually seen in men, sometimes in young adults but more often in the elderly, who arise from bed at night to urinate. The syncope occurs at the end of micturition or soon thereafter, and the loss of consciousness is abrupt, with rapid and complete recovery. Several factors are probably operative. A full bladder causes reflex bradycardia and, in some cases, a mild Valsalva effect may also be factors, and alcohol ingestion, hunger, fatigue, and upper respiratory infection are common predisposing factors. In some instances, especially in the elderly, the nocturnal
collapse has caused serious head injury.

**Tussive and Valsalva Syncope**

Syncope as a result of a severe paroxysm of coughing was first described by Charcot in 1876. Patients with this type of syncope are usually heavy-set males who smoke and have chronic bronchitis. Occasionally it occurs in children, particularly following the paroxysmal coughing spells of pertussis and whooping cough. The cough becomes weak and may lose consciousness; momentarily. This is mainly attributable to the greatly elevated intrathoracic pressure, which interferes with venous return to the heart. Increased cerebrospinal fluid (CSF) pressure and diminished Pco2, with resultant cerebral vasodilatation, are probably contributing factors.

Powerful efforts to exhale against a closed glottis (as occurs in tussive syncope) is referred to as the Valsalva maneuver. The unconsciousness that results from breath-holding spells in infants is probably based on this mechanism as well; the so-called palid attacks in infants probably represent reflex vasodilatation. Also, the loss of consciousness that occurs during competitive weight lifting ("weight lifters' blackout") is mainly the effect of a Valsalva maneuver, added to which are the effects of vascular dilatation produced by squatting and hyperventilation. Lesser degrees of this phenomenon (fairness and light-headedness) not infrequently follow ordinary physical activity, such as uncontrolled laughter, straining at stool, heavy lifting, underwater diving, or effortless trumpet playing. Rarely, a brief faint may occur in each of these circumstances.

Syncope may occur occasionally in the course of postictal arterial examination, but only if the patient is standing (prosthetic syncope). A Valsalva effect and reflex vagal stimulation appear to be contributing factors. Postprandial hypotension may occasionally lead to syncope in elderly persons, in whom impaired baroreflex function cannot compensate for pooling of blood in splanchnic vessels.

**Primary Failure of the Sympathetic Nervous System**

**Postural (Orthostatic) Hypotension**

This type of syncope affects persons whose peripheral vasomotor reflexes are defective. Although the character of the faint differs little from that of vasodepressor syncope, the effect of posture in its initiation is its most typical attribute. Standing still for prolonged periods or arising quickly from a recumbent position are the two combinations under which it is most likely to happen. The patient, on assuming an upright position, shows a steady decline in blood pressure to a level at which the cerebral circulation cannot be supported. It should be emphasized that the bedside testing of orthostatic blood pressure is best performed by having the patient stand quickly, and taking readings immediately, at 1 and at 3 min, rather than using the lying-sitting-standing sequence. With few exceptions (see Chap. 26), peripheral autonomic failure precludes a compensatory tachycardia, and contrary to what happens in vasodepressor syncope, there are no autonomic responses such as pallor, sweating, nausea, or release of norepinephrine. Mild mental clouding with staggering or falling may precede unconsciousness or be the only evidence of cerebral disorder.

The maintenance of blood pressure during various levels of activity and with postural changes depends on pressure-sensitive receptors (baroreceptors) in the aortic and carotid sinus and mechanoreceptors in the walls of the heart. These receptors, which are the sensory nerve endings of the glossopharyngeal and vagus nerves, send afferent impulses to the vasomotor centers in the medulla, more specifically the nucleus of the tractus solitarius (NTS). Axons from the NTS project to the reticular formation of the ventrolateral medulla, which, in turn, sends fibers to the intermediolateral cell column of the spinal cord, thereby controlling vasomotor tone in skeletal muscles, skin, and the splanchnic bed. A diminution of sensory impulses from baroreceptors increases the flow of excitatory signals, which raise the blood pressure and cardiac output, thus restoring cerebral perfusion. This subject is discussed further in relation to the regulation of blood pressure, in Chap. 26.

Postural syncope occurs under a wide variety of clinical conditions: (1) in otherwise normal individuals who, in certain circumstances, experience a failure of pressor-receptor reflex function, as described earlier; (2) as part of a chronic syndrome known as idiopathic orthostatic hypotension or primary autonomic insufficiency (see further on); (3) after a period of prolonged illness with recumbency, especially in elderly individuals with poor muscle tone; (4) in association with diseases of the peripheral nerves that involve autonomic nerve fibers—dilatation, tubes dorsalis, amyloidosis, Guillain-Barré syndrome, a primary idiopathic autonomic neuropathy, paraplegia, and several other polyneuropathies, all of which interrupt vasomotor reflexes; (5) after sympathectomy or high vagotomy; (6) in patients receiving L-dopa, antihypertensive agents and certain sedative and antidepressant drugs; (7) in spinal cord transection above the T6 level, particularly in the acute stage; and (8) in patients with hypovolemia.

These conditions are easily understood if one keeps in mind that, on assuming the erect posture, the pooling of blood in the lower parts of the body is normally prevented by (1) reflex arterial and arterial constriction, through alpha- and beta-adrenergic effector mechanisms; (2) reflex acceleration of the heart by means of aortic and carotid reflexes, as described above; and (3) muscular activity, which improves venous return. Unmyelinated (postganglionic sympathetic) fibers cease firing during vasovagal fainting at a point when the blood pressure falls below 80/40 mmHg and the pulse below 60. Lipsitz has pointed out that aging is associated with a progressive impairment of these compensatory mechanisms, thus rendering the older person especially vulnerable to syncope. However, even in some younger persons, after the blood pressure has fallen slightly and stabilized at a lower level, the compensatory reflexes may fail suddenly, with a precipitant drop in blood pressure.

**Postural Orthostatic Tachycardia Syndrome ("POTS").** The authors have limited experience with this process and are uncertain about its validity as an entity apart from an aversion of the patient to an upright posture and the tendency to become weak and tremulous. As described by Low et al, it consists of intolerance of the standing position accompanied by tachycardia up to 120 beats per minute or more, but without orthostatic hypotension. Dyspnea, fatigue, and tremulousness and a complaint of "dizziness" accompany the assumption of an upright posture, and the same constellation of symptoms may be brought out by upright tilting. There is a frequent association with fatigue and with exercise intolerance. The situation is comparable to orthostatic intolerance in the chronic fatigue syndrome (page 528), with which POTS shares many features. An impairment of cerebral autoregulation has been hypothesized; others consider it to be a limited form of dysautonomia.

**Primary Autonomic Insufficiency (Idiopathic Orthostatic Hypotension).** This presents in two forms. In one form (Bradbury-Eggleston) there is probably a selective degeneration of neurons in the sympathetic ganglia with denervation of smooth muscle vasculature and adrenal glands. The pathology has not been fully delineated but lesions in other parts of the nervous system are not evident. In the second type (Shy-Drager) there is a degeneration of preganglionic neurons in the lateral column of gray matter in the spinal cord, leaving postganglionic neurons isolated from spinal control. The latter lesion is often associated with degeneration of other systems of neurons in the central nervous system. Three such system degenerations have been identified, occurring singly or in combination: (1) degeneration of the substantia nigra and locus ceruleus (Parkinson disease), (2) striatalonigral degeneration, and (3) olivoponto cerebellar degeneration. In the first two syndromes, orthostatic hypotension is combined with a parkinsonian syndrome; in the third, it is associated with cerebellar ataxia. These forms of degenerative disease have their onset in adult life, and the associated hypertension and syncope are usually part of a more widespread autonomic dysfunction that includes a fixed cardiac rate, vocal cord paralysis, a loss of sweating in the lower parts of the body, atony of the bladder, constipation, and impotence in the male. As indicated on page 1137, the symptoms of Parkinson disease, autonomic dysfunction, and cerebellar atrophy are often associated—a distinctive combination that has been subsumed under the term multiple system atrophy.

**Syncope of Cardiac Origin**

This is due to a sudden reduction in cardiac output, usually because of arrhythmia, predominantly a bradyarrhythmia. Normally, a pulse as low as 35 to 40 beats per minute or as high as 150 beats per minute is well tolerated, especially if the patient is recumbent. Changes in pulse rate beyond these extremes impair cardiac function. In patients with hypovolemia there is an increased pulse rate at rest, as compared to normal individuals, which is termed "tachycardia of hypovolemia." Patients who require more than 15 to 20 s, there are a few clonic jerks. With still longer asystole, the clonic jerks merge with tonic spasms and stertorous respirations and the ashen-gray pallor gives way to cyanosis, incontinence, fixed pupils, and bilateral Babinski signs. As heart action resumes, the face and neck become flushed. The report of this syndrome). The block may be persistent or intermittent; it is often preceded by fascicular or second-degree heart block. Ventricular arrest of 4 to 8 s, if the patient is upright, is enough to cause syncope; if the patient is supine, the asystole must last 12 to 15 s. After asystole of 12 s, according to Engel, the patient turns pale and becomes momentarily weak or may lose consciousness without warning; this may occur regardless of the position of the body. If the duration of cerebral ischemia exceeds 15 to 20 s, there are a few clonic jerks. With still longer asystole, the clonic jerks merge with tonic spasms and stertorous respirations and the ashen-gray pallor gives way to cyanosis, incontinence, fixed pupils, and bilateral Babinski signs. As heart action resumes, the face and neck become flushed. The report of this syndrome occurs most frequently in patients with complete atrioventricular block and a pulse rate of 40 or less per minute (Adams-Stokes-Morgagni syndrome). On difficult or prolonged coughing, the patient may be at risk for unexpected heart block. Ventricular arrest of 4 to 8 s, if the patient is upright, is enough to cause syncope; if the patient is supine, the asystole must last 12 to 15 s. After asystole of 12 s, according to Engel, the patient turns pale and becomes momentarily weak or may lose consciousness without warning; this may occur regardless of the position of the body. If the duration of cerebral ischemia exceeds 15 to 20 s, there are a few clonic jerks. With still longer asystole, the clonic jerks merge with tonic spasms and stertorous respirations and the ashen-gray pallor gives way to cyanosis, incontinence, fixed pupils, and bilateral Babinski signs. If heart action resumes, the face and neck become flushed. The report of this sequence of signs by a dependable observer helps to distinguish syncope from epilepsy. In cases of even more prolonged asystole (4 to 5 min), there may be cerebral injury, caused by a combination of hypoxia and ischemia.coma may persist or may be replaced by confusion and other neurolgic signs. Focal ischemic changes, often seen in the fields of occluded atherosclerotic cerebral arteries or the border zones between the areas of supply of major arteries. Cardiac fants of the Stokes-Adams type may recur several times a day. The heart block is usually intermittent at first, and between attacks the ECG may remain normal.
show only evidence of myocardial ischemia. A continuous ECG using a Holter monitor or telemetry is then needed to demonstrate the arrhythmia (see further on).

Less easily recognized are faintness and syncope due to dysfunction of the sinus node, manifest by marked sinus bradycardia, sinoatrial block, or sinus arrest ("sinus-sinus syndrome"). The nodal block results in prolonged atrial asystole (>3 s). Supraventricular tachycardia or atrial fibrillation may occur, alternating with sinus bradycardia (bradycardia-tachycardia syndrome).

Tachyarrhythmias alone are less likely to produce syncope. Certainly intermittent ventricular fibrillation can cause fainting, and supraventricular tachycardias with rapid ventricular responses (usually over 160 beats per minute) cause syncope when sustained, predominantly in patients who are upright at the time. The long– QT interval syndrome is a rare familial condition in which syncope and ventricular arrhythmias are prone to occur. Another inherited syndrome with right bundle branch block and ST segment elevation in the right precordial leads is known to cause syncope and even sudden death (Brugada syndrome). Some patients with mitral valve prolapse seem disposed to syncope and presyncope and an inordinate number also have panic attacks.

Aortic stenosis or subaortic stenosis from cardiomyopathy often sets the stage for exertional syncope, because cardiac output cannot keep pace with the demands of exercise. Primary pulmonary hypertension and obstruction of right ventricular outflow (pulmonary valvular or infundibular stenosis) or intracardiac tumors may also be associated with exertional syncope. Vagal overactivity may be the factor responsible for the syncope in these conditions and possibly for the syncope that accompanies pulmonary embolism and aortic outflow obstruction. Tetralogy of Fallot is the congenital cardiac malformation that most often leads to syncope. Other cardiac causes are listed in the classification given at the opening of this chapter.

Syncope Associated with Cerebrovascular Disease

Syncope is an uncommon manifestation of cerebrovascular disease; cases that do occur are usually associated with occlusion of the large arteries in the neck. The best examples are found in patients with the aorto-arch syndrome (Takayasu pulseless disease, page 908), in which the brachiocephalic, common carotid, and vertebral arteries have become narrowed. Physical activity may then critically reduce blood flow to the upper part of the brainstem, causing abrupt loss of consciousness. Stenosis or occlusion of vertebral arteries and the "subclavian steal syndrome" are other examples (page 843). Fainting is said also to occur occasionally in patients with congenital anomalies of the upper cervical spine (Klippel-Feil syndrome) or cervical spondylosis, in which the vertebral circulation is compromised. Head turning may then cause vertigo, nausea and vomiting, visual scotomas, and finally unconsciousness. Syncope does not occur with ischemic attacks that are confined to the territory of the internal carotid artery. Nor, in the authors' experience, do pure syncopal attacks occur with vertebrobasilar ischemia (see further on).

Cerebral Hemorrhage and Syncope

The onset of a subarachnoid hemorrhage may be signaled by a syncopal episode, often with transient apnea. Because the bleeding is arterial, there is a momentary cessation of cerebral circulation as intracranial pressure and blood pressure approach one another. Unless there has been vomiting, a complaint of headache immediately preceding the syncope, or the discovery of hypertension or stiff neck when the patient awakens, the diagnosis may not be suspected until a CT scan or lumbar puncture is performed.

An associated problem, with which we have had numerous unsatisfactory encounters, is posed by the patient who is seen to fall suddenly forward without apparent cause, awakens with headache, and is found to have bifrontal hematomas and subarachnoid blood on CT. These cases highlight the difficulty of distinguishing a primary aneurysmal subarachnoid hemorrhage from an accidental fall or syncope with secondary frontal brain contusions; in almost every case, we have felt obliged to perform cerebral angiography to exclude an anterior communicating artery aneurysm but we have rarely found one.

Fainting in Hysteria

Hysterical fainting is rather frequent and usually occurs under dramatic circumstances (Chap. 56). The evident lack of change in pulse, blood pressure, or color of the skin or any outward display of anxiety distinguishes it from the vasodepressor faint. Irregular jerking movements and generalized spasms without loss of consciousness or change in the EEG are typical features. The diagnosis is based on these negative findings in a person who exhibits the general personality and behavioral characteristics of hysteria. Several interesting instances of mass faintness and syncope of hysterical type have been described in school marching bands (Levine RJ).

Syncope of Unknown Cause

Finally, it should be pointed out that after careful evaluation of patients with syncope and the exclusion of the many forms of the condition described above, there remains a significant proportion of patients (one-third to one-half, according to Kapoor) in which a cause for the syncope cannot be ascertained. The question of whether a single positive tilt table test signifies that a prior episode of syncope was neurocardiogenic is not resolved; this obviously has a bearing on the proportion of cases that remain without a diagnosis. If the episodes are repetitive and erratically spaced, a cardiac arrhythmia or intraventricular conduction defect should be sought by use of special monitoring devices and conduction studies.

DIFFERENTIAL DIAGNOSIS

Conditions Associated with Episodic Weakness and Faintness but Rarely with Syncope

**Anxiety Attacks and the Hyperventilation Syndrome** These are probably the most important diagnostic considerations in unexplained faintness without syncope. The light-headedness of anxiety and hyperventilation are frequently described as a feeling of faintness, but a loss of consciousness does not follow (see Liirzer et al.). Such symptoms are not accompanied by facial pallor or relieved by recency. The diagnosis is made on the basis of the associated symptoms, the absence of laboratory and tilt-table abnormalities, and the finding that part of the attack can be reproduced by having the patient hyperventilate. The symptoms produced in this way mimic the persistent or episodic dizziness that accompanies anxiety and panic states (Chap. 15). When anxiety attacks are combined with a Valsalva effect or prolonged standing, fainting may occur. The relationship of anxiety-panic to the previously described postural orthostatic tachycardia syndrome is uncertain.

**Hypoglycemia** In nondiabetics, hypoglycemia may be an obscure cause of episodic weakness and very rarely of syncope. With progressive lowering of blood glucose, the clinical picture is one of hunger, trembling, flushed faces, sweating, confusion, and finally, after many minutes, seizures and coma. The diagnosis depends largely upon the history, the documentation of reduced blood glucose during an attack, and reproduction of the patient's spontaneous attacks by an injection of insulin or an oral dose of tolbutamide (or ingestion of a high-carbohydrate meal in the case of reactive hypoglycemia).

**Acute Blood Loss** Acute hemorrhage, usually within the gastrointestinal tract, is a cause of weakness, faintness, or even unconsciousness when the patient stands suddenly. The cause (gastric or duodenal ulcer is the most common) may remain obscure until the passage of black stools.

**Transient Cerebral Ischemic Attacks** The many symptoms comprised by these attacks in the carotid system are fully described on page 859, but syncope is not one of the clinical presentations. In the case of attacks in the vertebrobasilar territory, an impairment of consciousness is a rare manifestation, but almost always in the context of transient cerebral ischemic attacks that are confined to the territory of the internal carotid artery. Nor, in the authors' experience, do pure syncopal attacks occur with vertebrobasilar ischemia (see further on).

**Seizures and Syncope** In the final analysis, the loss of consciousness in the different types of syncope must be caused by impaired function of the neural elements in those parts of the brain subserving consciousness, i.e., in the high brainstem reticular activating system. In this respect syncope and primary generalized (so-called
centrencephalic) epilepsy have a common ground; yet there is a fundamental difference. In epilepsy, whether major or minor, the arrest in consciousness is almost instantaneous, and, as revealed by the EEG, is accompanied by a paroxysm of electrical activity occurring simultaneously in all of the cerebral cortex and thalamus. The EEG changes (delta waves) in syncope appear later in the course of the attack. The difference relates to the essential pathophysiology—the rapid spread of an electrical discharge in epilepsy and a more gradual failure of cerebral circulation in syncope.

There are also a number of important clinical distinctions between epileptic and syncopal attacks. The epileptic attack may occur day or night, regardless of the position of the patient; syncope rarely appears when the patient is recumbent, the only common exception being the Stokes-Adams attack. The patient’s color usually does not change at onset of an epileptic attack; pallor is an early and invariable finding in all types of syncope except those due to chronic orthostatic hypotension or following recurrent carotid sinus syncope (see below). Syncope is rarely progressive, whereas the发作 is more sudden in onset; if an aura is present, it rarely lasts longer than a few seconds before consciousness is abolished. The onset of syncope is usually more gradual, and the prodromal symptoms are quite distinctive and different from those of seizures. In general, injury from falling is more frequent in epilepsy than in syncope, because protective reflexes are instantaneously abolished in the former. Nevertheless, carotid sinus syncope is an important cause of hurtful falls, especially in the elderly. Tonic spasm of muscles with upturning of the eyes is a prominent and often initial feature of epilepsy, but this occurs only rarely and late in the course of a faint; however, twitching and a few clonic contractions of the limbs may occur several seconds after the patient has fainted (see above). Urinary incontinence is a frequent occurrence in epilepsy, but it need not occur during an epileptic attack and may occur with syncope, so that it cannot be used as a means of excluding the latter disorder. The return of consciousness is slow in epilepsy, prompt in syncope; both may be Nicaragua and drowsiness are common sequelae of seizures, and with clear sensorium of syncope (a brief period of grogginess may follow vasodepressor syncope). Repeated spells of unconsciousness in a young person at a rate of several per day or month are much more suggestive of epilepsy than of syncope.

The EEG may be helpful in differentiating syncope from epilepsy. In the interval between epileptic seizures, the EEG, particularly if repeated once or twice, shows some degree of abnormality in 50 to 75 percent of cases, whereas it should be normal between syncopal attacks. Sometimes one must resort to continuous EEG monitoring by tape recording or telemetry to clarify the situation (this can be combined with continuous ECG recording.) Cases in which vertebrobasilar ischemia is the idiopathic type may show asymmetry of cerebral flow or, if needed, be clarified by angiography ( Chap. 34). Another useful laboratory marker of a seizure, especially if unwitnessed, is an elevation of the serum creatine kinase (CK) concentration; such a finding could conceivably occur only in the very rare case of syncope associated with extensive muscle trauma. Prolactin levels have not proved discriminating enough for routine use in separating seizure from syncope but remain useful in distinguishing both of these from other causes of loss of consciousness, particularly hysteria (see page 344).

No single one of these criteria will absolutely differentiate epilepsy from syncope, but taken as a group and supplemented by the EEG, they usually enable one to distinguish the two conditions.

SPECIAL METHODS OF EXAMINATION

In patients who complain of recurrent faintness or syncope but do not have a spontaneous attack while under observation of the physician, an attempt to reproduce attacks by various methods of great assistance to the physician. Here it will be recalled that normal persons do faint if they stand to squat and breathe and then to stand erect and hold their breath (Valsalva maneuver). Prolonged standing at attention in the heat often causes even well-conditioned soldiers to faint, as does compression of the chest and abdomen while holding one’s breath, as in the parox of adolescents (“fainting lark”).

When an anxiety state is accompanied by faintness, the pattern of symptoms can often be reproduced by having the subject hyperventilate—that is, breathe rapidly and deeply for 2 to 3 min. This test may also be of therapeutic value, because the underlying anxiety tends to be lessened when the patient learns that the symptoms can be produced and alleviated at will simply by controlling breathing.

Most patients with tussive syncope cannot reproduce an attack by the Valsalva maneuver but can sometimes do so by voluntary coughing if severe enough. Another useful procedure is to have the patient perform the Valsalva maneuver for more than 10 s (thus trapping blood behind closed valves in the veins) while the pulse and blood pressure are measured (see “Tests for Abnormalities of the Autonomic Nervous System,” Chap. 26).

In each of the aforementioned instances, the crucial point is not whether symptoms are produced but whether they reproduce the exact pattern of symptoms that occurs in the spontaneous attacks.

Other conditions in which the diagnosis is clarified by reproducing the attacks are carotid sinus hypersensitivity (massage of one or the other carotid sinus) and orthostatic hypotension (observations of pulse rate, blood pressure, and symptoms in the recumbent and standing positions or, even better, with the patient on a tilt table). The latter is now a regularly used procedure when the diagnosis of syncope is not evident from physical examination and routine studies such as ECG, blood count, and bedside sphygmomanometry. There is a distinct difference in the cardiovascular challenge imposed by a tilt table and that created by the simple act of standing up from a sitting or recumbent position. It is re-emphasized that, from the perspective of uncovering autonomic failure, having the patient stand abruptly from a lying position and then recording the blood pressure at intervals is more informative than interposing a period of sitting between the lying and standing positions.

The measurement of beat-to-beat variation in heart rate is a simple but sensitive means of detecting vagal dysfunction, as described in Chap. 26.

Careful, continuous monitoring of the ECG in the hospital or by using a portable recorder may determine whether an arrhythmia is responsible for the syncopal episode. A continuous cardiac loop ECG recorder (which continually records and erases cardiac rhythm) permits prolonged (a month or longer) ambulatory monitoring at reasonable cost. The diagnostic yield from loop recording is much greater than that from Holter monitoring ( Linzer et al). The signal-averaged ECG is reportedly a useful means of identifying individuals at risk for ventricular tachycardia as a cause of syncope ( Mandis).

Tilt Table Testing There are two types of abnormal response to upright tilting: early hypotension (occurring within moments of tilting), which signifies inadequate sympathetic tone and baroreceptor function; and a delayed (several minutes) hypotension and syncope, which indicates a neurocardiogenic mechanism or an idiopathic type. The nonresponse may be to 60 to 80-degree head-up tilt for 10 min in neurocardiogenic cases or, if necessary, be clarified by angiography ( Chap. 34). Another useful laboratory marker of a seizure, especially if unwitnessed, is an elevation of the serum creatine kinase (CK) concentration; such a finding could conceivably occur only in the very rare case of syncope associated with extensive muscle trauma. Prolactin levels have not proved discriminating enough for routine use in separating seizure from syncope but remain useful in distinguishing both of these from other causes of loss of consciousness, particularly hysteria (see page 344).

It should be repeated that the presence of a delayed faint with tilting only demonstrates a proclivity to neurocardiogenic fainting since it occurs in a proportion of individuals who have never fainted; it is not to be taken as incontrovertible evidence that a recent spell is explained by this mechanism.

TREATMENT

Patients seen during the preliminary stages of fainting or after they have lost consciousness should be placed in a position that permits maximal cerebral blood flow, i.e., with head lowered between the knees if sitting or preferably in the supine position with legs elevated. All tight clothing and other constrictions should be loosened and the head and body position so that the tongue does not fall back into the throat and the possible aspiration of vomitus is avoided. Nothing should be given by mouth until the patient has regained consciousness. The patient should not be permitted to rise until the sense of physical weakness has passed and he should be watched carefully for a few minutes after arising.

As a rule, the physician sees the patient after recovery from the faint and is asked to explain why it happened and how it can be prevented in the future. One should think first of those causes of fainting that constitute a therapeutic emergency. Among them are massive internal hemorrhage and myocardial infarction, which may be painless, and cardiac arrhythmias. In an elderly person, a sudden faint without obvious cause must always arouse the suspicion of a complete heart block or other cardiac arrhythmia, even though all findings are negative when the physician sees the patient.

The prevention of fainting depends on the mechanisms involved. In the usual vasodepressor faint of adolescents—which tends to occur in circumstances favoring vasodilatation (warm environment, hunger, fatigue, alcohol intoxication) and periods of emotional excitement—it is enough to advise the patient to avoid such circumstances. In postural hypotension, patients should be cautioned against arising suddenly from bed. Instead, they should first exercise the legs for a few seconds, then sit on the edge of the bed and make sure they are not light-headed or dizzy before starting to walk. Standing for prolonged periods can sometimes be tolerated without fainting by crossing the legs forcefully. Sleeping with the headposts of the bed elevated on wooden blocks 8 to 12 in. high and wearing a snug elastic
abdominal binder and elastic stockings are measures that often prove helpful. Alternatives should be found for medications that are conceivable causes of orthostasis. Beta-adrenergic blocking agents, diuretics, antidepressants, and sympatholytic antihypertensive drugs are the common culprits.

In the syndrome of chronic orthostatic hypotension, special corticosteroid preparations—such as fluorocortisone acetate (Florinef) 0.05 to 0.4 mg/day in divided doses—and increased salt intake to expand blood volume are helpful. Recently the alpha, agonist, midodrine, beginning with 2.5 mg every 4 h and slowly increasing the dose to 5 mg every 4 to 6 hours, has been successful in small studies, but this medication has the potential to worsen the situation, and must be used with care. Binding of the legs and sleeping with the head and shoulders elevated are other useful measures. Tyramine and monoamine oxidase inhibitors have given limited relief in some cases of Shy-Drager syndrome, and beta blockers (propranolol or pindolol) and indomethacin (25 to 50 mg tid) in others. The approaches that have proved useful in treating orthostatic hypotension are reviewed by Mathias and Kimber.

Neurally mediated syncope (neurocardiogenic, or vasodepressor syncope), identified by upright tilt-table testing, may be prevented by the use of beta-adrenergic blocking agents (we have used acebutolol) or the anticholinergic agent disopyramide (Milette et al). Several other drugs (e.g., ephedrine, metoclopramide, dihydroergotamine) have been variously successful in individual patients, but their utility as standard medications remains to be established; the beta-blocking agents are generally preferred.

The treatment of carotid sinus syncope involves, first of all, instructing the patient in measures that minimize the hazards of a fall (see below). Loose collars should be worn, and the patient should learn to turn the whole body, rather than the head alone, when looking to one side. Atropine or one of the ephedrine group of drugs should be used, respectively, in patients with pronounced bradycardia or hypotension during attacks. If atropine is not successful and the syncopal attacks are incapacitating, the insertion of a dual-chamber pacemaker should be considered. Radiation or surgical denervation of the carotid sinus has apparently yielded favorable results in some patients, but it is rarely necessary. Vagovagal attacks usually respond well to an anticholinergic agent (propantheline, 15 mg tid).

Treatment of the hypertrophic syndrome and of hysteria are considered in Chap. 56. For a discussion of the treatment of hypoglycemia and the various cardiac arrhythmias that may induce syncope, the reader is referred to Harrison's Principles of Internal Medicine.

In the elderly person, a faint carries the additional hazard of a fracture or other trauma due to the fall. Therefore, the patient subject to recurrent syncope should cover the bathroom floor and bathtub with mats and have as much of his home carpeted as is feasible. Especially important is the floor space between the bed and the bathroom, because this is the route along which faints in elderly persons most commonly occur. Outdoor walking should be on soft ground rather than hard surfaces, and the patient should avoid standing still for prolonged periods, which is more likely than walking to induce an attack.

Chapter 19
SLEEP AND ITS ABNORMALITIES

Sleep, that familiar yet inexplicable condition of repose in which consciousness is in abeyance, is obviously not abnormal, yet it is not illogical to consider it in connection with abnormal phenomena. There are a number of interesting irregularities of sleep, some of which approach serious extremes, just as there are unnatural forms of waking consciousness.

Everyone has had a great deal of personal experience with sleep, or lack of it, and has observed people in sleep, so it requires no special knowledge to know something about this condition or to appreciate its importance to health and well-being. The psychologic and physiologic benefits of sleep have seldom been so eloquently expressed as in the words of Tristram Shandy:

"Tis the refuge of the unfortunate—the enfranchisement of the prisoner, the downy lap of the hopeless, the weary, the broken-hearted; of all the soft delicious functions of nature this is the choicest; what a happiness it is to man, when the anxieties and passions of the day are over."

Physicians are often consulted by patients who suffer some derangement of sleep. Most often the problem is one of sleeplessness, but sometimes it concerns excessive sleep or some other peculiar phenomenon occurring in connection with sleep. Certain points concerning normal sleep and the sleep-wake mechanisms are worth reviewing, since familiarity with them is necessary for an understanding of disorders of sleep. A great deal of information about sleep and sleep abnormalities is now available as a result of the development, in relatively recent years, of the subspecialty of sleep medicine and the creation of a large number of centers for the diagnosis and treatment of sleep disorders.

Most disorders of sleep can be readily recognized and managed if one attends closely to the patient's description of his sleep disturbance. Only complex or odd cases or those requiring the documentation of apneic episodes or seizures and other motor disorders during sleep need study in special sleep laboratories.

Physiology of Sleep and Sleep-Wake Mechanisms

Sleep, as everyone knows, is an elemental phenomenon of life and an indispensable phase of human existence. It represents one of the basic 24-h (circadian) rhythms, traceable through all mammalian, avian, and reptilian species. The neural control of circadian rhythms is thought to reside in the ventral-anterior region of the hypothalamus—more specifically, in the suprachiasmatic nuclei. Lesions in these nuclei result in a disorganization of the sleep-wake cycles as well as in the rest-activity, temperature, and feeding rhythms. The ancillary role of melatonin and the pineal body in modulating this cyclic activity is described in Chap. 27.

Effects of Age
Observations of the human sleep-wake cycle show it to be age-linked. The newborn baby sleeps from 16 to 20 h a day and the child, 10 to 12 h. Total sleep time drops to 9 to 10 h at age 10 and to about 7 to 7.5 h during adolescence. A gradual decline to about 6.5 h develops in late adult life. However, there are wide individual differences in the length and depth of sleep, due apparently to genetic factors, early-life conditioning, the amount of physical activity, and particular psychologic states.

The pattern of sleeping, which in terrestrial life is adjusted to the 24-h day, also varies in the different epochs of life. The circadian rhythm, with predominance of daytime wakefulness and nighttime sleep, begins to appear only after the first few weeks of postnatal life of the full-term infant; as the child matures, the morning nap is omitted, then the afternoon nap; by the fourth or fifth year, sleep becomes consolidated into a single long nocturnal period. (Actually, a large part of the world's population continues to have an afternoon nap, or siesta, as a lifelong sleep-wake pattern.) This alternating pattern of sleeping and waking persists throughout the adolescent and adult years unless it is altered by emotional or physical disease; fragmentation of the sleep pattern begins in late adult life. Over ensuing years, night awakenings tend to increase in frequency and the daytime waking period tends to be interrupted by episodic sleep lasting seconds to minutes (microsleep) as well as by longer naps. From about 35 years of age onward, women tend to sleep slightly more than men.

Stages of Sleep
Seminal contributions to our understanding of the physiology of sleep were made by Loomis and associates and by Aserinsky, Dement, and Kleitman through EEG and polygraphic analysis. As a result of their studies, five stages of sleep, representative of two alternating physiologic mechanisms, were defined. In each stage, the electrical activity of the brain occurs in organized and recurring cycles, referred to as the architecture of sleep. These findings put to rest the antiquated ideas that sleep is a purely passive state and simply reflects fatigue and reduction in environmental stimuli, and that sleep and coma have fundamentally the same anatomic-physiologic basis. As the electrophysiologic stages of sleep progress, sleep becomes deeper, meaning that arousal requires a more intense stimulus.

Relaxed wakefulness with the eyes closed is accompanied in the electroencephalogram (EEG) by sinusoidal alpha waves of 9 to 11 Hz (cycles per second) and low-voltage fast activity of mixed frequency (as well as a 30- to 40-Hz gamma rhythm that is not evident on the routine EEG). The electromyogram (EMG) is silent when the patient is sitting or lying quietly except for the facial (mimetic) muscles. With drowsiness, as the first stage of sleep sets in, the eyelids begin to droop, the eyes may rove slowly from side to side, and the pupils become smaller. As the early stage of sleep evolves, the muscles relax, and the EEG pattern changes to one of progressively lower voltage and mixed frequency, with a loss of alpha waves; this is associated with slow, rolling eye movements and is called stage 1 sleep. As this changes into stage 2 sleep, 1/2- to 2-s bursts of biphasic 12- to 14-Hz waves (sleep spindle) and high-amplitude, sharp slow-wave (K) complexes appear (Fig. 19-2). The deep sleep of stages 3 and 4, also called slow-wave sleep, is composed of an increasing proportion of high-amplitude (>75-mV), delta (1- to 2-Hz) waves in the EEG. If the eyelids are raised gently, the globes are usually seen to be exotropic and the pupils are even smaller than before, but with retained responses to light. The last, or fifth, stage of the sleep cycle is associated with further reduction in muscle tone, except in the extraocular muscles, and with bursts of rapid eye movements (REMs) behind the closed lids. Concomitantly, the EEG becomes desynchronized, i.e., it has a low-voltage and high-frequency discharge pattern. The first four stages of sleep are called non-rapid eye movement (NREM) sleep or quiet or synchronized sleep; the last stage is variously designated as rapid-eye-movement (REM), fast-wave, nonsynchronized, or desynchronized sleep (these features are illustrated in Fig. 19-2).

Chapter References
In the first portion of a typical night's sleep, the normal young and middle-aged adult passes successively through stages 1, 2, 3, and 4 of NREM sleep. After about 70 to 100 min, a large proportion of which consists of stages 3 and 4 sleep, the first REM period occurs, usually heralded by a transient increase in body movements and a shift in the EEG pattern from that of stage 4 to stage 2. This NREM-REM cycle is repeated at about the same interval four to six times during the night, depending on the total duration of sleep. The first REM period may be brief; the later cycles have less stage 4 sleep or none at all. In the latter portion of a night's sleep, the cycles consist essentially of two alternating stages—REM sleep and stage 2 (spindle-K-complex) sleep.

Newborn full-term infants spend about 50 percent of their sleep in the REM stage (although they have different EEG and eye movement characteristics than adults). The newborn sleep cycle lasts about 60 min (50 percent REM, 50 percent NREM, generally alternating through a 3- to 4-h interfeeding period); with age, the sleep cycle lengthens to 90 to 100 min. About 20 to 25 percent of total sleep time in young adults is spent in REM sleep, 3 to 5 percent in stage 1, 50 to 60 percent in stage 2, and 10 to 20 percent in stages 3 and 4 combined. The amount of sleep in stages 3 and 4 decreases with age, and persons more than 70 years of age have virtually no stage 4 sleep and only small amounts of stage 3 sleep (Fig. 19-3). The 90- to 100-min cycle is fairly stable in any one person and is believed to continue to operate to a less perceptible degree during wakefulness in relation to cyclic gastric motility, hunger, degrees of alertness, and capacity for cognitive activity.

Figure 19-3 Normal sleep cycles. REM sleep (darkened areas) occurs cyclically throughout the night at intervals of approximately 90 min in all age groups. REM sleep shows little variation in the different age groups, whereas stage 4 sleep decreases with age. (Redrawn from Kales and Kales et al: by permission.)

Physiologic Changes and Dreaming in NREM and REM Sleep

A comparison of the physiologic changes in NREM and REM sleep is instructive. The change in the EEG pattern has already been indicated. Cortical neurons tend to discharge in synchronized bursts during NREM sleep and in nonsynchronized bursts in the wakeful states; in REM sleep, the EEG pattern is generally asynchronous as well. Most complex visual dreaming has been thought to occur in the REM period and is recalled most consistently if the subject is awakened at this time. Similar mental activity may be reported by subjects awakened from NREM sleep, though to a lesser extent. Since the time spent in NREM is so much greater than that in REM, a substantial portion of dreaming occurs outside of REM periods. Subjects are easily aroused from REM sleep, but arousing a person during stage 3 or stage 4 of NREM sleep is more difficult; full arousal may take 5 min or more, during which time the subject may be disoriented and confused (physicians called at night should, if possible, avoid making medical decisions during this brief period).

As mentioned above, tonic muscle activity is minimal during REM sleep, although small twitches in facial and digital muscles (hand and foot) can still be detected. Eye movements of REM sleep are conjugate and occur in all directions (horizontal more than vertical). Gross body movements occur every 15 min or so in all stages of sleep but are maximal in the transition between REM and NREM sleep, at which time the sleeping person changes position, usually from side to side (most people sleep on their sides). On closer study, REM sleep has been found to have phasic and tonic components. In addition to the rapid eye movements, phasic phenomena include alternate dilatation and constriction of the pupils and an increase in the blood pressure as well as fluctuation of the blood pressure, pulse, and respiration. The phasic activities are related to bursts of neuronal activity in the vestibular nuclei and are mediated through the medial longitudinal fasciculi and oculomotor nuclei, the median raphe nuclei, and the corticobulbar and corticospinal tracts. In the nonphasic periods of REM sleep, alpha and gamma spinal neurons are inhibited, the H
responses diminish, and the tendon (phasic myotatic) and postural and flexor reflexes diminish or are abolished. This flaccidity or atonia—which is prominent in the abdominal, upper airway, and intercostal muscles—may compromise breathing during REM sleep and pose a threat in infants with excessive respiratory difficulty and in patients with obesity, kyphoscoliosis, muscular dystrophy, and other neuromuscular paradoxes (Guilleminault and Dement).

It has long been known that body temperature falls slightly during sleep; however, if sleep does not occur, there is still a drop in body temperature as part of the circadian (24-h) temperature curve. This drop in temperature is also independent of the 24-h recumbency-ambulatory cycle. During sleep, the decline in temperature occurs mainly during the NREM period, and the same is true of the heartbeat and respiration, both of which become slow and more regular in this period. Cerebral blood flow and oxygen consumption in muscle diminish during NREM sleep and increase during REM sleep. Also, cerebral blood flow and metabolism are markedly reduced across the entire brain during deep NREM sleep; during REM sleep, metabolism and blood flow are restored to that of the waking state (Madison and Vorstopen). Braun and colleagues, who used positron emission tomography (PET) to study REM sleep, observed selective activation of the extrastriate visual cortices and limbic-paralimbic regions, with concomitant attenuation of activity in the primary visual cortex and frontal association areas. These authors have speculated that dissociation of these association areas and their paralimbic connections and that these regions operate independently of frontal lobe modulation, perhaps explaining the uncritical acceptance of the bizarre content of dreams and the disordered temporal relationships and heightened emotionality that characterize dreams.

Unrest decreases during sleep, and the absolute quantity of sodium and potassium that is eliminated also decreases; however, urine specific gravity and osmolality increase, presumably because of increased antidiuretic hormone excretion and reabsorption of water. Parasympathetic outflow is activated periodically in REM sleep; sympathetic activity is suppressed. Breathing is more irregular and heart rate and blood pressure fluctuate. Penile erections appear periodically, usually during REM periods.

A number of hormonal changes have a regular relationship to the sleep-wake cycle. The secretion of cortisol and particularly of thyroid-stimulating hormone is diminished at the onset of sleep. High concentrations of cortisol are characterized foound on awakening. Melatonin, elaborated by the pineal gland, is produced at night and ceases upon retinal stimulation by sunlight (see Chap. 27). During the first 2 h of sleep there is a surge of growth hormone secretion, mainly during sleep stages 3 and 4. This feature persists through middle and late adult life and then disappears. Prolactin secretion increases during the night in both men and women, which probably explains a number of spontaneous awakenings; the highest plasma concentrations being found soon after the onset of sleep. Also, an increased sleep-associated secretion of luteinizing hormone occurs in pubertal boys and girls.

**Neurophysiology of Sleep** Evidence from animal studies suggest that the physiologic mechanisms governing NREM and REM sleep lie in the pontine reticular formation and are influenced by acetylcholine and by the biogenic amines 5-hydroxytryptamine (serotonin) andnorepinephrine. Serotonergic neurons are located in and near the midline or raphe regions of the pons; the lower groups of raphe cells project to the medulla and spinal cord; the more rostral groups project to the midbrain (anterior ventral tegmental area, and thalamus). Cholinergic-rich neurons are concentrated in the locus ceruleus and related nuclei in the central tegmentum of the mesencephalon as well as in other lateral-ventral tegmental regions. These neurons project downward to the lateral horn cells of the spinal cord and upward via centrally located tegmental tracts to specific thalamic and hypothalamic nuclei and all of the cerebral cortex, and, via the superior cerebellar peduncle, to the cerebellar cortex. Cholinergic neurons are found in two major loci in the parahippocampal region of the diencephalon: the pedunculopontine group of nuclei and the lateral dorsal tegmental group. The cholinergic cell groups project rostrally, but the precise anatomy of this projection system has not been defined. Cells from these groups make up part of the ascending reticular activating system.

Hobson originally proposed that the basic oscillation of the sleep cycle is the result of reciprocal interaction of excitatory and inhibitory neurotransmitters. Single-cell recordings from the pontine reticular formation have suggested that there are two interconnected neuronal populations whose levels of activity fluctuate periodically and reciprocally. During wakefulness, according to this theory, the activity of amine (inhibitory) neurons is high, and, because of this inhibition, the activity of the cholinergic neurons is low. During NREM sleep, amine inhibition gradually declines and cholinergic excitation increases; REM sleep occurs when the shift is complete.

Despite the undoubted heuristic value of Hobson’s reciprocal-interaction hypothesis, some of its features remain controversial. Although it is generally agreed that cholinergic-catecholaminergic promiscuity (excitatory and inhibitory) exists, the precise definition of the reciprocal relationship and the particular neurotransmitters involved (e.g., acetylcholine, dopamine, and serotonin) in the physiological process of sleep regulation are still uncertain. Some physiologists have claimed that the oscillation of the sleep-wake cycle is the result of thalamocortical reverberation (see Sleep-Wake Cycle: The Thalamocortical Model).

The traditional view that dreaming and REM sleep are obligatorily or even closely connected has been further questioned by Solms. Among patients with lesions that eliminate or disrupt REM sleep he cites several cases in which dreaming was retained. Conversely, in nine of his patients with basal forebrain (frontal) lesions, dreaming was lost, at least for a time, while REM periods remained undisturbed through the night. This same observation had been made many years ago in patients who had prefrontal leukotomies. Solms has proposed that the dopaminergic systems in the basal forebrain areas efferent modulate dreaming. This view is supported by the observation that breathing in patients being treated with dopaminergic blockers and the enhancement of dreaming reported by patients taking L-dopa (major intracortical dopaminergic pathways originate in the frontal lobes).

Braun and colleagues, who used positron emission tomography (PET) to study REM sleep, observed selective activation of the extrastriate visual cortices and limbic-paralimbic regions, with concomitant attenuation of activity in the primary visual cortex and frontal association areas. The relation of these findings to the nature of dreams is discussed below.

It is evident from the comprehensive review of Culebras and other authors that there is as yet no agreement concerning the integration of all these brainstem mechanisms in the production of sleep and dreams.

**The Function of Sleep and Dreams**

This has been pondered by physiologists and psychiatrists. Parkes has reviewed the main theories—body restitution, facilitation of motor function, consolidation of learning and memory—and tends to agree with the ungrammatical but unambiguous conclusion of Popper and Eccles that “Sleep is a natural repeated unconsciousness that we do not even know the reason for.” There is no convincing proof that we stabilize learned material while asleep, nor can one logically entertain the notion that the function of sleep is to produce dreams, at least until the utility and meaning of dreams becomes known. On the basis of plausibility and logic, we favor the simple notion that sleep restores strength and physical and mental energy.

Based on the PET studies mentioned above, several authors have speculated that the suppression of frontal activity during dreaming is a time when visual association areas and their paralimbic connections are activated might explain the uncritical acceptance of the bizarre visual content, the disordered temporal relationships, and the heightened emotionality characteristic of dreams. This would be in keeping with Hobson’s most recently expressed view of dreams as a form of delirium. This is an interesting idea but explains little, since the nature of delirium is obscure. In contrast, Solms has suggested that activation of frontal dopaminergic systems involves the same pathways that participate in biologic drives, implies that dreams may express latent wishes and desires—a psychoanalytical interpretation—and expressed by Freud in his book *The Interpretation of Dreams*. The authors remain skeptical of these views.

**The Effects of Total and Partial Sleep Deprivation** Deprived of sleep, experimental animals will die within a few weeks, no matter how well they are fed, watered, and housed (Rechtschaffen et al.). But whether a similar degree of sleep deprivation leads to death in humans is unknown. Nevertheless, humans being deprived of sleep do suffer a variety of unpleasant symptoms quite distinct from the effects of the usual types of insomnia.

Despite many studies of the deleterious emotional and cognitive effects of sleeplessness, we still know little about them. If deprived of sleep (NREM and REM) for periods of 60 to 200 h, human beings experience increasing sleepiness, fatigue, irritability, and difficulty in concentration. Performance of skilled motor activities also deteriorates; if the periods are of short duration and slow pace, the subject can manage them; but if speed and perseverance are demanded, he cannot. Self-care is neglected, incentive to work wanes, sustained thought and action are interrupted by lapses of attention, judgment is impaired, and the subject becomes less and less interested in his environment. Arousal becomes more intense, momentary lapses of attention (“microsleeps”) become more intrusive, and the tendency to all types of errors and accidents becomes more marked. Eventually, subjects fail to perceive accurately and to maintain their orientation. Illusions and hallucinations, mainly visual and tactile ones, intrude into consciousness and become more persistent as the period of sleeplessness is
Neurologic signs to be noted include a mild and inconstant nyctagmus, impairment of saccadic eye movements, loss of accommodation, exophoria, a slight tremor of the hands, ptilosis of the eyelids, expressionless face, and thickness of speech, with mispronunciations and incorrect choice of words. The EEG shows a decrement of alpha activity, disappearance of sleep spindles, and loss of delta activity. The seizure threshold is reduced and seizure foci in the EEG may be activated. The concentration of 17-hydroxycorticosteroids increases in the blood, and catecholamine output rises.

Rarely, and probably only in predisposed persons, loss of sleep provokes a psychotic episode (2 to 3 percent of 350 sleep-deprived patients studied by Tyler). The subject may go berserk, screaming, sobbing, and muttering incoherently about seeing things and frequently expressing fragmentary delusions and paranoid thoughts.

During recovery from prolonged sleep deprivation, the amount of sleep obtained is never equal to the amount lost. This is probably due to the intrusion of brief sleep periods during the waking state and represents a sizable amount of time if summated (it is virtually impossible to deprive a human being or animal totally of sleep). When falling asleep after a long period of deprivation, the subject rapidly enters stage 4 of NREM sleep, which continues for several hours at the expense of stage 2 and REM sleep. But by the second recovery night, REM sleep rebounds and exceeds that of the predeprivation period. Stage 4 NREM sleep seems to be the most important sleep stage in restoring the altered functions that result from prolonged sleep deprivation.

The effects of different sleep deprivation are more difficult to interpret than the effects of total or near total deprivation. Some subjects in whom REM sleep is prevented from time to time show an increasing tendency to hyperactivity, emotional lability, and impulsivity—a state that has been compared to the heightened state following the consumption of alcohol. Excessive appetite and hypersexuality of animals deprived of REM sleep. It is noteworthy, however, that in humans, monoamine inhibitors—e.g., phenelzine—will completely suppress REM sleep for months to years without obvious harm. Differential deprivation of NREM sleep (stages 3 and 4) leads, instead, to hyporesponsiveness and excessive sleepiness.

Since the need for sleep varies considerably from person to person, it is difficult to decide what is partial sleep deprivation. Certain rare individuals apparently function well on 4 h or even less of sleep per 24-h period, and others, who sleep long hours, claim not to obtain maximum benefit from this.

**SLEEP DISORDERS**

**Insomnia**

The word insomnia signifies a chronic inability to sleep despite adequate opportunity to do so; it is used popularly to indicate any impairment in the duration, depth, or restorative properties of sleep. There may be difficulty in falling asleep or remaining asleep, or a combination of these complaints. This type of insomnia is usually transitory, can often be ascribed to pain or other identifiable bodily disorder, such as drug or alcohol abuse or, more commonly, to anxiety, worry, or depression. Of the medical disorders conducive to abnormal wakefulness, certain ones stand out—in the joints or in the spine, abdominal discomfort from peptic ulcer and carcinoma, pulmonary and cardiovascular insufficiency, prostatism, and the "restless legs" syndrome and periodic leg movements of sleep.

**"Restless Legs" and Periodic Leg Movements of Sleep**

The disorder known as the restless legs syndrome (anxietatis limborum) may regularly delay the onset of sleep or occur in its early stages. The patient complains of unpleasant aching and drawing sensations in the calves and thighs, often associated with creeping or crawling feelings—symptoms that are temporarily relieved by moving the legs. A compulsion to move the legs can be suppressed voluntarily for a brief period but is ultimately irresistible. The syndrome is usually benign but is occasionally a prelude to a peripheral neuropathy, particularly uremic polyneuropathy. Excessive fatigue may give rise to abnormal ("drawing") muscular sensations, but careful questioning will distinguish the latter disorder as well as benign nocturnal cramping of leg muscles from the restless legs syndrome.

A closely related disturbance and one resulting in sleep deprivation and daytime somnolence is period leg movements during sleep. Originally described as "nocturnal myoclonus," periodic leg movements are slower than myoclonic jerks.

Gross jerks that occur in normal persons on falling asleep (sleep starts, described further on under "Parasomnias Disruptions") and normal night muscle cramps are also to be distinguished from periodic leg movements. The latter consist of a series of repetitive movements of the feet and legs occurring every 20 to 90 s for several minutes to an hour; mainly the anterior tibialis is involved, with dorsiflexion of the foot and big toe, sometimes followed by flexion of the hip and knee. The movements are similar to the triple flexion (Babinski) response, which can be elicited in normal sleeping persons. These movements produce frequent microarousals or, if severe and periodic, full arousals. The patient, usually unaware of these sleep-related movements at the time they occur, is told of them by a bedmate or suspects their occurrence from the disarray of the bedclothes. This type of periodic leg movement may be associated with "restless legs"—as well as with narcolepsy, sleep apnea, the use of tetracyclic antidepressants and L-dopa, and withdrawal from anticonvulsants and hypnotic-sedative drugs.

There are, in addition, a few patients who have true myoclonic jerks in the legs or trunk muscles, often associated with dyskinesias that are difficult to characterize but may include walking-like movements and arrhythmic abduction-adduction of one or both legs or of an arm as discussed in a later section. In a few patients, mainly older ones with a severe form of the nighttime disorder, these movements and the myoclonus spout into wakefulness and are accompanied by foot stamping, body rocking, and marching in place that are only partly under voluntary control. These phenomena may be responsive to opiates in some cases.

Several medications have proved helpful in the treatment of both the restless-legs syndrome and periodic leg movements. Long-acting combinations of L-dopa/ carbidopa (12.5/50 or 25/100 dose) taken at bedtime have been the most successful. Large doses of L-dopa causes some patients to develop the movements earlier, i.e., in the daytime, or to have an exaggeration of the movements later in the night as the effect of the drug wears off. Bromocriptine (1.25 or 2.5 mg) and pergolide (0.15 to 1 mg in divided doses during the day) may be equally effective and do not appear to augment the problem, as L-dopa may. Clonazepam (0.5 to 2.0 mg), temazepam (30 mg at bedtime), diazepam (10 mg), oxazepam (15 mg), or imipramine (25 mg) taken 1/2 h before retiring are also useful in diminishing the number of movements, but their main benefit is to reduce the fragmentation of sleep.

**Other Causes of Secondary Insomnia**

Acroparesthesias, a predominantly nocturnal tingling and numbness of the fingers and palms due to tight carpal ligaments (carpal tunnel syndrome), may awaken the patient at night (see further on, under "Sleep Paralyses"). Cluster headaches characteristically awaken the patient within 1 to 2 h after falling asleep (page 189). In a few patients the headaches were found to occur during or immediately after the REM period.

Among the secondary insomnias, those due to some type of psychologic disturbance are particularly common. Domestic or business worries may keep the patient’s mind in a turmoil (situational insomnia). A strange bed or unfamiliar surroundings may prevent drowsiness and sleep. Under these circumstances the main difficulty is
in falling asleep, with a tendency to sleep late in the morning. These facts emphasize that, to a certain degree, conditioning and environmental factors (social and learned) are normally involved in readying the mind and body for sleep.

Illnesses in which anxiety and fear are prominent symptoms also result in difficulty in falling asleep and in light, fitful, or intermittent sleep. Disturbing dreams are frequent in these situations and may awaken patients at any time. Exceptionally, a patient may even try to stay awake in order to avoid them. In contrast, the depressive illness characteristically produce early-morning waking and inability to return to sleep; the quantity of sleep is reduced, and nocturnal motility is increased. REM sleep, although not always reduced, comes earlier in the night. If anxiety is combined with depression, there is a tendency for both the above patterns to be observed. Yet another pattern of disturbed sleep can be discerned in individuals who are under great tension and worry or are overworked and tired out. These people sink into bed and sleep through sheer exhaustion, but they awaken early with their worries and are unable to get back to sleep.

In states of mania and acute agitation, sleep diminishes and REM sleep may be abolished. Chronic and even short-term use of alcohol, barbiturates, and certain nonbarbiturate sedative-hypnotic drugs markedly reduces REM sleep as well as stages 3 and 4 of NREM sleep. Following withdrawal of these drugs, there is a rapid and marked increase of REM sleep, sometimes with vivid dreams and nightmares. "Rebound insomnia," a worsening of sleep compared with pretreatment levels, has also been reported upon discontinuation of short-half-life benzodiazepine hypnotics, notably triazolam ( 
Gillin et al). Furthermore, a form of drug-withdrawal or rebound insomnia may actually occur during the night in which the drug is administered. The drug produces its hypnotic effect in the first half of the night and a worsening of sleep in the second half of the night, as a result of the sleep-depriving effects of the drug wear off; the patient and the physician may be misled into thinking that these latter symptoms require more of the hypnotic drug or a different one. Alcohol taken in the evening acts in the same way.

A wide variety of other pharmacologic agents may give rise to sporadic or persistent disturbances of sleep. Caffeine-containing beverages, steroids, bronchodilators, central adrenergic blocking agents, amphetamines, certain "activating" antidepressants such as fluoxetine, and cigarettes are the most common offenders. Others are listed in the extensive review of 
Kuper and Reynolds.

The sleep rhythm may be totally deranged in acute confusional states and especially in delirium, and the patient may doze for only short periods, both day and night, the total amount and depth of sleep in a 24-h period being reduced. Frightening hallucinations may prevent sleep. The senile patient tends to catnap during the day and to remain at more persistent longer periods during the night, until sleep is obtained in a series of short naps throughout the 24 h: the total amount of sleep may be increased or decreased.

Treatment of Insomnia

In general, a sedative-hypnotic drug for the management of insomnia should be prescribed only as a short-term adjuvant during an illness or some unusual circumstance. For patients who have difficulty falling asleep, staying asleep, or both, a quick-acting, fairly rapidly metabolized hypnotic is useful. The ones most commonly used are flurazepam (Dalmane), 15 to 30 mg, triazolam (Halcion) 0.25 to 0.5 mg and the non-benzodiazepine hypnotic zopiclone (Ambien) 10 mg. Barbiturates are no longer used because they so often produce dependence and, after a few consecutive nights' use, unpleasant aftereffects. Chloral hydrate occupies a position between these two groups. All of these drugs are more or less equally effective in inducing and maintaining sleep, although they affect sleep stages somewhat differently. Flurazepam reduces stage 4 but not REM sleep, whereas the barbiturates reduce both stage 4 and REM sleep. If flurazepam or triazolam are given for longer than a week or two, they may have a cumulative effect and lead to daytime drowsiness and even dependence. Melatonin (300 to 900 mg) is sometimes as effective as the sedative-hypnotics and may have fewer short-term side effects and withdrawal symptoms. Amitriptyline (25 to 50 mg at bedtime) appears to be a sleep-enhancing drug even in those who are not anxious or depressed. When pain is a factor in insomnia, the sedative may be combined with a suitable analgesic. Nonprescription drugs, such as Nytol and Sleepeze, contain diphenhydramine (Benadryl) or doxylamine, which are minimally effective in inducing sleep but may impair the quality of sleep and lead to drowsiness the following morning.

The chronic insomniac who has no other symptoms should not be permitted to use sedative drugs as a crutch on which to limp through life. The solution of this problem is rarely to be found in medication: One should search out and correct, if possible, any underlying situational or psychologic difficulty, using medication only as a temporary measure. Patients should be encouraged to regularize their daily schedules, including their bedtimes, and to be physically active during the day but to avoid strenuous physical or mental activity before bedtime. It has been suggested that illumination from broad- spectrum light (television) in the late evening is detrimental. Dietary excesses must be corrected and all nonessential medications interdicted. A number of simple behavioral modifications may be useful, such as using the bedroom only for sleeping, arising at the same time each morning regardless of the duration of sleep, avoiding daytime naps, and limiting the time spent in bed strictly to the duration of sleep. A helpful approach is to lessen the patient's concern about sleeplessness by pointing out that the human organism will always get as much sleep as needed and that there is pleasure to be derived from staying awake and reading a good book.

 Disorders of Sleep due to Neurologic Disease

Many neurologic diseases seriously derange the total amount and patterns of sleep (see 
Culebras). Lesions in the upper pons, near the locus ceruleus, are particularly prone to do so. 
Markand and Dyken have described cases of pontine infarction with involvement of the tegmental raphe nuclei; the clinical abnormality took the form of diminished NREM sleep and near abolition of REM sleep lasting for weeks or months. Bilateral lacunar infarctions in the pontine tegmentum, demonstrable by MRI, also appear to be a basis of some instances of the so-called REM sleep behavior disorder ( 
Culebras and Moore), described further on, with the other parasomnias. Bilateral paramedian thalamic infarctions are a potent cause of hypersomnia, the result of disruption of both arousal mechanisms and NREM sleep ( 
Rassmuss et al).

Medullary lesions may affect sleep by altering automatic ventilation; the most extreme examples occur with bilateral tegmental lesions that may completely abolish breathing during sleep ("Ondine's curse," as described in 
Chap. 26). Lesser degrees of tegmental damage—as might occur with Ciliar malformations, unilateral medullary damage, or lateral medullary syndrome, or poliomyelitis—may affect the sleep-wakefulness cycle and cause apneas and daytime drowsiness. Patients with large hemispheric strokes may also be left with daytime lethargy on the basis of disruption of sleep-wake cycles. Certain instances of mesencephalic infarction that are characterized by vivid visual hallucinations (peduncular hallucinosis) may be associated with disruption of sleep.

Von Economo encephalitis, now extinct, was associated with a hypersomnolent state, but caused persistent insomnia in some instances. The latter was related to a predominance of lesions in the anterior hypothalamus and basal frontal lobes, in distinction to hypersomnia, which was related to lesions mainly in the dorsal hypothalamic system and subthalamic system. This subject and other forms of hypersomnia are elaborated further on, under "Excessive Sleep." A remarkable form of familial insomnia has been described by 
Lugaresi and colleagues. This disorder, with onset in middle age and a clinical course of 7 to 36 months, is characterized by a virtual incapacity to sleep and to generate EEG sleep patterns. The cerebral changes consist mainly of profound neuronal loss in the anterior and anteroventral and mediodorsal thalamic nuclei. This disease is characterized by a sleep disturbance, taking the form of an increased frequency of intermittent periods of wakefulness ( 
Martin et al).

Major head injury is an important cause of sleep disturbance. The abnormalities, which may persist for months or years, consist mainly of a decrease in stages 1 and 2 of NREM sleep and less than the expected amount of REM sleep and dreaming. Some patients in the persistent vegetative state show a cycle of changes in the EEG, progressing from a picture of abortive spindles and K complexes with cyclic alterations in respiration and pupil size to the acquisition of a more normally 2 of NREM sleep and less than the expected amounts of REM sleep and dreaming. Some patients in the persistent vegetative state show a cycle of changes in the EEG, progressing from a picture of abortive spindles and K complexes with cyclic alterations in respiration and pupil size to the acquisition of a more normally 2 of NREM sleep and less than the expected amounts of REM sleep and dreaming. Some patients in the persistent vegetative state show a cycle of changes in the EEG, progressing from a picture of abortive spindles and K complexes with cyclic alterations in respiration and pupil size to the acquisition of a more normally 2 of NREM sleep and less than the expected amounts of REM sleep and dreaming. Some patients in the persistent vegetative state show a cycle of changes in the EEG, progressing from a picture of abortive spindles and K complexes with cyclic alterations in respiration and pupil size to the acquisition of a more normally 2 of NREM sleep and less than the expected amounts of REM sleep and dreaming. Some patients in the persistent vegetative state show a cycle of changes in the EEG, progressing from a picture of abortive spindles and K complexes with cyclic alterations in respiration and pupil size to the acquisition of a more normally 2 of NREM sleep and less than the expected amounts of REM sleep and dreaming. Some patients in the persistent vegetative state show a cycle of changes in the EEG, progressing from a picture of abortive spindles and K complexes with cyclic alterations in respiration and pupil size to the acquisition of a more normally 2 of NREM sleep and less than the expected amounts of REM sleep and dreaming. Some patients in the persistent vegetative state show a cycle of changes in the EEG, progressing from a picture of abortive spindles and K complexes with cyclic alterations in respiration and pupil size to the acquisition of a more normally 2 of NREM sleep and less than the expected amounts of REM sleep and dreaming. Some patients in the persistent vegetative state show a cycle of changes in the EEG, progressing from a picture of abortive spindles and K complexes with cyclic alterations in respiration and pupil size to the acquisition of a more normally 2 of NREM sleep and less than the expected amounts of REM sleep and dreaming. Some patients in the persistent vegetative state show a cycle of changes in the EEG, progressing from a picture of abortive spindles and K complexes with cyclic alterations in respiration and pupil size to the acquisition of a more normally 2 of NREM sleep and less than the expected amounts of REM sleep and dreaming.

Disturbed sleep patterns have been described in patients with Alzheimer disease, Huntington chorea, olivopontocerebellar degeneration, and progressive supranuclear palsy ( 
Parkes). Dreaming is absent in some of these conditions. The peculiarities of sleep in 
Parkinson disease have been extensively studied; many patients have a parkinsonian disorder of sleep, a loss of normal rapid eye movement (REM) sleep and the alerting effects of L-dopa contribute to the insomnia. In striatongenral degeneration (multiple system atrophy), Lewy-body disease, and other parkinsonian syndromes, REM sleep is particularly affected, although some of the effects may be the result of abnormal respiratory patterns and obstructive sleep apnea.

Migraine, cluster headaches, and paroxysmal hemiconia all have been linked to certain sleep stages. Additional patients with epilepsy and myasthenia gravis and motor neuron disease may have sleep-related complaints; in the latter two the cause can be traced to mild respiratory failure or pharyngeal weakness leading to
Disorders of Sleep Associated with Changes in Circadian Rhythm

Sleep is also disturbed and diminished when the normal circadian rhythm of the sleep-wake cycle is excessively altered. This is observed most often in shift workers, who periodically change their work schedule from day to night, and as a result of transmeridian air travel i.e., jet lag (Baker and Lee). Eastbound travelers fall asleep late and face an early sunrise. The consequent fatigue is a product of both sleep deprivation and a phase change required by changing time zones. One antidote is to reset one's watch on the plane and conform to the routine of the destination—i.e., to stay awake all day until the usual evening hour for sleep—and to take a short nap (e.g., kroazol) at bedtime. Melatonin has also been used for this purpose, but its effects have not been studied extensively. These measures facilitate the resetting of the circadian rhythm. Westbound travelers face a late sunset and a long night's sleep and adjust more readily to resetting of the circadian rhythm. Exposure to light during the extended day is helpful in entraining the sleep cycle; this adjustment is accomplished more easily when traveling west than east. Shifting of the circadian rhythm in animals suggests that brief exposure to light at crucial times effectively resets the sleep-wake cycle; apparently the period just before 4 A.M. is a nodal time for susceptibility to this phase shift. The sleep problems caused by shift work are more complicated (see Morsky).

The delayed-sleep-phase syndrome is a chronic inability to fall asleep and to arise at conventional clock times. Sleep onset is delayed until 3 to 6 A.M., and the subject then sleeps normally until 11 A.M. to 2 P.M. An imposed sleep period from 11 P.M. to 7 A.M. leads to a prolonged sleep latency and daytime sleepiness. The advanced-sleep-phase syndrome is characterized by an early evening sleep onset (8 to 9 P.M.) and early-morning awakening (3 to 5 A.M.). Delaying the onset of sleep usually fails to prevent early-morning awakening. This pattern is not uncommon among healthy elderly persons, in whom it should probably not be dignified as an insomnia syndrome. Still other persons show a completely irregular sleep-wake pattern; sleep consists of persistent but variable short or long naps throughout the night and day, with a nearly normal 24-h accumulation of sleep.

Parasomnic Disturbances

Included under this title are several diverse disorders, the distinctive feature of which is their occurrence only during sleep—somnolent starts, sensory paroxysms, nocturnal paroxysmal dystonia, sleep paralysis, night terrors and nightmares, and REM sleep behavior disorder.

Somnolent (Sleep, Hypnic) Start As sleep comes on, certain motors centers may be excited to a burst of inordinate activity. The result is a sudden "start" or brief jerking of large muscle groups, which rouses the incipient sleeper. It may involve one or both legs and may be associated with a frightening dream or sensory experience. If the start occurs repeatedly during the process of falling asleep and is a nightly event, it may become a matter of great concern to the patient. The starts are more apt to occur in individuals in whom the sleep process develops slowly; they are especially frequent under conditions of tension, depression, or with sleep deprivation. During the early part of the night, when the patient is more deeply asleep, the attacks tend to be more frequent. Sometimes they appear as part of an arousal response to a faint external stimulus and are then associated with a frontal K complex in the EEG. It is probable that some relationship exists between these brusque nocturnal jerks and the sudden isolated jerk of a leg, or arm and leg, that occurs occasionally in a healthy, fully conscious person. These bodily jerks are not variants of epilepsy. Nor should these "somnolent starts" be referred to as nocturnal myoclonus, a term that has also been used incorrectly to designate the relatively mild, repetitive leg movements that occur during sleep, mainly in stages 3 and 4 (see above, under "Insomnia").

A small proportion of otherwise healthy infants exhibit rhythmic jerking of the hands, arms, and legs or abdomen, both at the onset and in the later stages of sleep (benign neonatal myoclonus). The movements begin in the first days of life and disappear within months. There may be a familial proclivity to these movements. Coulter and Allen differentiate this state from myoclonic epilepsy and neonatal seizures by the absence of EEG changes and its occurrence only during sleep.

Sensory Paroxysms Sensory centers may be disturbed in a similar way, either as an isolated phenomenon or in association with motor phenomena. The patient, dozing or asleep, may respond to a sensation that starts through the body, a sudden flash of light, or a sudden crashing sound or thunderclap sensation—"the exploding head syndrome" (Pearce). Sometimes there is a sensation of being turned or lifted and dashed to the ground; conceivably these are also paroxysms involving the labyrinthine-vestibular mechanism. A paroxysm of head pain (cerebellal fugax) is yet another example. Though causes for concern, these sensory paroxysms are benign.

Nocturnal Paroxymal Dystonia This is yet another parasomnic disorder, characterized by paroxysmal bursts of generalized choreothetotic, ballistic, and dystonic movements occurring during NREM sleep (Luppaes et al.). Sometimes the patient appears awake and has a fearful or astonished expression, or there are repetitive utterances and an appearance of distress, similar to what is seen in night terrors, discussed further on. The attacks may begin at any age, affect both sexes, and are usually nonfamilial. Two forms of this disorder have been recognized: in one, the attacks last 60 s or less; they may be diurnal as well as nocturnal; some patients in addition have epileptic seizures of the usual type; and all respond to treatment with carbacholine. The studies of Tinuper and co-workers, utilizing prolonged video-EEG monitoring, indicate that these brief attacks of nocturnal paroxymal dystonia may actually be epileptic seizures of frontal lobe origin. In a second and much rarer type, the attacks are longer lasting (2 to 40 min). Again, ictal and interictal EEGs during wakefulness and sleep are normal, but these attacks do not respond to anticonvulsants of any type. Except for the lack of familial incidence, the disorder is very much the same as the "familial paroxymal dystonic choreothetosis" described by Lance (see page 83).

Sleep Paralysis Curious paralytic phenomena, referred to as pre- and postmotoric paralyses, may occur in the transition from the sleeping to the waking state. Sometimes in the morning and less frequently when falling asleep, otherwise healthy persons—though awake, conscious, and fully oriented—are seemingly unable to activate their muscles. Respiratory and diaphragmatic function and eye movements are usually not affected, although a few patients have reported a sensation of being unable to breathe. They lie as though still asleep, with eyes closed, and they become quite frightened while engaged in a struggle for movement. They have the impression that if they could move one muscle, the paralysis would be dispelled instantly and they would regain full power. It has been stated that the slightest stimulus, such as the touch of a hand or calling the patient's name, will abolish the paralysis. Such attacks are observed in patients with narcolepsy (discussed later in this chapter) and with the hypersomnia of the pickwickian syndrome and other forms of sleep apnea. Some cases are familial. The weakness or paralysis is thought to be a dissociated form of the atonia of REM sleep. Usually the attacks are brief (minutes) and transient; if they occur in isolation and only on rare occasions, they are of no special significance. If frequent, as in narcolepsy, they can be prevented by the use of tricyclic antidepressants or clonipramine.

Night Terrors and Nightmares The night terror (pavor nocturnus) is mainly a problem of childhood. It usually occurs soon after falling asleep, during stage 3 or 4 of sleep. The child awakens abruptly in a state of intense fright, screaming or moaning, with marked tachycardia (150 to 170 beats per minute) and deep, rapid respirations. Children with night terrors are often sleepwalkers as well, and both kinds of attack may occur simultaneously. The entire episode lasts only a minute or two, and in many the child recovers nothing of it or only a vague unpleasant dream. It has been suggested that night terrors and somnambulism represent improper or partial arousal from deep sleep, since EEGs taken during such episodes show a waking type of mixed frequency and alpha pattern. Children with night terrors and somnambulism do not show an increased incidence of psychologic abnormalities and tend to outgrow these disorders. The persistence of such problems into adult life, however, is said to be associated with significant psychopathology (Kales et al.). It has been said that dayzepam, which reduces the duration of stages 3 and 4 of sleep, also reduces night terrors. Selective serotonin reuptake inhibitors have also been used successfully, especially when night terrors are associated with sleepwalking. Frequent night terrors have reportedly been eliminated by having parents awaken the child for several successive nights, just prior to the usual time of the attack or at the first sign of restlessness and autonomic arousal (Lasek).

Frightening dreams or nightmares are far more frequent than night terrors and affect children and adults alike. They occur during periods of normal REM sleep and are particularly prominent during periods of increased REM sleep (REM rebound), following the withdrawal of alcohol or other sedative-hypnotic drugs that had suppressed REM sleep chronically. Autonomic changes are slight or absent, and the content of the dreams can usually be recalled in considerable detail. Some of these dreams (e.g., the ones occurring in the alcohol-withdrawal period) are so vivid that the patient may later have difficulty in separating them from reality; they may merge with the forces of delirium tremens, and situations and events as isolated events. Fever and high fevers are being used to produce and classify sleepwalking is a familial history of this disorder. Motor performance and responsiveness during the sleepwalking incident vary considerably. The most common behavioral abnormality is for a patient to sit up in bed or on the edge of the bed without actually walking. When walking about the house, he may turn on a light or perform some other familiar act. There may be no outward show of emotion, or the patient may be frightened (night terror), but in the child, the frenzied, aggressive
behavior of the adult sleepwalker, described below, is rare. Usually the eyes are open, and such sleepwalkers are guided by vision, thus avoiding familiar objects; the sight of an unfamiliar object may awaken them. Sometimes they make no attempt to avoid obstacles and may injure themselves. If spoken to, they make no response; if told to return to bed, they may do so, but more often they must be led back. Sometimes they repeatedly mutter strange phrases or perform certain repetitious acts, such as pushing against a wall or turning a doorknob back and forth. The episode lasts for only a few minutes, and the following morning they usually have no memory of it or only a fragmentary recollection.

A popular belief is that the sleepwalker is acting out a dream. The observations of sleep laboratories are at variance with this view, since somnambulism has been found to occur almost exclusively during stage 4 of NREM sleep and during the first third of the night, when stage 4 sleep is most prominent and dreaming is least likely to occur. In fact, the entire nocturnal sleep pattern of such individuals does not differ from normal. Also, there is no evidence that somnambulism is a form of epilepsy. It is probably allied to talking in one's sleep, although the two conditions seldom occur together. Sleepwalking must be distinguished from fugue states and ambulatory automatons of complex partial seizures (pages 339–340).

The major consideration in the treatment of childhood somnambulism is to guard against injury by locking doors and windows, removing dangerous objects from the patient's usual routes of march, having them sleep on the ground floor, etc. Children usually outgrow this disorder; parents should be reassured on this score and disabled of the notion that somnambulism is a sign of psychiatric disease.

**Somnambulism in Adults**

The onset of sleepwalking or night terrors in adult life is most unusual and suggests the presence of psychiatric disease or drug intoxication. Almost always, adult sleepwalkers have a history of sleepwalking as a child, although there may have been a period of freedom between the childhood episodes and their reemergence in the third and fourth decades. Adult somnambulism also occurs during stages 3 and 4 of NREM sleep but, unlike the childhood type, need not be confined to the earlier part of the night. Somnambulism in the adult, as in the child, can be a purely passive event unaccompanied by fear or other signs of emotion. More frequently, however, the attack is characterized by frenzied or violent behavior associated with fear and tachycardia, like that of a night terror and often with self-injury. Very rarely, crimes have been committed during sleepwalking; there is some anecdotal evidence that large bedtime doses of psychotropic or sedative drugs may have induced this phenomenon (Luchins et al.). Polysomnographic distinguishes these attacks from complex partial seizures. These attacks can be eliminated or greatly reduced by the administration of clonazepam (0.5 to 1.0 mg at bedtime). Some patients respond better to a combination of clonazepam and phenytoin or to flurazepam (Kavey et al.).

Half-waking somnambulism, or sleep automatism, is a closely related disorder in which an adult, half-roused from sleep, goes through a fairly complex series of purposeful but inappropriate acts, such as going to a window, opening it, and looking out, but afterward recalling the episode only vaguely and partially.

**REM Sleep Behavior Disorder**

This is a more recently recognized parasomnic disorder, occurring in adult life, most commonly in older men without a history of childhood sleepwalking. It is characterized by attacks of vigorous and often dangerous motor activity that accompanies vivid dreams (Mahowald and Schenck). The episodes are of varying frequency, occurring once every week or two or several times nightly. The characteristic features are angry speech with shouting, violent activity with injury to self and bedmate, a very high arousal threshold, and the detailed recall of a nightmare of being attacked and fighting back or attempting to flee. The violent episodes, which occur exclusively during REM sleep, are out of keeping with the patient's waking personality. Polysomnographic recordings during these episodes have disclosed augmented muscle tone (i.e., absence of intermittent atonia) but no seizure activity. The rare appearance of this disorder with pontine infarctions has already been mentioned (page 414). In a series of 93 such cases reported by Olson et al., more than one-half were associated with some other neurologic disorder, such as Parkinson disease, multiple system atrophy, and dementia.

These episodes can be successfully suppressed by the administration of clonazepam in doses of 0.5 to 1.0 mg at bedtime. Discontinuation of medication, even after years of effective control, has resulted in relapse.

**Nocturnal Epilepsy**

It has long been known that convulsive seizures often occur during sleep, especially in children. This is such a frequent occurrence that the practice of inducing sleep has been adopted as an activating EEG procedure to obtain confirmation of epilepsy. Seizures may occur soon after the onset of sleep or at any time during the night, but mainly in stages NREM sleep or in REM sleep. They are also common during the first hour after awakening. On the other hand, deprivation of sleep may be conducive to a seizure.

Sleeping epileptic patients attract attention to their seizures by a cry, violent motor activity, unusual but stereotyped actions, such as sitting up and crossing the arms over the chest, or labored breathing. As in diurnal seizures, after the tonic-clonic phase, patients become quiet and fall into a state resembling sleep, but they cannot be roused from it. The appearance of such a seizure depends on the phase of the seizure in which the patient happens to be when first observed. If the nocturnal seizure is unobserved, the only indication of it may be disheveled bedclothes, a few drops of blood on the pillow from a bitten tongue, wet bed linen from urinary incontinence, or sore muscles. Or the occurrence of a seizure may be betrayed only by confusion or headache, the common aftermaths of a major generalized seizure. Rarely, a patient may die in an epileptic seizure during sleep, sometimes from smothering in the bedclothes or aspirating vomitus or for some obscure reason (possibly respiratory or cardiac dysrhythmia). These accidents and similar ones in awake epileptics account for the higher mortality rate in epileptics than in nonepileptics.

Rarely, epilepsies occur in conjunction with night terrors and somnambulism; the question then arises whether the latter disorders represent postepileptic automatons. Usually no such relationship is established. Electroencephalographic (EEG) studies during a nocturnal period of sleep are most helpful in such cases.

**Excessive Sleep (Hypersomnia) and Reversal of Sleep-Wake Rhythm**

Encephalitis lethargica, or von Economo “epidemic encephalitis,” the remarkable illness that appeared on the medical horizon as a pandemic following World War I, provided some of the most dramatic instances of pathologic somnolence. In fact, protracted sleep lasting for days to weeks was such a prominent symptom of this disease that it was called sleeping sickness. The patient appeared to be in a state of continuous sleep, or somnolence, and could be kept awake only by constant stimulation. Although the infective agent was never isolated, the pathologic anatomy was fully divulged by many excellent studies, all of which demonstrated a destruction of neurons in the midbrain, substantia nigra, and hypothalamus. Patients who survived the acute phase of the illness often had difficulty in reestablishing their normal sleep-wake rhythm. As the somnolence disappeared, some patients exhibited a reversal of the normal pattern, tendency to sleep by day and stay awake at night; many of them also developed a parkinsonian syndrome months or years later. Possibly the hypersomnia was related to destruction or functional paralysis of dopamine-rich neurons in the substantia nigra, resulting in overactivity of the raphe (serotoninergic) neurons.

Hypothalamic hypersomnia is also a manifestation of trypanosomiasis, the common cause of “sleeping sickness” in Africa, and of other diseases localized to the mesencephalon and the floor and walls of the third ventricle, as indicated earlier in this chapter. Small tumors in this area have been associated with arterial hypotension, diabetes insipidus, hypo- or hyperthermia, and protracted somnolence lasting many weeks. Such patients can be aroused; but, if left alone, they immediately fall asleep. Traumatic and vascular lesions and other diseases affecting the mesencephalon may have a similar effect.

**Sleep drunkenness** is the name given to a special form of hypersomnia, characterized by a failure of the patient to attain full alertness for a protracted period after awakening. Unsteadiness, drowsiness, disorientation, and automatic behavior are the main features. This disorder is usually associated with sleep apnea or other forms of sleep deprivation, but sometimes no such connection can be discerned, in which case a motivational factor should be suspected.

**Kleine-Levin Syndrome**

This form of hypersomnia occurs three or four times a year, for periods lasting a few days to several weeks. These patients (most often adolescent boys), after a brief prodromal period of inertia and drowsiness, have daily attacks of prolonged diurnal sleep lasting many hours, or the duration of nocturnal sleep may be greatly prolonged, or they may sleep for days on end. Nevertheless, the organization of components of the sleep cycle is normal. Food intake during and around the period of hypersomnia may exceed three times the normal (bulimia), and to a variable extent there are other behavioral changes such as social withdrawal, negativism, slowness of thinking, incoherence, inattentiveness, and disturbances of memory. The basis of this condition has never been elucidated. A psychiatric mechanism has been proposed, but without foundation. The condition usually disappears during adulthood, and there is limited pathologic material (see page 598).

Finally, it should be mentioned that sleep laboratories now recognize a form of idiopathic hypersomnia in which there are repeated episodes of drowsiness throughout the day. This condition is discussed further on, in relation to the diagnosis of narcolepsy, with which it is most often confused.
Sleep Apnea and Excessive Daytime Sleepiness

Excessive daytime sleepiness is a common complaint in general medical practice (see Table 19-1). Certainly the most frequent cause is the use of any one of the large variety of medications that are not prescribed for their sedative effect. Abuse of alcohol and illicit drugs should also be included in this category. Most conditions associated with severe fatigue produce daytime sleepiness and a desire to nap. One notable medical cause is infectious mononucleosis, but many other viral infections have the same effect. Certain chronic neurologic conditions produce fatigue and sleepiness, multiple sclerosis being the outstanding example. Among general medical conditions, hypothyroidism and hypercapnia must always be considered when daytime sleepiness is a prominent feature. Also, one must not overlook the possibility that excessive daytime drowsiness is the result of repeated episodes of sleep apnea and the disruption of nocturnal sleep by disorders such as the restless legs syndrome.

As mentioned above, REM sleep is characterized by irregular breathing, and this may include several brief periods of apnea up to 10 s in duration. Such apneas and those occurring at the onset of sleep are not in themselves considered to be pathologic. In some individuals, however, sleep-induced apneic periods are particularly frequent and prolonged (greater than 10 s), and such a condition may be responsible for a variety of clinical disturbances in children and adults. This pathologic form of sleep apnea may be due to a cessation of respiratory drive (so-called central apnea), an obstruction of the upper airway, or a combination of these two mechanisms.

Central sleep apnea has been observed in patients with a variety of severe and life-threatening lower brainstem lesions—bulbar poliomyelitis, lateral medullary infarction, spinal (high cervical) surgery, syringobulbia, brainstem encephalitis, striatoniqral degeneration, Creutzfeldt-Jakob disease, anoxic encephalopathy, olivopontocerebellar degeneration—and with a disorder referred to as the primary, or idiopathic, hyperventilation syndrome ("On line’s curse," as described in Chap. 28). This last term is now applied to many forms of total or partial loss of automatic breathing, especially during sleep. When a unilateral lesion (e.g., infarction) of the medulla is the cause, there is almost always involvement of crossing fibers between respiratory nuclei (page 578). In the few autopsied cases of congenital central hyperventilation, Liu and colleagues found the external arcuate nuclei of the medulla to be absent and the neuron population in the medullary respiratory areas to be depleted. Patients with primary hyperventilation syndromes are usually of normal body habitus. Awakenings during the night are frequent, usually after an apneic course, and insomnia is a common complaint. Snoring is mild and intermittent.

Apnea of the obstructive type is more common than the purely central variety. Obstructive apnea is often associated with obesity and less frequently with acromegaly, myxedema, micrognathia, and myotonic dystrophy. In children, far more than in adults, adrenocortical hyperthyropathy may be a factor. Other instances occur in neuromuscular diseases that weaken the posterior pharyngeal musculature; motor neuron disease is the most common example of this group. Obstructive sleep apnea is characterized by noisy snoring of a special form. After a period of regular albeit noisy breathing, there occurs a waning of breathing efforts; then, despite repeated inspiratory efforts, airflow ceases. After a prolonged period of apnea (10 to 30 s or even longer), the patient makes a series of progressively greater breathing efforts until breathing resumes, accompanied by very loud snorting sounds and a brief arousal.

Obstructive sleep apnea occurs during both REM and NREM sleep. The upper respiratory muscles (genioglossus, geniohyoid, tensor veli palatini, and medial pterygoid) normally contract just before the diaphragm contracts, resisting the collapse of the oropharynx. If the airway is obstructed or the muscles are weakened and then go slack, the negative intrathoracic pressure causes narrowing of this passage. Sedative medications, excessive tiredness, a recent stroke, head trauma or other acute neurologic disease, and primary pulmonary disease may all exaggerate obstructive sleep apnea, particularly in the obese patient with a tendency to snore.

The occurrence of a prolonged period of apnea, from whatever cause, is accompanied by progressive hemoglobin desaturation, hypercapnia and hypoxia, a transient increase in systemic and pulmonary arterial pressures, and sinus bradycardia or other arrhythmias. The blood gas changes or perhaps other stimuli induce an arousal response, either a lightening of sleep or a very brief awakening, which is followed by an immediate resumption of breathing. The patient quickly falls asleep again and the sequence is repeated; several hundred times a night in severe cases, greatly disrupting the sleep pattern and reducing the total sleep time. Paradoxically, these patients are very difficult to arouse at all times during the night.

Sleep apnea syndromes occur in persons of all ages. In adults, obstructive sleep apnea is predominantly a disorder of overweight, middle-aged men and usually presents as excessive daytime sleepiness, a complaint that is often mistaken for narcolepsy (see below). Other patients, usually those with the much less common central form of apnea, complain mainly of a disturbance of sleep at night, or insomnia, which may be incorrectly attributed to anxiety or depression. Morning headache, inattention, and decline in school or work performance are other symptoms attributable to sleep apnea. Ultimately, systemic and pulmonary arterial hypertension, cor pulmonale, polycythemia, and heart failure may develop, particularly in patients with obstructive apnea. These symptoms, if combined with obesity, are frequently referred to as the pickwickian syndrome, so named by Burwell and coworkers (1956), who identified this clinical syndrome with that of the extraordinarily sleepy, red-faced fat boy described by Dickens in The Pickwick Papers. The term is no longer apt, since it fails to take note of the facilitatory role of reduced respiratory drive of central type in the genesis of obstructive apnea. Furthermore, obesity need not be present in patients with sleep apnea; conversely, sleep apnea occurs in only a small proportion of obese persons.

In infants with delayed maturation of the respiratory centers, sleep apnea is not infrequent and not without danger, accounting for a certain number of crib deaths. In approximately half of the observed infants with this condition, the apnea represents a respiratory arrest during a seizure. This can be demonstrated by EEG.

The full-blown syndrome of sleep apnea is readily recognized. In patients who complain only of excessive daytime sleepiness or insomnia, the diagnosis may be elusive and require special tests of respiratory function in addition to all-night polygraphic sleep monitoring. Treatment is governed by the severity of symptoms and the predominant type of apnea, central or obstructive. In central apnea, any underlying abnormality, such as congestive heart failure or nasal obstruction, should, of course, be treated insofar as possible. Trazodone (50 mg at bedtime) has reportedly been successful in reducing sleep apnea associated with olivopontocerebellar degeneration (Salazar-Grueso et al.). Where no underlying cause can be found, one of several medications—acetazolamide, medroxyprogesterone, protriptyline, and particularly clomipramine—may be helpful in the short run (Brownell et al.). Low-flow oxygen may also be useful in reducing central sleep apnea.

In the treatment of obstructive apnea, continuous positive airway pressure (CPAP, or BiPAP) is the most useful measure. This is delivered by a tight-fitting nasal mask that is worn at night and connected to a pressure-cycled ventilator circuit triggered by the patient's breath. Patients also benefit from losing weight, lateral positioning during sleep, avoidance of alcohol and other sedative drugs, and the use of the medications mentioned above. Surgical correction of an upper airway defect may be helpful, but it is difficult to predict which patients will benefit and there are no clear guidelines for procedures such as uvulotomy or tonsillectomy. Patients with severe hypersomnia and cardiopulmonary failure may require tracheostomy and nocturnal respirator care. (See Parkes for a full account of therapeutic measures.) Some patients with nonobstructive apnea may also benefit from nighttime treatment with CPAP, but the results are far less consistent than with the obstructive type.

Narcolepsy and Cataplexy

This clinical entity has long been known to the medical profession. Gelineau gave it the name narcolepsy in 1880, although several authors had described the
recurring attacks of irresistible sleep even before that time. Gelineau had also mentioned that the sleep attacks were sometimes accompanied by falls ("astasias"), but it was probably Loewenfeld (1902) who first recognized the common association between the sleep attacks and the temporary paralysis of the somatic musculature during bouts of laughter, anger, and other emotional states; this was referred to as cataplectic inhibition by Hennenberg (1916) and later as cataplexy by Adie (1926).

The term sleep paralysis—used to designate the brief, episodic loss of voluntary movement that occurs during the period of falling asleep (hypnagogic or predormital) or upon awakening (hypnopompic or predawn) (Ecker and Wilson in 1928). Actually, Weir Mitchell had described this latter disorder in 1876, under the title of night palsy. Sometimes sleep paralysis is accompanied or just preceded by vivid and terrifying hallucinations (hypnagogic hallucinations), which may be visual, auditory, vestigial, or somatic (a feeling that a limb or finger or other part of the body is enlarged or otherwise transformed).

The association of hypnagogic hallucinations with narcolepsy was first noted by Lhermitte and Tournay in 1926. In four conditions—narcolepsy, cataplexy, hypnagogic paralysis, and hallucinations—constitute a clinical tetrad. The historical aspects and early accounts of this subject have been reviewed by Wilson.

### Clinical Features

This syndrome is not infrequent, as shown by the fact that Daly and Yoss recorded the occurrence of about 100 new cases a year at the Mayo Clinic. Dement and his colleagues have estimated the prevalence at 50 to 70 per 100,000 in the San Francisco and Los Angeles areas. Men and women are affected about equally. Family studies have disclosed an increased incidence of excessive sleep disturbances among the parents, siblings, and children of probands with narcolepsy, but a recessive or dominant pattern of transmission has not been identified (Kessler et al.). Nevertheless, tissue typing of narcoleptics defined by strict clinical and laboratory criteria has disclosed an increased association with specific allelles of the HLA-DQ histocompatibility antigens, suggesting a genetically determined susceptibility to the disease (Neuweit et al. Kramer et al.).

As a rule, narcolepsy has a gradual onset between the ages of 15 and 35 years; in fully 90 percent of narcoleptics, the condition is established by the 25th year. Narcolepsy is a sleep disorder, characterized by daytime sleepiness, sleep attacks, and cataplexy. The essential disorder of the sleep attacks is a tendency to fall asleep at inappropriate times, which are irresistible. Several times a day, usually after meals or while sitting in class or in other boring or sedentary situations, the affected person is assailed by an uncontrollable desire to sleep. The eyes close, the muscles relax, breathing deepens slightly, and by all appearances the individual is dozing. A noise, a touch, or even the cessation of the lecturer's voice is enough to awaken the patient. The periods of sleep rarely last longer than 15 minutes since the patient is reawakening when he may continue to sleep for an hour or longer. At the conclusion of a nap, the patient feels somewhat refreshed. There are, however, some narcoleptics who tend to be perversively drowsy throughout the day. What distinguishes the typical narcoleptic sleep attacks from commonplace postprandial drowsiness is the frequent occurrence of the former (two to six times every day, as a rule), their irresistibleity, and their occurrence in unusual situations, as while standing, eating, or carrying on a conversation. Blurring of vision, diaphoria, and ptosis may attend the drowsiness and may bring the patient first to an ophthalmologist.

It is not generally appreciated that, in addition to episodes of outright sleep, narcoleptics, like other very drowsy persons, may experience episodes of automatic behavior and amnesia. These episodes may last for a few seconds or as long as an hour or more and occur more often in the afternoon and evening than in the morning. The patient is alone or performing some unrelated task, such as driving. Initially the patient feels only transient sleepiness and then falls asleep. The sleep attacks are characterized by loss of muscle tone which is irresistible. Several times a day, usually after meals or while sitting in class or in other boring or sedentary situations, the affected person is assailed by an uncontrollable desire to sleep. The eyes close, the muscles relax, breathing deepens slightly, and by all appearances the individual is dozing. A noise, a touch, or even the cessation of the lecturer's voice is enough to awaken the patient. The periods of sleep rarely last longer than 15 minutes since the patient is reawakening when he may continue to sleep for an hour or longer. At the conclusion of a nap, the patient feels somewhat refreshed. There are, however, some narcoleptics who tend to be perversively drowsy throughout the day. What distinguishes the typical narcoleptic sleep attacks from commonplace postprandial drowsiness is the frequent occurrence of the former (two to six times every day, as a rule), their irresistibleity, and their occurrence in unusual situations, as while standing, eating, or carrying on a conversation. Blurring of vision, diaphoria, and ptosis may attend the drowsiness and may bring the patient first to an ophthalmologist.

Nocturnal sleep is often interrupted and reduced in amount. The number of hours in a 24-h day spent in sleep by the narcoleptic is no greater than that of a normal individual. Narcoleptics have an increased incidence of sleep apnea and periodic leg and body movements, but not of somnambulism.

Approximately 70 percent of narcoleptics first seeking professional help will report having some form of cataplexy, and about half of the remainder will develop cataplexy later in life. Cataplexy refers to a sudden loss of muscle tone brought on by strong emotion—that is, circumstances in which hearty laughter or, more rarely, excitement, surprise, anger, or intense athletic activity cause the patient's head to fall forward, the jaw to drop, the knees to buckle, even with sinking to the ground—all with perfect preservation of consciousness. Cataplectic attacks occur without provocation in perhaps 5 percent of cases. The attacks last only a few seconds or a minute or two and are of variable frequency. In most of our cases they have appeared at intervals of a few days to weeks. Exceptionally there are many attacks each day, and some patients have attacks in REM period, when the patient is assumed to be awake. Another important finding in narcoleptics is that hypnagogic hallucinations do not occur consistently at the onset of sleep (see further on).

Once established, narcolepsy and cataplexy usually continue for the remainder of the patient's life. The degree of sleepiness, once it has stabilized, rarely lessens, although cataplexy, sleep paralysis, and hallucinations improve or disappear with age in more than half of a large series of patients with narcolepsy-cataplexy (Guelmin and Dement). Such patients are frequently involved in driving accidents, even more frequently than epileptics.

### Cause and Pathogenesis

Narcolepsy bears no relation to epilepsy or migraine. Narcolepsy and cataplexy, as well as unambiguous sleep-onset REM periods, have been described in several breeds of dogs—discrediting the notion that this condition might be psychogenic. Neuropathic defects have been found in the septal nuclei, diencephalic areas, and hypothalamic neurons that best the identified by Lin and colleagues of a canine narcolepsy gene that encodes the receptor for a little understood neuropeptide, orexin (also called hypocretin). This peptide appears to regulate feeding behavior and energy metabolism in the lateral and posterior hypothalamus, but precisely how this affects sleep is unclear.

Rarely, the narcolepsy-cataplexy syndrome follows cerebral trauma or accompanies multiple sclerosis, cranio-phyaryngioma or other tumors of the third ventricle or brainstem, or a sarcoïd granuloma in the hypothalamus (Servan et al.) (secondary or symptomatic narcolepsy).

Our understanding of narcolepsy was greatly advanced by the demonstration, by Dement and his group, that this disorder is associated with a reversal in the order of the two states of sleep, with REM rather than NREM sleep occurring at the onset of the sleep attacks. Not all the diurnal sleep episodes of the narcoleptic begin with REM sleep, but almost always a number of sleep attacks with such an onset can be identified in narcoleptic-catapletic patients in the course of a polygraphic sleep study. The hypnagogic hallucinations (which in this formulation are viewed as dream phenomena), cataplexy, and sleep-onset paralysis (inhibition of anterior horn cells in REM period) have a characteristic pattern as well as being present in REM period. This, too, almost never occurs in normal subjects. Furthermore, the nocturnal sleep pattern is altered in narcoleptics, who have frequent body movements and transient awakenings and a decrease in sleep stages 3 and 4 as well as in total sleep. Another important finding in narcoleptics is that sleep latency (the interval between the point when an individual tries to sleep and the point of onset of EEG sleep patterns), measured repeatedly in diurnal nap situations, is greatly reduced. This prolonged latency is not simply a matter of excessive diurnal sleepiness (essential daytime drowsiness) or even a disorder of REM sleep but a generalized disorganization of sleep-wake function.

### Diagnosis

Diagnosis is the greatest difficulty in diagnoses relates to the problem of separating narcolepsy from the daytime sleepiness of certain sedentary, obese adults who, if unoccupied, doze readily after meals, when watching television, or in the theater. (Many of these patients prove to have obstructive sleep apnea.) A more serious form of recurrent daytime sleepiness, referred to as independent narcolepsy or essential narcolepsy, is described further on. However, both of these forms of daytime sleepiness are isolated disturbances, lacking the other sleep and motor disturbances that characterize the narcolepsy syndrome. The distinguishing features of narcolepsy and cataplexy are the irresistible need for sleep even under unusual circumstances, and the tendency of the sleep attacks to recur, sometimes abruptly, several times each day. When cataplexy is conjoined, diagnosis becomes certain. The brief attacks of automatic behavior and amnesia of the narcoleptic must be distinguished between the point when an individual tries to sleep and the point of onset of sleep patterns, measured repeatedly in diurnal nap situations, is greatly reduced.
documented by laboratory techniques is imperative for the diagnosis which is indeed in doubt, in part because of the potential for abuse of stimulant drugs used for treatment. Overnight polysomnography followed by a standardized multiple sleep latency test in which the patient is afforded opportunities for napping at 2-h intervals permit the quantification of drowsiness and increase the probability of detecting short-latency REM activity (within 5 min from the onset of each sleep period). We would comment, however, that we rarely resort to these studies in clinically typical cases.

**Treatment** No single therapy will control all the symptoms. The narcolepsy responds best to (1) strategically placed 15- to 20-min naps (during lunch hour, before or after dinner, etc.); (2) the use of stimulant drugs—modafinil, dextroamphetamine sulfate (Dexedrine), methylphenidate hydrochloride (Ritalin), or pemoline (Cyterl)—to heighten alertness; and (3) a tricyclic antidepressant (protriptyline, imipramine, or clomipramine) for control of cataplexy. All these drugs are potent suppressants of REM sleep.

The timing and frequency of the scheduled naps has to be individualized, depending on the pattern of hypersomnolence and the work and social demands for full wakefulness. Similarly, the medication schedule should be adjusted to the study or work habits of the patient. Until now the drug of choice has been methylphenidate, because of its prompt action and relative lack of side effects. It is usually, given in doses of 10 to 20 mg three times daily, on an empty stomach. Alternatively amphetamine 5 to 10 mg may be given three to five times a day; this is ordinarily well tolerated and does not cause wakefulness at night. Pemoline (50 to 75 mg daily) and mazindol (1 mg tid) may also be useful in reducing daytime sleep episodes. These drugs have rather little effect on cataplexy but are partially effective in the Korsakoff psychosis. A recently introduced drug, modafinil (200 mg once daily) may prove to be the safest of the stimulants (Fry), but experience with this is currently being acquired. Protriptyline (Vivactil) 5 to 15 mg in the morning, imipramine (Tofranil), in doses of 25 mg three to four times a day, and clomipramine (10 mg daily) are effective in preventing cataplexy.

The combined use of these stimulant and tricyclic antidepressant drugs is often indicated. A problem with the stimulant drugs is the development of tolerance over a 6- to 12-month period, which requires the switching and periodic discontinuation of drugs. Excessive amounts of amphetamine may induce a schizophriniform psychosis (page 1268). The stimulant drugs and the tricyclic antidepressants increase catecholamine levels; their chronic administration may produce hypertension.

Narcoleptics must be warned of the dangers of falling asleep and lapses of consciousness while driving or during engagement in other activities that require constant alertness. The earliest feeling of drowsiness should prompt the patient to pull off the road and take a nap. Long-distance driving should probably be avoided completely.

**Pathologic Wakefulness**

This state, as remarked earlier, has been induced in animals by lesions in the tegmentum (median raphe nuclei) of the pons. Comparable states are known to occur in humans but are very rare (Lugaresi et al; see page 414). The commonest causes of asomnia in hospital practice are delirium tremens and certain other drug withdrawal syndromes. Drug-induced psychoses and mania (bipolar disease) may induce a similar state. We have seen a number of patients with a delirious pathologic wakefulness lasting a few days to a week or more after temporofrontal trauma or in association with a hypothalamic tumor (lymphoma). None of the various treatments we have tried has been successful in suppressing this state. Fortunately, it was transitory in the traumatic cases.

**Sleep Palsies and Acroparesthesias**

Several types of paresthetic disturbances, sometimes distressing in nature, may arise during sleep. Everyone is familiar with the phenomenon of an arm or leg "falling asleep." Immobility of the limbs and maintenance of uncomfortable postures, without any awareness of them, permit undue pressure to be applied on peripheral nerves (especially the ulnar, radial, and peroneal). Pressure of the nerve against the underlying bone may interfere with intraneural function in the compressed segment of nerve. Sustained pressure may result in a sensory and motor paralysis—sometimes referred to as sleep or pressure palsy. Usually, this condition lasts only a few hours or days, but if compression is prolonged, the nerve may be severely damaged, so that recovery of function awaits remyelination or regeneration.

Deep sleep or stupor, as in alcohol intoxication or anesthesia, renders patients especially liable to pressure palsies merely because they do not heed the discomfort of a sustained unnatural posture. A form of familial pressure palsies in which there is a disposition to involvement of one nerve after another under conditions not usually conducive to the condition is also known (page 1417).

Acroparesthesias are frequent in adult women and are not unknown to men. The patient, after being asleep for a few hours, is awakened by a numbness, tingling, prickling, "pins-and-needles" feeling in the fingers and hands. There are also aching, burning pains or tightness and other unpleasant sensations. With vigorous rubbing or shaking of the hands or extension of the wrists, the paresthesias subside within a few minutes, only to return later, or upon first awakening in the morning. At first, there is a suspicion of having slept on an arm, but the frequent bilaterality of the symptoms and their occurrence regardless of the position of the arms dispels this notion. Usually the paresthesias are in the distribution of the median nerves, and almost invariably the symptoms prove to be due to carpal tunnel syndrome (see page 1433).

**Bruxism**

Nocturnal grinding of the teeth, sometimes diurnal as well, occurs at all ages and may be as distressing to the bystander as it is to the patient. It may also cause serious dental problems unless the teeth are protected in some way. There are many hypothetical explanations, all without proof. Stress is most often blamed, and claims point to EMG studies that show the masseter and temporalis muscles to be excessively contracted in states of nervous tension. We are more inclined to regard it as a tic or automatism. When present in the daytime, it may also represent a fragment of segmental dystonia or tardive dyskinesia.

**Nocturnal Enuresis**

Nocturnal bedwetting with daytime continence is a frequent disorder during childhood, and it may persist into adult life. Approximately 1 of 10 children 4 to 14 years of age is affected, boys more frequently than girls (in a ratio of 4:3); even among adults (military recruits), the incidence is 1 to 3 percent. The incidence is much higher if one or both parents were enuretic. Though the condition was formerly thought to be functional, i.e., psychogenic, the studies of Gusfield and Broughton revealed a predominantly organic pathology. The intracranial pressure periodically rises to much higher levels in the enuretic than in normal persons, and the functional bladder capacity of the enuretic is smaller than normal. This suggests a maturational failure of certain modulating nervous influences.

An enuretic episode is most likely to occur 3 to 4 h after sleep onset and usually but not necessarily in stages 3 and 4 sleep. It is preceded by a burst of rhythmic delta waves associated with a general body movement. If the patient is awakened at this point, he does not report any dreams. Imipramine (10 to 75 mg at bedtime) has proved to be an effective agent in reducing the frequency of enuresis. A series of training exercises designed to increase the functional bladder capacity and sphincter tone may also be helpful. Sometimes all that is required is to proscribe fluid intake for several hours prior to sleep and to awaken the patient and have him empty his bladder before falling asleep. One elderly physician with lifelong enuresis, reported that he had finally obtained relief (after all other measures had failed) by using a nasal spray of an analogue of antidiuretic hormone (desmopressin) at bedtime. This has now been adopted for the treatment of intractable cases. Diseases of the urinary tract, diabetes mellitus or diabetes insipidus, epilepsy, sleep apnea syndrome, sickle cell anemia, and spinal cord or cauda equina disease must be excluded as causes of symptomatic enuresis.

**Relation of Sleep to Other Medical Illnesses**

The high incidence of thrombotic stroke that is apparent upon awakening, a phenomenon long known to neurologists, has been studied epidemiologically by Palomaki and colleagues. These authors have summarized the evidence for an association between snoring, sleep apnea, and an increased risk for stroke. As already
mentioned, cluster headache and migraine have an intricate relationship to sleep, the former almost always occurring during or soon after the first REM period, and the latter often curtailed by a sound sleep.

Patients with duodenal ulcer secrete more HCl during sleep (peaks coincide with REM sleep) than normal subjects. Patients with coronary arteriosclerosis may show ECG changes during REM sleep, and nocturnal angina has been recorded at this time. Snoring is strongly associated with hypertension. Asthmatics frequently have their attacks at night, but not concomitantly with any specific stage of sleep; they do have a decreased amount of stage 4 NREM sleep and frequent awakenings, however. Patients with hypothyroidism have shown a decrease of stages 3 and 4 NREM sleep and a return to a normal pattern when they become euthyroid.

Demented patients exhibit reduced amounts of REM sleep and stage 4 NREM sleep, as do children with Down syndrome, phenylketonuria, and other forms of brain damage. A correlation has been demonstrated between the level of intelligence and the amount of REM sleep in all these conditions and in normal persons as well. Alcohol, barbiturates, and other sedative-hypnotic drugs, which suppress REM sleep, permit extraordinary excesses of it to appear during withdrawal periods, which may in part account for the hyperactivity and confusion and perhaps the hallucinosis seen in these states.

CHAPTER REFERENCES

The singular event in which a patient with previously intact mentality becomes acutely confused is observed almost daily on the medical and surgical wards of a general hospital. Occurring, as it often does, during an infection with fever or in the course of a toxic or metabolic disorder (such as renal or hepatic failure) or as an effect of medication or alcohol, it never fails to create grave problems for the physician, nursing personnel, and family. The physician has to cope with the problem of diagnosis, often without the advantage of a lucid history, and any program of therapy to be initiated is constantly threatened by the patient's agitation, sleeplessness, and inability to cooperate. The nursing personnel are burdened with the need of providing satisfactory care for the patient and, at the same time, maintaining a tranquil atmosphere for other patients. The family must be supported as it faces the appalling specter of a deranged mind and all it signifies.

These difficulties are greatly magnified when the patient arrives in the emergency ward, having behaved in some irrational way, and the physician must begin the clinical analysis without knowledge of the patient's background and underlying medical illnesses. Such patients should be admitted to a general medical or neurologic ward and not to a purely psychiatric unit, which often lacks the wherewithal to properly investigate and manage the great variety of medical diseases with which the confusional state may be associated. Transfer of the patient to a psychiatric service is undertaken only if the behavioral disorder proves impossible to manage in a general hospital, or, if warranted, when the underlying medical problems have been identified and a program of treatment has been started.

DEFINITION OF TERMS

The definition of normal and abnormal states of mind is difficult, because the terms used to describe these states have been given so many different meanings in both medical and nonmedical writings. Compounding the difficulty is the fact that the pathophysiology of the confusional states and delirium is not fully understood, and the definitions depend on their clinical relationships, with all the imprecision that this entails. The following nomenclature, though tentative, has proved useful to us and is employed in this and subsequent chapters throughout this textbook.

Confusion is a general term denoting the patient's incapacity to think with customary speed, clarity, and coherence. Its most conspicuous attributes are impaired attention and concentration, manifest disorientation, an inability to properly register immediate events and to recall them later, an appearance of bewilderment, and a diminution of all mental activity, including the normally constant inner ideation. Thinking, speech, and the performance of goal-directed actions may be impersistent or abruptly arrested by the intrusion of irrelevant thoughts. Reduced perceptiveness with visual and auditory illusions and even hallucinations and paranoid delusions (a veritable psychosis) are variable features.

These psychologic disturbances may appear in many contexts. Confusion, as defined above, is an essential ingredient of delirium (discussed further on), in which case the disorder of attention and perception is associated with agitation, hallucinations, convulsions, and tremor. As pointed out in Chap. 17, a confusional state may appear at any stage in the evolution and devolution of a number of diseases that lead to drowsiness, stupor, and coma—typically in the metabolic encephalopathies but also in diseases affecting the anatomic regions that maintain normal arousal; in the latter instances the confusional state is closely aligned with diminished levels of consciousness. Confusion is also a characteristic feature of the chronic syndrome of dementia, where it is the product of a progressive failure of language, memory, and other intellectual functions. Intense emotional disturbances, of either manic or depressive type, may interfere with attentiveness and coherence of thinking and thereby produce an apparent confusional state. Finally, an element of confusion may appear in association with focal cerebral lesions, particularly of the frontoparietal and sometimes the temporal lobe association areas. Then, instead of tremor, astasia, and myoclonus—the generalized motor abnormalities that characterize confusional states of toxic-metabolic origin—there may be unilateral neglect of self and environment and unilateral motor-sensory defects.

The many mental and behavioral aberrations that are seen in confused patients, and their occurrence in various combinations and clinical contexts, make it unlikely that they all derive from a single psychologic abnormality such as a disturbance of attention. Phenomena as diverse as drowsiness and stupor, hallucinations and delusions, disorders of perception and registration, impersistance and perseveration, and so forth cannot logically be reduced to a disorder of one psychologic or physiologic mechanism. More likely, a number of separable disorders of function are involved, all acute and usually reversible. All of them are included under the rubric of the confusional states, for want of a better term.

We use the term delirium to denote a special type of confusional state. In addition to many of the negative elements mentioned above, delirium is marked by a prominent disorder of perception, terrifying hallucinations and vivid dreams, a kaleidoscopic array of strange and absurd fantasies and delusions, inability to sleep, a tendency to twitch and convulse, and intense fear or other emotional reactions. Delirium is distinguished not only by extreme inattentiveness but also by a state of heightened alertness, i.e., an increased readiness to respond to stimuli, and by overactivity of psychomotor and autonomic nervous system functions, sometimes striking in degree. Implicit in the term delirium are its nonmedical connotations as well—intense agitation, frenzied excitement, and trembling. All these positive aspects of disordered consciousness, after the classic studies of French authors, are designated by the term "oneirics" or "dreams." The twilight states are closely related disorders, but the clinical descriptions have been so diverse that the term now has little useful meaning.

It should be noted that this distinction between delirium and other acute confusional states is not universally accepted. Some authors attach no particular significance to the autonomic and psychomotor overactivity and the dreamlike features of delirium, or to the underactivity and somnolence that characterize certain other confusional states. All such states are lumped together under headings such as organic brain syndrome, acute organic reaction, toxic-infective psychosis, febrile delirium, exogenous reaction type of psychosis, acute organic reaction, and symptomatic psychosis, with the implication that they are induced by toxic or metabolic disturbances of the brain. (The term organic is unfortunate, for it implies the existence of other nonorganic states.) We believe that delirium should be set apart from other confusional states because the two conditions are descriptively different and tend to occur in different clinical contexts, as indicated further on. Nevertheless, implicit in both designations is the idea of an acute, transient, completely reversible disorder—modified, of course, by the underlying cause, clinical setting, and age of the patient.

An impairment of memory is often included among the symptoms of delirium and other confusional states. More precisely, the term amnesia should refer to a loss of past memories as well as an inability to form new ones, despite an alert state of mind and normal attentiveness; the definition further presupposes an ability of the patient to grasp the meaning of what is going on around him, to use language normally, and to maintain adequate motivation to learn and to recall. Only if defined this way does the term amnesia have any clinical usefulness. The failure in the amnesic state is mainly one of retention, recall, and reproduction and must be distinguished from states of drowsiness, acute confusion, and delirium, in which information and events seem never to have been adequately perceived and registered in the first place. In the latter circumstances the patient will, of course, be left with a permanent gap in memory for his acute illness.

In a similar way, the term dementia (literally, an undoing of the mind) denotes a deterioration of all intellectual or cognitive functions with little or no disturbance of...
consciousness or perception. Implied by the word is the idea of a gradual enfeeblement of mental powers in a person who formerly possessed a normal mind. Amenities, by contrast, indicate a congenital feeblemindedness more commonly referred to as mental retardation. Dementia and amnesia are defined more explicitly in Chap. 21.

**OBSERVABLE ASPECTS OF BEHAVIOR AND INTELLIGENCE IN STATES OF CONFUSION, DELIRIUM, AMNESIA, AND DEMENTIA**

The intellectual, emotional, and behavioral activities of the human organism are so complex and varied that one may question the feasibility of using derangements of these activities as reliable indicators of cerebral disease. Certainly they do not have the same reliability and ease of anatomic and physiologic interpretation as sensory and motor paralysis or aphasia. Yet observations of disturbed perceptual and cerebrocortical function occurring with such regularity as to be clinically useful in identifying certain diseases. And some of these disturbances gain in specificity because they are often combined in certain ways to form syndromes, which are essentially what states of confusion, delirium, amnesia, and dementia are.

The components of mentation and behavior that lend themselves to bedside examination are (1) the processes of attention, sensation, and perception; (2) the capacity to remember and to recall events of the recent and distant past; (3) the ability to think and reason; (4) temperament, mood, and emotion; (5) initiative, impulse, and drive; (6) social behavior; and (7) insight. Of these, the first is sensorial, the second and third are cognitive, the fourth is affective, the fifth is volitional, the sixth refers to the patient's relationships with those around him, and the seventh refers to the patient's capacity to assess his own normal or disordered functioning. Each component of behavior and intellect has its objective side, expressed in the behavioral responses produced by certain stimuli, and its subjective side, expressed in the thinking and feeling described by the patient in relation to the stimuli. Less accessible to the examiner but nevertheless possible to study by repeated questioning of the patient is the constant stream of inner thought, memories, planning, and other psychic activities that continuously occupy the mind of an alert person. They, too, are disarranged or qualitatively diminished by cerebral disease.

**Disturbances of Perception**

Perception—i.e., the process of acquiring through the senses a knowledge of the “world about” or of one’s self—(apprehension, in classic psychology)—involves much more than the simple sensory process of being aware of the attributes of a stimulus. New visual stimuli, for example, activate the striate cortex and visual association areas wherein are stored the coded past presentations of these stimuli. Recognition involves the reactivation of this system by the same or similar stimuli at a later time. Essential elements in the perceptual process are the maintenance of attention, the selective focusing on a stimulus, elimination of all extraneous stimuli, and identification of the stimulus by recognizing its relationship to personal remembered experience.

The perception of stimuli undergoes predictable types of derangement in disease. Most often there is a reduction in the number of perceptions in a given unit of time and a reduction in the accuracy with which they are properly and relate them to the ongoing activities of the mind. Or there may be a proper inattentiveness or fluctuations of attention, distractibility (pertinent and irrelevant stimuli now having equal value), and inability to concentrate and persist in an assigned task. This often leads to disorientation in time and place. Qualitative changes also appear, mainly in the form of sensory distortions, causing misinterpretations of environmental stimuli (illusions) and misidentifications of persons; these, at least in part, form the basis of hallucinatory experience in which the patient reports and reacts to environmental stimuli that are not really there. There is an intriguing illusion of a large complex of phenomena which is actually a “failure of subjective organization.” These major disturbances in the perceptual sphere, traditionally referred to as “clouding of the sensorium,” are characteristic of delirium and other acute confused states, but a quantitative deficiency may also become evident in the advanced stages of mental retardation and dementia.

More specific partial losses of perception are manifest in the “neglect syndromes” (amorphopsia). The most dramatic examples are observed with right parietal lesions, which render a patient unaware of the left half of his body and the environment on the left side. There are numerous other examples of focal cerebral lesions that disturb or distort sensory perceptions, each subject to neurologic testing; these are discussed in Chap. 22.

**Disturbances of Memory**

Memory, i.e., the retention of learned information and experiences, is involved in all mental activities. It may be arbitrarily subdivided into several parts: (1) registration, which includes all that was mentalized under perception; (2) fixation, mnemonic integration, and retention; (3) recognition and recall; and (4) reproduction. As stated above, there may be a failure of learning and memory in patients with impaired perception and attention because the material to be learned was never registered in the first place. In the Korsakoff amnesic syndrome, newly presented material appears to be correctly registered but cannot be retained for more than a few minutes (anterograde amnesia or failure of learning). There is always an associated defect in the recall and reproduction of memories that had been formed several days, weeks, or even years before the onset of the illness (retrograde amnesia). The fabrication of stories, called confabulation, constitutes a third feature of the syndrome, but is neither specific nor invariably present. Intact retention with failure of recall (retrograde amnesia without anterograde amnesia) is at times a normal state; when it is severe and extends to all events of past life and even personal identity, it is usually a manifestation of hysteria or malingerer. Proof that the processes of registration and recall are intact under these circumstances comes from hypnosis and suggestion, by means of which the lost items are fully recalled. Since memory is involved to some extent in all mental processes, it becomes the most testable component of mentation and behavior.

**Disturbances of Thinking**

Thinking, the highest order of intellectual activity, remains one of the most elusive of all mental operations. If by thinking one means the selective ordering of symbols for learning and organizing information and for problem solving as well as the capacity to reason and form sound judgments, then the working units of this type of mental activity are words and numbers. The substitution of words and numbers for the objects for which they stand (symbolization) is a fundamental part of the process, and so is the transformation into ideas of new and remembered ideas, to the arrangement of new and remembered ideas into certain orders or relationships, according to the rules of logic, constitutes another intricate part of thought, presently beyond the scope of analysis. On page 474, reference is made to Luria's analysis of the steps involved in problem solving in connection with frontal lobe function; but actually, as he himself points out, the whole cerebrum is implicated. In a general way one may examine thinking in terms of speed and efficiency, ideational content, coherence and logical relationships of ideas, quantity and quality of associations to a given idea, and the propriety of the feeling and behavior engendered by an idea.

Information concerning the thought processes and associative functions is best obtained by analyzing the patient's spontaneous verbal productions and by engaging him in conversation. If the patient is taciturn or mute, one may have to depend on responses to direct questions or upon written material, i.e., letters, etc. One notes the prevailing trends of the patient's thoughts; whether the ideas are reasonable, precise, and coherent or vague, circumstantial, tangential, and irrelevant, indicating that the thought processes are shallow and fragmented.

Disorders of thinking are prominent in delirium and other confusional states, in mania, in dementia, and in schizophrenia. In confusional states of all types, the organization of thought processes is disrupted, with fragmentation, repetition, and perseveration; this is spoken of as an "incoherence of thinking." The patient may be excessively critical, rationalizing, and hair-splitting; this disturbance of thinking is often seen in depressive psychoses. Derangements of thinking may also take the form of a flight of ideas; patients move nimbly from one idea to another, and their associations are numerous and loosely linked. This is a common feature of hypomanic and manic states. The opposite condition, poverty of ideas, is characteristic both of depressive illnesses, in which it is combined with gloomy thoughts, and of dementia, in which it is part of a reduction of all inner psychic intellectual activity. Thinking may be distorted in such a way that ideas are not checked against reality. When a false belief is maintained in spite of convincing evidence to the contrary, the patient is said to have a delusion. This abnormality is common to so-called manic-depressive psychoses and schizoaffective, as well as the early stages of dementia. Some patients believe that ideas have been implanted in their minds by some outside agency, such as radio, television, or atomic energy; these “passivity feelings” are highly characteristic of schizophrenia and sometimes of manic disease. Also diagnostic of schizophrenia are distortions of logical thought, such as gaps in sequential thinking, irrationality of ideas, and condensation of associations.

**Disturbances of Emotion, Mood, and Affect**

The emotional life of the patient is expressed in a variety of ways. In the first place, rather marked individual differences in basic temperament are observed in the normal population; some persons are throughout their lives cheerful, gregarious, optimistic, and free from worry, whereas others are just the opposite. The usually volatile, cyclothymic person is said to be liable to manic-depressive disease, and the suspicious, withdrawn, introverted person to schizophrenia and paranoia, but there are frequent exceptions to this statement. Strong, persistent emotional states, such as fear and anxiety, may occur as reactions to life situations and may be accompanied by derangements of visceral function. If excessive and disproportionate to the stimulus, they are usually manifestations of an anxiety neurosis or depression. In the latter state, all stimuli tend to enhance the somber mood of unhappiness. Emotional responses that are excessively labile and poorly controlled or
uninhibited are a common manifestation of many cerebral diseases, particularly those involving the corticospinal and corticobulbar pathways. This disorder constitutes part of the syndrome of spastic bulbar (pseudobulbar) palsy (pages 517 and 541). Conversely, all emotional feeling and expression may be lacking, as in states of profound apathy or severe depression. Or excessive cheerfulness may be maintained in the face of serious, potentially fatal disease or other adversity; this is called euphoria. Finally, the emotional response may be inappropriate to the stimulus, e.g., a depressing or morbid thought may seem amusing and be attended by a smile, as in schizophrenia.

Temperament, mood, and other emotional experiences described above are evaluated by observing the patient's behavior and appearance and questioning him about his feelings. For these purposes it is convenient to divide emotionality into mood and affect. By mood is meant the prevailing emotional state of an individual without reference to the stimulus immediately impinging upon him. It may be cheerful and optimistic or gloomy and melancholic. The patient's language (e.g., the adjectives used), facial expression, attitude, posture, and speed of movement most reliably reflect his prevailing mood. By contrast, affect (or feeling) refers to the emotional reactions evoked by a thought or an environmental stimulus. As such, it is the observable aspect of emotion. According to some psychiatrists, feeling is the subjective component, and affect is the overt manifestation. Others use either term to describe the subjective emotional reaction. These distinctions may seem rather tenuous, but they are considered valuable by psychiatrists.

The emotional disturbances are discussed more fully in Chap. 25.

**Disturbances of Impulse (Conation) and Activity**

Reference was made, in Chap. 3 and Chap. 4, to motor weakness, akinesia, and bradykinesia as cardinal manifestations of corticospinal and extrapyramidal disease. Disorders of these parts of the motor system interfere with voluntary or automatic movements, much to the distress of the patient. But motility and activity can be impaired for other reasons, one of which is a lack of conation, or impulse. These terms designate that basic biologic urge, driving force, or purpose by which every organism is motivated to achieve an endless series of objectives. Indeed, motor activity is a necessary and satisfying objective in itself, for few individuals can remain still for long (fidgets, doodling), and even the severely retarded obtain gratification from certain rhythmic movements, such as rocking, head-banging, etc.

It is the authors' impression that a quantitative reduction in spontaneous activity, i.e., in the amount of activity per unit of time, is one of the most important manifestations of cerebral disease. And an important aspect of this state, called abulia, is the concomitant reduction in speech, ideation, and emotional reaction (apathy). It is well known that individuals vary greatly in strength of impulse; drive, and energy. Some are born low in impulse, with a lifelong tendency to inactivity, a constitutional inadequacy that Kahn called asthenic psychopathy; others are excessively active from early life. But with certain cerebral diseases the disinclination to move and act may reach an extreme degree, to a point where a wide-awake person, perceptive of the environment, does not speak or move for weeks on end (akinetic mutism, see page 371). Such patients seem indifferent to what is happening around them and unconcerned about the consequences of their inactivity.

Abulia must be distinguished from two allied states, catatonia and the psychomotor retardation of depression. Kahlbaum, who first used the term catatonia in 1874, described it as a condition in which the patient sits or lies still and motionless, with a staring countenance, completely without volition and without reaction to sensory impressions. Sometimes there is resistance to the examiner's efforts to move the patient (negativism), which is separable from an inability to relax (cataracta or gegenhalten); or there are certain movements or phrases that are repeated hour after hour. If the limbs are moved passively, they may retain their new position for a prolonged period (flexibilitas cerei), but usually there is nothing except that of voluntary resistance. The psychomotor retardation of depression may be so profound that the patient makes no attempt to help himself in any way and ultimately starves unless fed with a nasogastric tube. The speech and demeanor of such patients express their sadness and desire to die.

In both catatonia and depression, the mind is usually sufficiently alert to record events and later to remember them, in which respect these states differ from stupor. But this distinction is not always valid, for we have seen catatonic schizophrenic and retarded depressive patients who occasionally could not recall what had happened during the period of catatonia or depression. Moreover, Stauder has described a form of "lethal catatonia" in which the completely inert patient develops a high fever, collapses, and dies. In some respects this state resembles the neureptic malignant syndrome, the consequence of intoxication with neuroleptic drugs (page 1265). Also, there is a close relationship if not identity between catatonia and some forms of akinetic mutism.

Pathologic degrees of restlessness and hyperactivity represent the opposite extreme to abulia. Akathisia refers to the constant restless movements and inability to sit still consequent upon the prolonged use of phenothiazines, butyrophenones, and L-dopa (pages 1264 and 1637). On page 629 is described the hyperactivity-inattention syndrome of children, mostly boys. In the manic form of manic-depressive disease (and to a lesser extent in hypomania), continuous activity and insomnia are added to the flight of ideas and the euphoric though somewhat irritable mood. Following certain cerebral diseases, notably some forms of encephalitis, the patient may remain in a state of constant activity, destroying uncontrollably what he can reach. Kahn referred to this state as "organic drivenness."

**Disorders of Social Behavior**

Behavioral disturbances of this type are common manifestations of all delirious-confusional states, particularly those of toxic-metabolic origin but also those due to more obvious structural disease of the brain. The patient may be completely indifferent to all persons around him. Close relatives may not be recognized or the patient may mistake one for a relative. Any person approaching the patient may excite anger and aggressive action. Family members may be treated with disrespect, regarded with suspicion, or falsely accused of harming the patient, stealing his possessions, or trying to poison him. The embarrassment of urinating in public or soiling the bed may be lost and, particularly in men, there may be lwed behavior towards the opposite sex. In its most extreme form, usually seen in the later stages of delirious states, irresistible behavior splitting, and an aversion to being touched by others, may produce a complete inability to approach the patient. These aspects of disordered mental function are the most alarming to the family and difficult to manage in the hospital.

In contrast, docility and amiable social behavior characterize the Down and Williams syndromes (pages 1066 and 1098), and social indifference is a major feature of autism (page 1098).

**Loss of Insight**

Insight, the state of being aware of the nature and degree of one's deficits and their consequences, becomes manifestly impaired or abolished in relation to all types of cerebral disease that cause complex disorders of behavior. Lack of insight is a far more complex phenomenon than this operational definition suggests. There are many restricted forms of unawareness of particular neurologic deficits. These are inseparable from the agnosias, which are discussed in several other parts of this textbook.

The loss of insight means that the patient cannot recall what happened during the period of catatonia or depression. He cannot recall what sickness he had or what illness he is now suffering. He cannot recall how he has become paralysed or why he is bedridden. He does not recall the stupor from which he is just waking up. His thoughts and actions may appear to be those of a normal person, while the actual situation is quite different. The patient may be mistaken for a relative. Any person approaching the patient may excite anger and aggressive action. Family members may be treated with disrespect, regarded with suspicion, or falsely accused of harming the patient, stealing his possessions, or trying to poison him. The embarrassment of urinating in public or soiling the bed may be lost and, particularly in men, there may be lwed behavior towards the opposite sex. In its most extreme form, usually seen in the later stages of delirious states, irresistible behavior splitting, and an aversion to being touched by others, may produce a complete inability to approach the patient. These aspects of disordered mental function are the most alarming to the family and difficult to manage in the hospital.

Thus, diseases that produce the aforementioned abnormalities of mentation not only evoke observable changes in behavior but also alter or reduce the capacity of the patient to make accurate introspections concerning his psychic functions. As a fact stands as proof that the locus is in the organ both of behavior and of all inner sensations, feelings, and emotions. This fact stands as proof that the brain is the organ both of behavior and of all inner sensations, feelings, and emotions.

**COMMON SYNDROMES**

To summarize, the entire group of acute confusional and delirious states is characterized principally by an alteration of consciousness and prominent disorders of attention and perception, which interfere with the speed, clarity, and coherence of thinking, the formation of memories, and the capacity for performance of self-directed and controlled activities. Three major clinical syndromes can be recognized. One is an acute confusional state in which there is manifest reduction in alertness and psychomotor activity. A second syndrome, here called delirium, is marked by overactivity, sleeplessness, tremulousness, and prominence of vivid hallucinations, with convulsions often preceding or associated with the delirium. These two illnesses tend to develop acutely, to have multiple causes, and, except for certain cerebral diseases, to terminate within a relatively short period of time (days to weeks), leaving the patient without residual damage or with whatever defects were present before their onset. The third syndrome is one in which a confusional state occurs in persons with some underlying, more chronic medical or cerebral disease. The cerebral disease may be focal or diffuse and, in the latter case, may dispose the patient to an acute psychosis, which we have chosen to designate as a beclouded dementia. From the neurologic perspective, the generic term psychosis applies to states of confusion in which elements of hallucinations, delusions, and disordered thinking make up prominent elements.
Acute Confusional States Associated with Reduced Alertness and Psychomotor Activity

Clinical Features Some features of this syndrome have already been described in Chap. 17, “Coma and Related Disorders of Consciousness.” In the most typical examples, all mental functions are reduced to some degree; but alertness, attentiveness, orientation, and the ability to concentrate and to grasp all elements of the immediate situation suffer most. Characteristically, these abnormalities fluctuate in severity, typically being worse at night (“sundowning”). In the mildest form of the syndrome, the patient appears alert and may even pass for normal; only the failure to recollect and accurately reproduce happenings of the past few hours or days reveals the subtle inadequacy of mental function. The more obviously confused patients spend much of their time in idleness, and what they do may be inappropriate and annoying to others. Only the more automatic acts and verbal responses are performed properly, but these may permit the examiner to obtain from the patient a number of relevant and accurate replies to questions about age, occupation, and residence. Answers tend to be slow and indecisive. Orientation to the date, day, and place is frequently imprecise, often with the exact date being off by several days, the year being given as several years or one decade previous, or with the last two numbers transposed, i.e., 2002 given as 2020 (see page 441 for techniques of testing for confusion). Such patients may, before answering, repeat every question that is put to them, and their responses tend to be brief and mechanical. It is difficult or impossible for them to sustain a conversation. Their attention wanders and they constantly have to be brought back to the subject at hand. They may even fall asleep during the interview, and, if left alone, are observed to sleep more hours each day than is natural or to sleep at irregular intervals.

Frequently there are perceptual disturbances in which voices, common objects, and the actions of other persons are misinterpreted. Frank hallucinations may occur, but often one cannot discern whether these patients hear voices and see things that do not exist, i.e., whether they are hallucinating or are merely misinterpreting stimuli in the environment (illusions). Some patients are irritable and others are suspicious; in fact, a paranoid trend may be pronounced and troublesome feature of the illness. There may also be mild degrees of anemia and dysphasia and a labile affect.

As the confusion deepens, conversation becomes more difficult, and at a certain stage these patients no longer notice or respond to much of what is happening around them. Questions may be answered with a single word or a short phrase, spoken in a soft tremulous voice or whisper, or the patient may be mute. Asterixis is a common accompaniment if a metabolic or toxic encephalopathy is responsible for the confusional state. In the most advanced stages of the illness, confusion gives way to stupor and finally to coma (see Chap. 17). As these patients improve, they may pass again through the stages of stupor and confusion in the reverse order. All this informs us that at least one category of confusion is but a manifestation of the same disease processes that in their severest form cause coma.

Typical confusional states, in which impairments of alertness and attention dominate, are readily distinguished from delirium; in others, with more than the usual degree of irritability and restlessness, and perhaps a fleeting hallucination, one cannot fail to notice their resemblance to one another. Further, when a delirium is complicated by an illness that superimposes stupor (e.g., delirium tremens with pneumonia, meningitis, or hepatic encephalopathy), it may be difficult to differentiate from other acute confusional states. This explains why some psychiatrists (Engel and Romano, Lipowski) insist that there is only one disorder, which they call delirium.

Etiology The many causes of this type of confusional state are listed in Table 20-1. The most frequent are drug intoxications and metabolic encephalopathies: electrolyte imbalance, disorders of water metabolism (hypo- and hypernatremia, hyperosmolality), hypercalcemia, etc., disorders of acid-base balance, renal and hepatic failure, hyper- and hypoglycemia, septic states, and chronic cardiac and pulmonary insufficiency as well as hypertensive encephalopathy. Concussion and seizures, especially petit mal or psychomotor status, and certain focal (e.g., right parietal and temporal) cerebral lesions may also be followed by a period of confusion.

Table 20-1 Classification of delirium and acute confusional states

| Pathophysiology of Confusional States All that has been said on this subject in Chap. 17, “Coma and Related Disorders of Consciousness,” is applicable to at least one subgroup of the confusional states. In most cases no consistent pathologic change has been found because the abnormalities are metabolic and subcellular. As discussed in Chap. 2, the electroencephalogram (EEG) is almost invariably abnormal in even mild forms of this syndrome, in contrast to delirium, where the changes may be relatively minor. Bilateral high-voltage slow waves in the 2- to 4-per-second (delta) range or the 5- to 7-per-second (theta) range are the usual findings. These changes surely reflect one aspect of the central problem—the diffuse impairment of the cerebral mechanisms governing alertness and attention. |
| Delirium Clinical Features These are most perfectly depicted in the patient undergoing withdrawal from alcohol after a sustained period of intoxication. The symptoms usually develop over a period of 2 or 3 days. The first indications of the approaching attack are difficulty in concentration, restless irritability, increasing tremulousness, insomnia, and poor appetite. The patient’s sleep is troubled by unpleasant or terrifying dreams. There may be momentary disorientation, an occasional inappropriate remark, or transient illusions or hallucinations. One or several generalized convulsions often precede or initiate the delirium. |
| These initial symptoms rapidly give way to a clinical picture that, in severe cases, is one of the most colorful in medicine. There is “clouding of the sensorium,” that is, the patient is inattentive and unable to perceive all elements of his situation. He may talk incessantly and incoherently and be unable to respond. He is put to them, and their responses tend to be brief and mechanical. It is difficult or impossible for them to sustain a conversation. Their attention wanders and they constantly have to be brought back to the subject at hand. They may even fall asleep during the interview, and, if left alone, are observed to sleep more hours each day than is natural or to sleep at irregular intervals. |
| Delirium is subject to all degrees of variability, not only from patient to patient but in the same patient from day to day and even hour to hour. Further, when a delirium is complicated by an illness that superimposes stupor (e.g., delirium tremens with pneumonia, meningitis, or hepatic encephalopathy), it may be difficult to differentiate from other acute confusional states. This explains why some psychiatrists (Engel and Romano, Lipowski) insist that there is only one disorder, which they call delirium. |

This explains why some psychiatrists (Engel and Romano, Lipowski) insist that there is only one disorder, which they call delirium. |
| Pathophysiology of Confusional States All that has been said on this subject in Chap. 17, “Coma and Related Disorders of Consciousness,” is applicable to at least one subgroup of the confusional states. In most cases no consistent pathologic change has been found because the abnormalities are metabolic and subcellular. As discussed in Chap. 2, the electroencephalogram (EEG) is almost invariably abnormal in even mild forms of this syndrome, in contrast to delirium, where the changes may be relatively minor. Bilateral high-voltage slow waves in the 2- to 4-per-second (delta) range or the 5- to 7-per-second (theta) range are the usual findings. These changes surely reflect one aspect of the central problem—the diffuse impairment of the cerebral mechanisms governing alertness and attention. |
| Delirium Clinical Features These are most perfectly depicted in the patient undergoing withdrawal from alcohol after a sustained period of intoxication. The symptoms usually develop over a period of 2 or 3 days. The first indications of the approaching attack are difficulty in concentration, restless irritability, increasing tremulousness, insomnia, and poor appetite. The patient’s sleep is troubled by unpleasant or terrifying dreams. There may be momentary disorientation, an occasional inappropriate remark, or transient illusions or hallucinations. One or several generalized convulsions often precede or initiate the delirium. |
| These initial symptoms rapidly give way to a clinical picture that, in severe cases, is one of the most colorful in medicine. There is “clouding of the sensorium,” that is, the patient is inattentive and unable to perceive all elements of his situation. He may talk incessantly and incoherently and be unable to respond. He is put to them, and their responses tend to be brief and mechanical. It is difficult or impossible for them to sustain a conversation. Their attention wanders and they constantly have to be brought back to the subject at hand. They may even fall asleep during the interview, and, if left alone, are observed to sleep more hours each day than is natural or to sleep at irregular intervals. |
| Delirium is subject to all degrees of variability, not only from patient to patient but in the same patient from day to day and even hour to hour. Further, when a delirium is complicated by an illness that superimposes stupor (e.g., delirium tremens with pneumonia, meningitis, or hepatic encephalopathy), it may be difficult to differentiate from other acute confusional states. This explains why some psychiatrists (Engel and Romano, Lipowski) insist that there is only one disorder, which they call delirium. |
delirium and can hardly be distinguished from the confusional states described above.

**Pathology and Pathophysiology of Delirium**

The brains of patients who have died in delirium tremens, without associated disease or injury usually show no pathologic changes of significance. Delirium may also occur in association with a number of recognizable pathologic states, such as viral encephalitis or meningitis, encephalomyelitis, stroke, trauma, or multiple focal embolic strokes due to subacute bacterial endocarditis, cholesterol or fat embolism, or cardiac surgery. The topography of the lesions in these conditions is of particular interest. They tend to be localized in the midbrain and hypothalamus and in the temporal lobes, where they involve the reticular activating and limbic systems. Involvement of the hypothalamus probably accounts for the autonomic hyperactivity that characterizes delirium.

Electrical stimulation studies of the human cerebral cortex during surgical exploration and studies by positron emission tomography (PET) have indicated the importance of the temporal lobe in the genesis of complex visual, auditory, and olfactory hallucinations. Subthalamic and midbrain lesions may give rise to visual hallucinations that are not unpleasant and are accompanied by good insight (“peduncular hallucinosis” of Lhermitte). With pontine-midbrain lesions, there may be unformed auditory hallucinations (page 309).

The EEG may show symmetrical, generalized slow activity in the 5- to 7-per-second range, a state that rapidly returns to normal as the delirium clears. In other cases, only activity in the fast beta frequency range is seen; in milder degrees of delirium, there is usually no abnormality at all.

Analysis of several conditions conducive to delirium suggests at least three physiologic mechanisms. The withdrawal of alcohol or other sedative-hypnotic drugs, following a period of chronic intoxication, is the most common (see Chap. 43). These drugs are known to have a strong depressant effect on certain regions of the central nervous system, presumably, the depressant effects of chronic withdrawal of the drugs may be the basis of delirium. In this respect it is of interest that the symptoms of delirium tremens are the antithesis of those of alcoholic intoxication. Another mechanism is operative in the case of bacterial infections and poisoning by certain drugs, such as atropine and scopolamine, in which visual hallucinations are a prominent feature. Here the delirious state probably results from the direct action of the toxin or chemical agent on the same parts of the brain. Third, destructive lesions of the undersurfaces of the temporal lobes, as occur in herpes simplex encephalitis or severe concussive injury, may cause delirium.

Psychophysiologic mechanisms have also been postulated in the genesis of delirium. It has long been suggested that some persons are much more liable to delirium than others, but there is reason to doubt this hypothesis. Many years ago, Wolff and Curran showed that all of a group of randomly selected persons developed delirium if the causative mechanisms were strongly operative. This is not surprising, for any normal person may, under certain circumstances, experience phenomena akin to those of delirium. After a sustained period of auditory or visual stimulation, the same impressions may continue to be perceived even though the stimuli are no longer present. The whine of artillery shells may continue to be heard long after the bombardment has ceased. Also, a healthy person can be induced to hallucinate by the intravenous administration of chemicals. A relationship between the psychosis and medical illness is sought but cannot be established. The psychosis may have preceded the medical illness but was not determined by preexisting brain disease, most often Alzheimer disease, which may or may not have been obvious to the family before the onset of the complicating illness. Presumably the liability to this state is determined by preexisting brain disease, most often Alzheimer disease, which may or may not have been obvious to the family before the onset of the complicating illness. The effects of other cerebral diseases (vascular, neoplastic, demyelinating) may also have been too subtle to be appreciated by the patient or the family. All the clinical features that one observes in the acute confusional states may be present. The severity varies greatly. The confusion may be reflected only in the patient's inability to relate the history of the illness sequentially, or it may be so severe that the patient is virtually non compos mentis.

Almost any complicating illness may bring out a confusional state in an elderly person, the most common are febrile infectious diseases, especially those that resist the effects of antibiotics; trauma, notably concussive brain injuries; surgical operations, particularly those requiring general anesthesia and pre- and postoperative medication; even small amounts of pain or sedative medications used for any cause; and congestive heart failure, chronic respiratory disease, and severe anemia, especially pernicious anemia. Often it is difficult to determine which of several possible factors is responsible for the patient’s confusion, and there may be more than one. In a cardiac patient, for example, there may be fever, a marginally reduced cerebral blood flow, intoxication with one or more drugs, and electrolyte imbalance. The same may be true of a patient in a postoperative confusional state, in which a number of factors such as fever, infection, dehydration, and drug effects may be incriminated. In a study of 1218 postoperative patients by Moller and colleagues, increasing age was by far the most important association with confusion that persisted for weeks and months after an operation; but a number of factors—including the duration of anesthesia, need for a second operation soon after the first, postoperative infection, and respiratory complications—were each predictive of cognitive difficulty in the days after the procedure. Alcoholism and withdrawal effects may further complicate the problem. A more extensive review of this subject has been written by Kasien and Rosser (see also page 881).

When such patients recover from the medical or surgical illness, they usually return to their premorbid state, though their shortcomings, now drawn to the attention of the family and physician, may be more obvious than before. In this case, families will date the onset of a dementia to the time of the medical illness and minimize the previous decline in cognition.

**Confusional States Complicating Focal and Diffuse Cerebral Disease**

Confusional States due to Focal Cerebral Lesions

A variety of cerebral diseases may be associated with confusional states. Among these are meningitis, encephalitis, disseminated intravascular coagulation, tumors, and trauma. As remarked above, focal lesions (most often infarcts) of the right cerebral hemisphere may evoke an acute confusional state. Such states have been described with strokes in the territory of the right middle cerebral artery (Mesulam et al; Caplan et al; Mori and Yamadori); mainly the infarcts have involved the posterior parietal lobe or inferior frontotemporal regions, but they have also occurred with strokes in the territory of one posterior cerebral artery. An acute agitated delirium has been noted at one time or another with lesions involving the fusiform and lingual gyri and calcarine cortex (Horenstein et al); the hippocampal, and lingual gyr (Medina et al); or the middle temporal gyrus (Mori and Yamadori). Of course, there may be elements of confusion with stroke in almost any cerebral territory, but with the aforementioned lesions the confusional state has occasionally been unattended by other paralytic motor and sensory disorders.

Confusional States Complicating Diffuse Cerebral Disease: Beclouded Dementia

Apart from the aforementioned types of focal cerebral disease, there are many elderly patients newly acquired state of mental confusion. Presumably the liability to the state is determined by preexisting brain disease, most often Alzheimer disease, which may or may not have been obvious to the family before the onset of the complicating illness. The effects of other cerebral diseases (vascular, neoplastic, demyelinating) may also have been too subtle to be appreciated by the patient or the family. All the clinical features that one observes in the acute confusional states may be present. The severity varies greatly. The confusion may be reflected only in the patient's inability to relate the history of the illness sequentially, or it may be so severe that the patient is virtually non compos mentis.
The first step in diagnosis is to recognize that the patient is confused. This is obvious in most cases, but, as pointed out above, the mildest forms of confusion, particularly when some other alteration of personality is prominent, may be overlooked. In these mild forms, a careful analysis of the patient's thought processes, as detailed in the history and the patient's personal life are obtained, will usually reveal an incoherence. A subtle disorder of orientation may be betrayed by an incorrect response regarding dates (off by more than one day of the month or day of the week), or in misnaming the hospital. Digit span can be performed (normally 7) and backward (normally 5), spelling the word world backward, reciting the months of the year in reverse order, and serial subtraction of 3s from 30 or 7s from 100 are useful bedside tests of the patient's capacity for attentiveness and sustained mental activity. Another is his efficiency in performing dual tasks such as tapping alternately with each hand while reading aloud. Memory of recent events is one of the most delicate tests of adequate mental function and is readily accomplished by having the patient relate the details of entry to the hospital; ancillary examinations; naming the president, vice president, and mayor; and summarizing major current events, etc., as outlined in Chap. 21.

Once it is established that the patient is confused, the differential diagnosis must be made between delirium, an acute confusional state associated with psychomotor underactivity, a beclouded dementia, and a confusional state that complicates focal cerebral disease. This is done by taking into account the degree of the patient's alertness, wakefulness, psychomotor and hallucinatory activity, and disturbances of memory and impulse as well as the presence or absence of asterixis or myoclonus or signs of overactivity of the autonomic nervous system and of generalized or focal cerebral disease.

At times, a left hemispheric lesion causing a mild Wernicke aphasia resembles a confusional state in that the stream of thought, as judged by verbal output, is incoherent. The prominence of paraphasias and neologisms in spontaneous speech, difficulties in auditory comprehension, and normal nonverbal behavior mark the disorder as aphasic in nature.

The distinction between an acute confusional state and dementia may be difficult at times, particularly if the mode of onset and the course of the mental decline are not known. The patient with an acute confusional state is said to have a "clouded sensorium" (a somewhat ambiguous term referring to a symptom complex of inattention, disorientation, perhaps drowsiness, and an inclination to inaccurate perceptions and sometimes to hallucinations and delusions), whereas the patient with dementia usually has a clear sensorium. In the demented patient, there are usually a number of "frontal-release" signs such as grasping, groping, sucking, and parataxic rigidity of the limbs. However, some demented patients are as beclouded and bewildered as those with confusional psychosis, and the two conditions are distinguishable only by differences in their mode of onset and clinical course. This suggests that the affected parts of the nervous system may be the same in both conditions. As indicated earlier, schizophrenia and manic-depressive psychosis can usually be separated from the confusional states by the presence of a clear sensorium and relatively intact memory function.

Once a case has been appropriately classified, it is important to determine its clinical associations [Table 20-1]. A thorough medical and neurologic examination, computed tomographic or magnetic resonance imaging of the brain, and—in cases with fever or with no obvious cause—further laboratory workup should be performed. The medical, neurologic, and laboratory findings (including measurements of Na, Ca, CO₂, BUN, NH₃, calcium, glucose, "toxic screen," etc.) determine the underlying disease and its treatment, and they also give information concerning prognosis. In the neurologic examination particular attention should be given to the presence or absence of focal neurologic signs and to asterixis, myoclonus, and seizures.

Care of the Delirious and Confused Patient

The primary therapeutic effort is directed to the control of the underlying medical disease. Other important objectives are to quiet the patient and protect him from injury. A nurse, attendant, or member of the family should be with the patient at all times if this can be arranged. Depending on the degree of restlessness and hyperactivity, a locked room, screened windows that cannot be opened by the patient, and a low bed are desirable. It is often better to let such a patient walk about the room than to tie him in bed, which may increase his fright or excitement and cause him to struggle to the point of exhaustion and collapse. The less active patient can usually be kept in bed by side rails, wrist restraints, or a restraining sheet or vest. The patient should be permitted to sit up or walk about the room part of the day unless this is contraindicated by the primary disease.

All drugs that could possibly be responsible for the acute confusional state or delirium should be discontinued if this can be done safely. In particular, these include sedatives, antianxiety, narco, anticholinergic, antispasmodic, and corticosteroid medications, L-dopa, metoclopramide (Reglan), and cimetidine (Tagamet) as well as antidepressants, antihypertensives, anticonvulsants, and antibiotics. Despite the need to be sparing with medications in these circumstances, haloperidol, quetiapine, and risperidone are helpful in calming the agitated and hallucinating patient, but they too should be used in the lowest effective doses. Another exception is alcohol or sedative withdrawal, in which chloralazepoxide (Librium) is the drug favored by most physicians, but chloral hydrate, lorazepam, and diazepam are trustworthy and equally effective sedatives if given in full doses (see Chap. 42). In delirious patients, the purpose of sedation is to assure rest and sleep, avoid exhaustion, and facilitate nursing care, but one must be cautious in attempting to suppress delirium completely. Warm baths are also effective in quieting the delirious patient, but few hospitals have facilities for this valuable method of treatment.

It would seem obvious that attempts should be made to preempt the onset of confusion (beclouded dementia) in the hospitalized elderly patient. Inouye and colleagues have devised an intervention program that includes frequent reorientation to the surroundings, mentally stimulating activities, ambulation at least three times a day or similar exercises when possible, and attention to the need for visual and hearing aids in patients with these impairments. They recorded a 40-percent reduction in the frequency of a confusional state in patients who did not receive this type of attention and preventive strategies of the type they outline are most important in the elderly, even those without overt dementia, and they must be assiduously applied by nurses and ancillary staff.

Finally, the physician should be aware of the benefit of many small therapeutic measures that allay fear and suspicion and reduce the tendency to hallucinations. The room should be kept dimly lighted at night and, if possible, the patient should not be moved from one room to another. Every procedure should be explained to the patient, even such simple ones as the taking of blood pressure or temperature. The presence of a member of the family may help the patient to maintain contact with reality.

It may be some consolation and also a source of professional satisfaction to remember that most confused and delirious patients recover if they receive competent medical and nursing care. The family should be reassured on this point but forewarned that improvement may take several days or more. They must also understand that the patient's abnormal behavior is not willful but rather symptomatic of a brain disease. (See also Chap. 42 and Chap. 43 for specific aspects of management of delirium due to withdrawal of alcohol and other sedative-hypnotic drugs.)

Section 5

INCOORDINATION AND OTHER DISORDERS OF CEREBELLAR FUNCTION

Physicians sooner or later discover, through clinical experience, the need for special competence in assessing the mental faculties of their patients. They must be able to observe with detachment and complete objectivity the patient's intelligence, memory, judgment, mood, character, and other attributes of personality in much the same fashion as they observe the patient's nutritional state and the color of the mucous membranes. The systematic examination of these intellectual and affective functions permits the physician to reach certain conclusions regarding the patient's mental status and its relationship to his illness. Without such data, one cannot judge the reliability of the history, and errors will be made in the diagnosis and treatment of the patient's neurologic or psychiatric disease.

Perhaps the content of this section will be more clearly understood if we anticipate a few of the introductory remarks to the section on psychiatric diseases. The main thesis of the neurologist is that mental and physical functions of the nervous system are simply two aspects of the same neural process. Mind and behavior both have their roots in the self-regulating, goal-seeking activities of the organism, the same ones that provide impulse to all forms of mammalian life. The prodigious complexity of the human brain permits, to an extraordinary degree, the solving of difficult problems, the capacity for remembering past experiences and casting them in a symbolic language that can be written and read, and the planning of events that have yet to take place. Somehow there emerges in the course of these complex cerebral functions a more complete and continuous awareness of one's self and the operation of one's psychic processes than is found in any other species. It is this continuous inner consciousness of one's self and one's past experiences and ongoing cognitive activities that is called mind. Any separation of the mental from the observable behavioral aspects of cerebral function is illusory. Biologists and psychologists have reached this view by placing all protoplasmic activities of the nervous system (growth, development, behavior, and mental function) on a continuum and noting the inherent purposiveness and creativity common to all of them. The physician is persuaded of the truth of this view through daily clinical experience, in which every known aberration of behavior and intellect appears at some time or other as an expression of cerebral disease. Further, in many brain diseases one witnesses parallel disorders of the patient's behavior and the introspective awareness of his own psychic capacities.

The reader will find that in this section of the book, Chapter 20 and Chapter 21 are concerned with common disturbances of the sensorium and of cognition, which stand as cardinal manifestations of certain cerebral diseases. The most frequent of these are delirium and other acute confusional states as well as disorders of learning, memory, and other intellectual functions. A consideration of these abnormalities—indicative, as a rule, of a diffuse disturbance of cerebral function—leads naturally to an examination of the symptoms consequent upon focal cerebral lesions (Chap. 22), and of derangements of language (Chap. 23), which fall between the readily localizable functions of the cerebrum and those that cannot be localized.
Increasingly, as the number of elderly in our population rises, the neurologist is consulted because an otherwise healthy person begins to fall mentally and lose his capacity to function effectively at work or in his household. This may indicate the development of a degenerative brain disease, a brain tumor, multiple strokes, a chronic subdural hematoma, chronic drug intoxication, chronic meningoencephalitis (such as caused by acquired immunodeficiency syndrome or syphilis), normal-pressure hydrocephalus, or a depressive illness. Formerly, when there was little that could be done about these clinical states, no great premium was attached to diagnosis. But modern medicine offers the means of treating several of these conditions and in some instances of restoring the patient to normal mental competence. Moreover, a number of modern diagnostic technologies now allow earlier recognition of the underlying pathologic process, improving the chances of recovery or preventing its progression.

**DEFINITIONS**

The definitions of normal and abnormal states of mind have already been considered in Chap. 20. There it was pointed out that the term dementia denotes a deterioration of intellectual, or cognitive, function, with little or no disturbance of consciousness or perception. In current neurologic parlance the term is commonly used to designate a syndrome of failing memory and impairment of other intellectual functions due to chronic progressive degenerative disease of the brain. Such a definition is too narrow. The term more accurately includes a number of closely related syndromes characterized not only by intellectual deterioration but also by certain behavioral abnormalities and changes in personality. Moreover, it is not entirely logical to set apart any one constellation of cerebral symptoms on the basis of the speed of onset, rate of evolution, severity, or duration. Alternatively, we would propose that there are several states of dementia of differing causes and mechanisms and that a degeneration of widely distributed systems of cerebral neurons, albeit common, is only one of the many causes. Therefore it is more correct to speak of the dementias or the dementing diseases.

To understand the phenomenon of intellectual deterioration, it is helpful to have some idea of how intellectual functions, in particular intelligence and memory, are normally organized and sustained and the manner in which deficits in these functions relate to diffuse and focal cerebral lesions. The neurology of intelligence is considered first, as a prelude to a discussion of the dementias, and the neurology of memory further on, in relation to the clinical amnestic syndromes.

**THE NEUROLOGY OF INTELLIGENCE**

Intelligence, or intelligent behavior, has been variously defined as a “general mental efficiency,” as an “innate cognitive ability,” or as “the aggregate or global capacity of an individual to act purposefully, to think rationally, and to deal effectively with his environment” (Wechsler). It is global because it characterizes an individual’s behavior as a whole; it is an aggregate in the sense that it is composed of a number of independent and qualitatively distinguishable cognitive abilities.

As every educated person knows, intelligence has something to do with normal cerebral function. It is also apparent that the level of intelligence differs widely from one person to another, and members of certain families are exceptionally bright and intellectually accomplished while members of other families are just the opposite. If properly motivated, intelligent children excel in school and score high on intelligence tests. Indeed, the first intelligence tests, devised by Binet and Simon in 1905, were for the purpose of predicting scholastic success. The term intelligence quotient, or IQ, was introduced by Terman in 1916; it denotes the figure that is obtained by dividing the subject’s mental age (as determined by the Binet-Simon scale) by his chronological age (up to the fourteenth year) and multiplying the result by 100. The IQ correlates with achievement in school and eventual success in professional work. IQ increases with age up to the fourteenth to sixteenth year and then remains stable, at least until late adult life. At any given age a large sample of normal children attain test scores that range in conformity with the normal, or Gaussian, distribution.

The original studies of pedigrees of highly intelligent and mentally inferior families, which revealed a striking concordance between parent and child, lent support to the idea that intelligence is to a large extent inherited. However, it became evident that the tests being used depended also on skill with words and verbal relationships and on specific cultural experiences provided to children by educated parents, and that the tests were less reliable in identifying children who were talented but never had similar educational opportunities. This led to the widespread belief that intelligence tests are only achievement tests and that environmental factors fostering high performance are the important factors determining intelligence. Neither of these views is entirely correct. Studies of monzygotic and dizygotic twins raised in the same or different environmental conditions have put the matter in a clearer light. Identical twins reared together or apart are more alike in intelligence than nonidentical twins brought up in the same home (see reviews of Willerman, of Shields, and of Slater and Cowie). A more recent study of elderly twins, by McLean and colleagues, has shed further light on the issue; even in twins who were above 80 years of age, a substantial part (an estimated 62 percent) of cognitive performance could be accounted for by genetic traits. These findings suggest that life experience alters intelligence in only a limited way. There can be no doubt, therefore, that genetic endowment is the more important factor, a view that has long been championed by Piercy and more recently by Hermstein and Murray (The Bell Curve). However, there is also convincing evidence that early learning can modify the level of ability that is finally attained. The latter should be looked upon not as the sum of genetic and environmental factors but as the product of the two. Moreover, it is generally appreciated that nonscholastic achievement or success is governed by a number of factors other than intellectual ones, such as a readiness to learn, interest, persistence, and ambition or motivation—factors that vary considerably from person to person and are not measured by tests of intelligence. Not surprisingly, severe malnutrition in utero or early-life exposure to lead and other toxins have a detrimental effect on brain weight and IQ.

As to the genetic mechanisms involved in the inheritance of intelligence, very little is known. Based on the excess of males with mental retardation, the common inheritance of mental retardation in an X-linked pattern, and the somewhat different patterns of subtest performance between males and females (males perform better on subtests of spatial ability and certain mathematical tasks), Lehke has proposed that genes coding for intelligence reside on the X chromosome. This view has received support from Turner and his associates on the basis of their extended study of families in which the sole manifestation of an X-linked disorder was a nonspecific mental retardation. Turner has suggested that the male is more likely to be affected by advantageous or aberrant genes on a single X chromosome, while the female benefits from the mosaic provided by two X chromosomes. Turner also alludes to pedigrees in which high intelligence segregates to certain individuals through an X-linked pattern. Further study will determine the validity of this view and its contribution to our understanding of what will certainly prove to be a polygenic inheritance of intellectual traits.

One would think that neurologic structure and function would correlate in some way with intelligence; but except in the pathologically retarded (Chap. 39), such an association has been difficult to document. Brain weight has a weak correlation with IQ. Only laboratory measures of vigilance and facility of sensory registration (speed of motor responses and rapid recognition of differences between lines, shapes, or pictures) have definite but modest correlations with IQ.

As to psychologic theories of intelligence, two have traditionally held sway. One is the two-factor theory of Spearman, who noted that all the separate tests of cognitive abilities correlated with each other, suggesting that a general factor (g) enters into all performance. Since none of the correlations between subtests...
The most recent elaboration of Thurstone's multifactorial theory of intelligence is that of Gardner. He recognizes six categories of high-order cerebral function: the linguistic (encompassing all language functions); the musical (including composition and performance); the logical-mathematical (the ideas and works of mathematicians); the spatial (including artistic talent and the creation of visual impressions); the bodily-kinesthetic (including dance and athletic performance); and the personal (consciousness of self and others in social interactions). He refers to each of these as an intelligence, defined as the ability to solve problems or resolve difficulties within the particular field, and to be creative. The following lines of evidence are marshaled in support of this parceling of what are really separable skills and abilities: (1) each of these abilities may be developed to an exceptionally high level in certain individuals, constituting virtuosity or genius; (2) each can be destroyed or spared in isolation as a consequence of a lesion in a certain part of the nervous system; (3) in certain individuals, i.e., in prodigies, special competence in one of these abilities is evident at an unusually early age; (4) in the autistic mentally retarded, one of these abilities may be spared (idiot savant). Each of these abstracted entities is genetic but the full development of each is influenced by environmental factors.

There are only limited data regarding the highest levels of intelligence identified as genius. Terman and Osgood's longitudinal study of 1500 California school children, who were initially tested in 1921, supported the idea that an extremely high IQ predicted future scholastic accomplishments (though not necessarily occupational success). On the other hand, most individuals recognized as geniuses have been especially skilled in one domain—such as painting, linguistics, music, chess, or mathematics—and such “domain genius” is not necessarily predicated on IQ, although certain individuals display cross-modal superiorities, for example, in mathematics and music.

Concerning the way in which intelligence develops, the most widely known theory is that of Piaget, who proposed that this is accomplished in discrete stages related to age: sensorimotor, from 0 to 2 years; preconceptional thought, from 2 to 4 years; intuitive thought, from 4 to 7 years; concrete operations (conceptualization), from 7 to 11 years; and finally the period of “formal operations” (logical or abstract thought), from 11 years on. This scheme implies that the capacity for logical thought, developing as it does according to an orderly timetable, is coded in the genes. Simply one can recognize these states of intellectual development in the child, but Piaget's theory has been criticized as being too anecdotal and lacking the quantitative validation that could be derived only from studies of a large normal population. Further, it does not take into account the individual's special abilities, which do not develop and reach their maximum at the same time as the more general intellectual capacities.

One would suppose that in neurology, where one is exposed to so many diseases affecting the cerebrum, it might be possible to verify one of these several theories of intelligence and to determine its anatomy. Presumably the g factor of intelligence would be maximally impaired by diffuse lesions, in proportion to the mass of brain involved (mass-action principle of Lashley). Indeed, according to Chapman and Wolff, there is a correlation between the volume of tissue lost and a general deficit of cerebral function. Others have disagreed, claiming that no universal psychologic deficit can be recognized with lesions affecting particular parts of the brain. Probably the truth lies between these two divergent points of view. According to Tomlinson and colleagues, who studied the effects of vascular lesions in the aging brain, lesions that involve more than 50 mL of tissue cause some general reduction in performance, especially in speed and capacity to solve problems. Piercy, on the other hand, found positive correlations only between specific intellectual deficits and lesions of particular parts of the left and right hemispheres. (These are discussed in Chap. 22.) It is surprising that lesions of the frontal lobes, and particularly the prefrontal regions, which so profoundly disorder planning and “executive” functions, do not measurably affect IQ except in subtests specific to these skills.

The authors conclude from personal experience and from evidence provided by neurolologic studies that intelligence is a gestalt of multiple primary abilities, each of which seems to be inherited and each of which has a separate but as yet poorly delineated anatomy. We would disagree with Thurstone and with Gardner that these special abilities are of equivalent rank with regard to what is generally considered as “intelligence” and would attach a disproportionate importance to some of them (linguistic and mathematical and perhaps spatial-dimensional abilities). These last abilities are integral to ideation and problem solving and are accomplished by forming associations with a previously established informational skill, which is largely absent in the mentally retarded and is lost early in dementing diseases. Also, we would insist that retentive memory and capacity to learn constitute a cognitive entity with its own neuroanatomic localization. The relationships of some of these special abilities have been thoughtfully analyzed by Luria (see the section on frontal lobes in Chap. 22). Neurologic data do not exclude the possibility of a g factor—one that is unavoidable measured in many different tests of cerebral function. It is expressed in thinking and abstract reasoning and is operative only if the connections between the frontal lobes and other parts of the brain are intact. Attention, drive, and motivation are non-cognitive psychologic attributes of fundamental importance, the precise anatomy and physiology of which remain to be identified. A current account of the subject of IQ and intelligence can be found in the monograph by Mackintosh.

THE NEUROLOGY OF DEMENTIA

Dementia is a syndrome, consisting of a loss of several separable but overlapping intellectual abilities and presenting in a number of different combinations. These varied constellations of intellectual deficits constitute the preeminent clinical abnormalities in several cerebral diseases and are sometimes (e.g., in Alzheimer disease) virtually the only abnormalities, in which case the syndrome is virtually equivalent to the disease. The most common types of dementing diseases and their relative frequency are listed in Table 21.1.

Table 21-1 The common types of dementing diseases and their approximate frequencies

What is noteworthy about the figures in this table is the apparently high level of accuracy of diagnosis. Rather consistently, postmortem examination confirms the diagnosis in about 80 percent of cases or a larger percentage when research criteria are used for the clinical diagnosis of Alzheimer disease ( Table 21.2). In many cases, the degenerative diseases can be differentiated by one or two characteristic clinical features, but these distinctions may be difficult to discern early in the disease process. In particular, a small proportion of patients thought to have Alzheimer disease are found to have multi-infant dementia or a combination of the two disorders. Less often, they are found to have other types of cerebral atrophy, such as progressive supranuclear palsy, Pick, Huntington, Parkinson, or Lewy-body disease; or a variety of other processes. Of special importance is the fact that approximately 10 percent of patients who are referred to a neurologic center with a question of dementia prove to have a potentially reversible psychiatric or metabolic disorder simulating degenerative brain disease.
Dementia due to Degenerative Diseases

The earliest signs of dementia due to degenerative disease may be so subtle as to escape the notice of the most discerning physician. An observant relative of the patient or an employer may become aware of a certain lack of initiative or lack of interest in work, a neglect of routine tasks, or an abandonment of pleasurable pursuits. Initially, these changes may be attributed to fatigue or boredom. More often, gradual development of forgetfulness is the most prominent early symptom. Proper names are no longer remembered, to a far greater extent than can be attributed to so-called benign senescent forgetfulness (see page 641). Difficulty in balancing a checkbook and making change becomes evident. The purpose of an errand is forgotten, appointments are not kept, a recent conversation or social event has been forgotten. The patient may ask the same question repeatedly, having failed to retain the answers that were previously given.

Later it becomes evident that the patient is easily distracted by every passing incident. No longer is it possible to think about or discuss a problem with customary clarity or to comprehend all aspects of complex situations. The patient's judgement and ability to make proper deductions and inferences from given premises are greatly reduced. One feature of a situation or some relatively unimportant event may become a source of unreasonable concern or worry. Tasks that require several steps cannot be accomplished, and all but the simplest directions cannot be followed. The patient may get lost, even along habitual routes of travel. Day-to-day events are not recalled, and perseveration or impersistence in speech, action, and thought becomes evident.

In yet other instances, an abnormality may be in the nature of emotional instability, taking the form of unreasonable outbursts of anger, easy tearfulness, or aggressiveness. Frequently a change in mood becomes apparent, deviating more toward depression than elation. Apathy is common. Some patients are grumpy and irascible; a few are cheerful and factitious. The direction of the mood change is said to depend on the previous personality of the patient rather than on the character of the disease, but one can think of glaring exceptions to this dictum. Excessive liability of mood may also be observed—for example, easy fluctuation from laughter to tears on slight provocation.

A few patients come to the physician with physical complaints, the most common being dizziness, a vague mental "fogginess," and nondescript headaches. The patient's inability to give a coherent account of his symptoms bears witness to the presence of a dementia. Sometimes the mental failure is brought to light more dramatically by a severe confusional state attending a febrile illness, a concussive head injury, an operative procedure, or the administration of some new medicine, as discussed in Chap. 20. As noted there, the family may mistakenly date an abrupt onset of dementia to the time of the intercurrent illness.

Loss of social graces and indifference to social customs occur, but usually later in the course of illness. Judgment becomes impaired, early in some, late in others. At certain phases of the illness, suspiciousness or frank paranoia may develop. Visual and auditory hallucinations, sometimes quite vivid in nature, may be added. Wandering, pacing, and other aimless activities are common in the intermediate stage of the illness, while other patients sit placidly for hours. As a rule, these patients have little or no realization of such changes within themselves; i.e., they lack insight.

As the condition progresses, all intellectual faculties are impaired; but in the commonest degenerative diseases, memory is most affected. Up to a certain point in the illness, memories of the distant past are relatively well retained at a time when more recently acquired information has been lost (Ribot's law). Eventually patients also fail to retain remote memories, to recognize their relatives, or even to recall the names of their children. Apraxias and agnosias may be prominent, and these defects may alter the performance of the simplest tasks, such as preparing a meal, setting the table, or even using the telephone or a knife and fork, dressing, or walking.

Language functions tend to be impaired almost from the beginning of certain forms of dementia. Loss is the capacity to understand nuances of the spoken and written word, as are the suppleness and spontaneity of verbal expression. Vocabulary becomes restricted and conversation is rambling and repetitious. The patient gropes for proper names and common nouns and no longer formulates ideas with well-constructed phrases or sentences. Instead, there is a tendency to resort to cliches, stereotyped phrases, and expletives, which may hide the underlying defect during conversation. Paraphasias and difficulty in comprehending complex conversations are almost universal abnormalities. Subsequently, more severe degrees of aphasia, dysarthria, palilalia, and echolalia may be added to the clinical picture.

As pointed out by Chapman and Wolff, there is loss also of the capacity to express feelings, to suppress impulses, and to tolerate frustration and restrictions. If the patient is restrained, disagreeable behavior, petulance, agitation, shouting, and whining may occur. Nighttime confusion and inversion of the normal sleep pattern as well as increased confusion and restlessness in the early evening ("sundowning") are common.

It would be an error to think that the abnormalities in the atrophic-degenerative dementing diseases are confined to the intellectual sphere. The appearance of the patient and the physical examination yield highly informative data. The first impression is often revealing; the patient may be unkempt and unshaved. He may look bewildered, as though lost, or his expression may be vacant, and he does not maintain a lively interest or participate in the interview. There is a kind of psychic inertia. Deference to a spouse or child when the patient is unable to answer the examinee's questions is characteristic. All movements are slightly slow, sometimes suggesting an oncoming Parkinson syndrome.

Sooner or later gait is characteristically altered (Chap. 7). Passive movements of the limbs encounter a fluctuating resistance, or paratonia (gegenhalten). Mouthing movements and a number of abnormal reflexes—grasping and sucking (in response to visual as well as tactile stimuli), inability to inhibit blink on tapping the glabellum, snout reflex (protrusion of the lips in response to perioral tapping), biting or jaw clamping (bulldog) reflex, corneomandibular reflex (jaw clenching when the cornea is touched), and palmothenar reflex (retraction of one side of the mouth and chin caused by contraction of the mentalis muscle when the cornea is stroked)—all occur with increasing frequency in the advanced stages of the dementia. Many of these abnormalities are considered to be motor disinhibitions that appear when the premotor areas of the brain are involved.

In the later stages, physical deterioration is inexorable. Food intake, which may be increased at the onset of the illness, sometimes to the point of gluttony, is in the end reduced, with resulting emaciation. Any febrile illness, drug intoxication, or metabolic upset is poorly tolerated, leading to severe confusion, stupor, or coma—an indication of the precarious state of cerebral compensation (see "Bclouded Dementia," page 441). Finally, these patients remain in bed most of the time, oblivious of their surroundings, and succumb to pneumonia or to some other intercurrent infection. Some patients, should they not succumb in this way, become virtually decorticate—totally unaware of their environment, unresponsive, mute, incontinent, and, in the end, adopting a posture of paraplegia in flexion. They lie with their eyes open but do not look at food. Drink and food are no longer requested but are swallowed if placed in the mouth. The term persistent vegetative state is appropriately applied to these patients, although it was originally devised to describe patients in this same state after cardiac arrest or head injury. Occasionally diffuse choreothetotic movements or random myoclonic jerking can be observed, and seizures occur in a few advanced cases. Pain or an uncomfortable posture goes unheeded. The course of Alzheimer disease extends for 5 to 10 years or more from the time that the memory defect becomes evident.

Naturally, every case does not follow the exact sequence outlined above. Not infrequently a patient is brought to the physician because of an impaired facility with

language. In other patients, impairment of retentive memory with relatively intact reasoning power may be the dominant clinical feature in the first months or even years of the disease; or low impulsivity (apathy and abulia) may be the most conspicuous feature, resulting in obscurcation of all the more specialized higher cerebral functions. Gait disorder, though usually a late development, may occur early, particularly in patients in whom the dementia is associated with or superimposed on Parkinson disease, normal pressure hydrocephalus, cerebellar ataxia, or progressive supranuclear palsy. Insofar as the several types of degenerative disease do not affect discrete parts of the diencephalon and neocortex equally, it is not surprising that the symptomatology varies; moreover, frank psychosis with delusions and hallucinations may be woven into the dementia. These variations and others are discussed more fully in Chap. 39.

The aforementioned alterations of intellect and behavior are the direct consequences of neuronal loss in certain parts of the cerebral cortex. In other words, the symptoms are the primary manifestations of neurologic disease. However, some symptoms are secondary; i.e., they may represent the patient's reaction to his mental incapacity. For example, a demented patient may seek solitude to hide his affliction and thus may appear to be asocial or apathetic. Again, excessive orderliness may be an attempt to compensate for failing memory; apprehension, gloom, and irritability may reflect a general dissatisfaction with a necessarily restricted life. According to Goldstein, who has written about these "catastrophic reactions," as he called them, even patients in a state of fairly advanced deterioration are still capable of reacting to their illness and to persons who care for them.

In the early and intermediate stages of the illness, special psychologic tests aid in the quantitation of some of these abnormalities, as indicated in the latter part of this chapter.

Frontotemporal Dementia As indicated above, not all degenerative dementias have a uniform mode of onset and clinical course. Several clinical variants have long been recognized and in recent years; three of them—frontotemporal dementia, primary progressive aphasia, and semantic dementia—have been subclassed under a newly defined category, frontotemporal dementia. Two recent studies on the clinical diagnostic criteria for these syndromes were published relatively recently, although not all writings on this subject are in agreement (see Moris).

The most common clinical syndrome is characterized by features that would be expected of diffuse cortical degeneration of the frontal lobes (see also Chap. 23) early personality changes, particularly apathy or disinhibition, euphoria, perseveration in motor and cognitive tasks, ritualistic and repetitive behaviors, laconic speech leading to mutism—all with relative preservation of memory and orientation. With anterior temporal lobe involvement, hyperorality, excessive smoking or overeating occur and there may be added anxiety, depression, and anomia. Diminished capacity for abstraction, attention, planning, and problem solving may be observed as the degenerative process continues.

Primary progressive (nonfluent) aphasia is a highly circumscribed syndrome, characterized by effortful speech,agrammatism, and impairment of reading and writing, with relative preservation of the understanding of the meaning of words. Such aphasic syndromes may persist in isolation for several years before other features of certain degenerative dementias become evident. Semantic dementia, the least is defined of the three syndromes. It is said to be characterized by a fluent aphasia in which impaired semantic memory causes severe anomia and impaired word comprehension.

Certainly frontotemporal dementia, however, it is defined, does not have a unique pathology; the same degenerative diseases that cause primary dementia (prostate Alzheimer but also Pick and Lewy-body disease) also underlie so-called frontotemporal dementia. Furthermore, dementias, in which language problems are early and preeminent, have long been known to result from Pick or Alzheimer disease and at other times to have an ambiguous pathology, i.e., an ill-defined neuronal loss and gliosis. It is specifically to this latter type of nonobstructive pathologic change that the term "frontotemporal dementia" is now being applied by some authors, and this at least in part follows from the realization that is not so prominent as a criterion for separation of clinical and pathologic grounds from Alzheimer disease. Current opinion supports the separation of one subgroup of cases on the basis of a heritable frontotemporal dementia; these and the sporadic cases share the pathologic features of cell loss, microvacuolation of the frontal and temporal cortex, gliosis, and the ubiquitous deposition of tau protein. A separate group is similar in clinical presentation but displays Pick bodies as well as deposition of tau (Neary et al; Morris).

It is evident that a wide variety of pathologic entities underlie the clinical conditions subsumed under the rubric of fronto-temporal dementia; moreover, a full clinical classification of this presumed entity remains to be completed. (See also Chap. 39.)

Subcortical Dementia McHugh, who introduced the concept of subcortical dementia, pointed out that the dementias of certain predominantly basal ganglionic diseases such as primary progressive supranuclear palsy, Huntington chorea, and Parkinson disease, though similar to one another, are different in several respects from the cortical dementia of Alzheimer disease. The former diseases, in addition to the obvious disorders of motility and involuntary movements, are characterized by lesser degrees of forgetfulness, slowed thought processes, lack of initiative, and depression of mood. Relatively spared are vocabulary, naming, and praxis. By contrast, the "cortical dementias" (exemplified by Alzheimer disease) are distinguished by more severe disturbances of memory, language, and calculation, prominent signs of apraxia and agnosia, and impaired capacity for abstract thought.

The pathologic changes underlying the subcortical dementias predominate in the basal ganglia, thalamus, rostral brainstem nuclei, and the ill-defined projections from these regions to the cortex, particularly of the frontal lobes.

Certain authors, notably Mayeux and Stern and their colleagues as well as Tierney and coworkers, have been critical of the concept of subcortical dementia. They have argued that the distinctions between cortical and subcortical dementias are not fundamental and that any differences between them are probably attributable to differences in the relative severity of the processing of the dementias. Nonetheless, a number of recent studies do indeed indicate that the constellations of cognitive impairments in the two groups of dementias differ along the lines indicated above (Brandt et al; Pitton et al).

One of the problems with the concept of subcortical dementia is the name itself, implying as it does that symptoms of dementia are attributable to lesions confined to subcortical structures. Anatomically, none of the neurodegenerative dementias is strictly cortical or subcortical. The attribution of dementia to subcortical gliosis, for example, has always proved to be incorrect; invariably there are cortical neuronal changes as well. In a similar way, the changes of Alzheimer disease may extend well beyond the cerebral cortex, involving the striatum, thalamus, and even cerebellum. Also, functionally, it is unlikely that the symptoms of dementia are due to the basal ganglionic lesions themselves. More likely these lesions produce their effects by interrupting neural links to the frontal and other parts of the cerebral cortex. McHugh has suggested, and we would concur, that dementia without aphasia or apraxia is a more apt term than subcortical dementia for the dementia associated with basal ganglionic-thalamic disease.

Pathology and Pathogenesis of Dementia

Attempts to relate the impairment of particular intellectual functions to lesions in certain parts of the brain have been, with a few notable exceptions, unsuccessful. Two types of difficulty have obstructed progress in this field. First, there is the problem of defining and analyzing the nature of the so-called intellectual functions. Second, the pathologic anatomy of the dementing diseases often is so diffuse and complex that it cannot be fully localized and quantitated. Memory impairment, which is a constant feature of most dementias, may occur with extensive disease in several different parts of the cerebrum. Yet it is important to note that the integrity of certain discrete parts of the diencephalon and infralimbic parts of the temporal lobes is more fundamental to the cognitive and retentive memory than is the rest of the brain. Impairment of language function is closely associated with disease of the dominant cerebral hemisphere, particularly the perisylvian parts of the frontal, temporal, and parietal lobes. Loss of capacity for reading and calculation is related to lesions in the posterior part of the left (dominant) cerebral hemisphere; loss of use of tools and imitation of gestures (apraxias) is related to loss of tissue in the dominant parietal region. Impairment in drawing or constructing simple and complex figures with blocks, sticks, picture arrangements, etc., is observed with parietal lobe lesions, more often with right-sided (nondominant) than with left-sided ones. And problems with modality of behavior and stability of personality are generally related to frontal lobe degeneration. Thus, the clinical picture resulting from cerebral disease depends in part on the extent of the lesion, i.e., the amount of cerebral tissue destroyed, and in part on the region of the brain that bears the brunt of the pathologic change.

Dementia of the degenerative type is usually related to obvious structural diseases mainly of the cerebral cortex, but also of the diencephalon and possibly the basal ganglia. In some pathologic entities, such as Alzheimer disease, the main process is a degeneration and loss of nerve cells in the cortical association areas and medial temporal lobes. In Pick disease and the primary frontotemporal dementia group, the atrophy is mainly frontal or temporal or both and sometimes quite asymmetrical. In other diseases, such as Huntington chorea, the neuronal degeneration predominates in the caudate nuclei, putamens, and other parts of the basal ganglia. In general, dementia associated with basal ganglia degenerations is of "subcortical" type, described earlier. Rarely, purely thalamic degenerations may be the basis of a dementia because of the integral relationship of the thalamus to the cerebral cortex. Arteriosclerotic cerebrovascular disease, which pursues a different course than the neurodegenerative diseases, results in multiple foci of infarction throughout the
The lesions of severe trauma, if they result in dementia, are to be found in the cerebral convolutions (mainly frontal and temporal poles), corpus callosum, and mesencephalon; rarely, there is widespread degeneration of the white matter and hydrocephalus. Most traumatic lesions that produce dementia are quite extensive.

Mechanisms other than the overt destruction of brain tissue may operate in some cases. Chronic hydrocephalus, regardless of cause, is often associated with a general impairment of mental function. Compression of the cerebral white matter is probably the main factor. The compression of one or both of the cerebral hemispheres by chronic subdural hematomas may have the same effect. A diffuse inflammatory process is at least in part the basis of dementia in syphilis, cryptococcosis, other chronic meningitides, and viral infections such as AIDS, herpes simplex encephalitis, and subacute sclerosing panencephalitis; presumably there is a loss of some neurons and an inflammatory derangement of function in the neurons that remain. The prior diseases (Creutzfeldt-Jakob disease) cause a diffuse loss of cortical neurons, replacement gliosis, and spongiform change and produce special patterns of cognitive dysfunction.

The adult forms of leukodystrophy (Chap. 37) also give rise to a dementing syndrome, generally with a “subcortical” syndrome and prominent frontal lobe features. Or extensive lesions in the white matter may be due to advanced cerebral multiple sclerosis, progressive multifocal leukoencephalitis, or some of the vascular dementias already alluded to (Binswanger disease). Last, several of the metabolic and toxic disorders discussed in Chap. 37, Chap. 40, and Chap. 43 may interfere with nervous function over a period of time and create a clinical picture similar if not identical to that of one of the dementias. One must suppose that the altered biochemical environment has affected neuronal function.

Bedside Classification of the Dementing Diseases

Conventionally, the dementing diseases have been classified according to cause, if known, to the pathologic changes, or more recently, to a genetic mutation. Another, more practical approach, which follows logically from the method by which much of the subject matter is presented in this book, is to subdivide the diseases into three categories on the basis of the neurologic signs and associated clinical and laboratory signs of medical disease (see Table 21-3). Once it has been determined that the patient suffers from a dementing illness, it must then be decided from the medical, neurologic, and ancillary data into which category the case fits. This classification may at first seem somewhat cumbersome. However, it is likely to be more useful to the student or physician not conversant with the many diseases that cause dementia than a classification based on pathology or genetics.

Table 21-3 Bedside classification of the dementias

Differential Diagnosis

Although confusion or dementia per se does not indicate a particular disease, certain combinations of symptoms and neurologic signs are more or less characteristic and may aid in diagnosis. The age of the patient, the mode of onset of the dementia, its clinical course and time span, the associated neurologic signs, and the accessory laboratory data constitute the basis of differential diagnosis. It must be admitted, however, that some of the rarer types of degenerative brain disease are at present recognized only by pathologic examination. The correct diagnosis of treatable forms of dementia—subdural hematoma, certain brain tumors, chronic drug intoxication, normal-pressure hydrocephalus, AIDS (treatable to some extent), neurosyphilis, cryptococcosis, pellagra, vitamin B<sub>12</sub> and thiamine deficiency states, hypothyroidism, and other metabolic and endocrine disorders—is, of course, of greater practical importance than the diagnosis of the untreatable ones. Important also is the detection of a depressive illness, which may masquerade as a dementia and is treatable.

The first task in dealing with this class of patients is to verify the presence of intellectual deterioration and personality change. It may be necessary to examine the patient serially before one is confident of the clinical findings. There is always a tendency to assume that mental function is normal if a patient complains only of nervousness, fatigue, insomnia, or vague somatic symptoms and to label the patient as neurotic. This will be avoided if one keeps in mind that a neurosis rarely has its onset in middle or late adult life. A practical rule is to assume that all mental illnesses beginning during this period are due either to structural disease of the brain or to depression.

A mild aphasia must not be mistaken for dementia. Aphasias appear uncertain of themselves, and their speech may be incoherent. Furthermore, they may be anxious and depressed over their inaptitude. Careful attention to the patient's language performance will lead to the correct diagnosis in most instances. Further observation will disclose that the patient's behavior, except that which is related to the language disorder or to an associated apraxia, is not abnormal. Also, progressive deafness or loss of sight in an elderly person may sometimes be misinterpreted as dementia.

Clues to the diagnosis of depression are the presence of sighing, crying, loss of energy, psychomotor underactivity or its opposite, agitation with pacing, persecutory delusions, persistent hypochondriasis, and a history of depression in the past and in the family. Although depressed patients may complain of memory failure, scrutiny of their complaints will show that they can usually remember the details of their illness and that no qualitative change in other intellectual functions has taken place. Their difficulty is either a lack of energy and interest or preoccupation with personal worries and anxiety, which prevent the focusing of attention on anything except their own problems. Even during mental tests, their performance may be impaired by emotional blocking, in much the same way as the worried student blocks during an examination ("experiential confusion"). When such patients are calmed by reasurance and encouraged to try harder, their mental function improves, indicating that intellectual deterioration has not occurred. Conversely, it is helpful to remember that demented patients rarely have sufficient insight to complain of mental deterioration; if they admit to poor memory, they do so without conviction or full appreciation of the degree of their disability. The physician must never rely on the patient's statements alone in gauging the efficiency of mental function. Yet another problem is that of the impulsive, cantankerous, and quarrelsome patient who is a constant source of distress to employer and family. Such changes in personality and behavior (as, for example, in Huntington disease) may precede or mask early intellectual deterioration.

It is a clinical truism that the abrupt onset of mental symptoms points to a delirium or other type of acute confusional state and occasionally to a stroke; inattention, perceptual disturbances, and often drowsiness are conjoined (Chap. 20). Inasmuch as these latter conditions are practically always reversible, it is important that they be distinguished from dementia. The neuropsychiatric symptoms associated with metabolic, endocrine, or toxic disorders may present difficulties in diagnosis because of the wide variety of clinical pictures by which they manifest themselves. Whenever any such disorder is suspected, a thorough review of the patient's medications is crucial. Medications with atropinic activity, for example, can produce an apparent dementia or worsen a structurally based dementia. Occupational exposure to toxins and heavy metals should also be explored.
Once it is decided that the patient suffers from a dementia condition, the next step is to determine by careful physical examination whether there are other neurologic signs or indications of a particular medical disease. This enables the physician to place the case in one of the three categories in the bedside classification (see above and Table 21-3). Ancillary examinations—such as CT, MRI, EEG, lumbar puncture, measurement of blood urea nitrogen and serum concentrations of calcium and other blood chemistry variables—will help rule out other function tests—that should be done. This was done in most cases. The MRI and CT are or major importance in objectifying hydrocephalus, lobar atrophy, leukoencephalopathy, cerebrovascular disease, tumor, and subdural hematoma. Testing for syphilis, vitamin B₁₂ deficiency, and thyroid function is done also almost as a matter of routine because the tests are simple and the deficiencies they cause are reversible. These are supplemented in individual circumstances by serologic testing for human immunodeficiency virus (HIV) infection, measurement of copper and ceruloplasmin levels, (Wilson disease), heavy metal concentrations in urine or tissues, serum cortisol levels, and drug toxicology screening. The final step is to determine, from the total clinical picture, the particular disease within any one category.

THE AMNESIC SYNDROME (KORSAKOFF SYNDROME; AMNESIC OR AMNESIC-CONFABULATORY SYNDROME); See alsoChap. 41.

Definition The terms above are used interchangeably to designate a unique but common disorder of cognitive function in which memory and learning are deranged out of proportion to all other components of mentation and behavior. The amnesic state, as originally defined by Ribot, possesses two salient features that may vary in severity but are always conjoined: (1) an impaired ability to recall events and other information that had been firmly established before the onset of the illness (retrograde amnesia) and (2) an impaired ability to acquire certain types of new information, i.e., to learn or to form new memories (anterograde amnesia). This dual aspect inspired one of Lewis Carroll's characters to say that one's memory works both ways, past and future. In other words, memory and learning are inseparable. A third invariable feature of the Korsakoff amnesic syndrome, contingent upon the retrograde amnesia, is an impaired temporal localization of past experience (see below, under "Confabulation"). Other cognitive functions (particularly the capacity for concentration, spatial organization, as well as visual and verbal abilities, as well as the ability to deliberate or not at all on memory, are usually impaired as well, but to a lesser degree than memory function. The patient is usually lacking in initiative, spontaneity, and insight.

Equally important in the definition of the Korsakoff syndrome or amnesic state (these terms are preferable to Korsakoff psychosis) is the integrity of certain aspects of behavior and mental function. The patient must be awake, attentive, and responsive—capable of perceiving and understanding the written and spoken word, of making appropriate deductions from given premises, and of solving such problems as can be included within his forward memory span. These "negative" features are of particular diagnostic importance because they help to distinguish the Korsakoff amnesic state from a number of other disorders in which the basic defect is not in retentive memory but in other psychologic abnormalities—e.g., an impairment in attention and perception (as in the delirious, confused, or stuporous patient), in recall (as in the hysterical patient), or in volition, i.e., the will to learn (as in the apathetic or abulic patient with frontal lobe disease or depression).

So-called short-term or working memory, as demonstrated by the ability to repeat a string of digits, is intact, but this is more a measure of attention and registration than of retentive memory. Remote memory is relatively less affected than recent memory (Ribot's rule, as discussed below).

Confabulation The creative falsification of memory in an alert, responsive individual is often included in the definition of the Korsakoff amnesic state but is not a requisite for the diagnosis. It is provoked by the inherent need in the individual to fill gaps in his personal experiences that are inaccurately localized in the past and related with no regard to their proper temporal sequence. Whether one calls this a memory defect or confabulation is an academic matter. Far less frequent but more dramatic is a spontaneous recital of personal experiences, many of which are fantasies. These two forms of confabulation have been referred to as "momentary" and "fantastic," respectively, and it has been implied, on uncertain grounds, that the latter form reflects an associated lesion in the frontal lobes (Brocine). In our patients with the alcoholic Korsakoff syndrome, so-called fantastic confabulation was observed mainly in the initial phase of the illness, in which it could be related to a state of profound general confusion; "momentary confabulation" came later, in the convalescent stage. In the chronic, stable stage of the illness, confabulation was rarely elicitable irrespective of how broadly this symptom was defined.

Neuropsychology of Memory Loss It is noteworthy that memory function obeys certain neurologic laws. As memory fails, it first loses its hold on recent events. The degree of retrograde amnesia is proportionate to the magnitude of the underlying neurologic disorder. Early life memories are better preserved and integrated into habitual responses; nevertheless, with natural aging, there is also a gradual loss of early life memories. In transitory amnesias (e.g., concussive head injury), memory loss appears in reverse order, i.e., last to be remembered are the events of the remote past. All these principles were enunciated by Ribot in the latter half of the nineteenth century. The enduring aspect of early life memories in contrast to more recently experienced and learned material, a restatement of Ribot's rule, is apparent in both normal adults and in demented patients.

In the further analysis of the Korsakoff amnesic syndrome, it is necessary to consider the proposition that memory is not a unitary function but takes several forms. Thus, a patient with virtually no capacity to learn any newly presented information can still acquire some simple manual and pattern-analyzing skills (e.g., mirror reading). Moreover, having acquired these skills, the patient may have no memory of the circumstances in which they were acquired (implicit memory). The learning of simple mechanical skills has been referred to as procedural memory, in distinction to learning new data-based information, referred to as nonprocedural or declarative memory. Cohen and Squire have described this dichotomy as "knowing how" as opposed to "knowing that."

Much has also been written in the psychologic literature about two systems of memory referred to as episodic and semantic. A pervasive problem with these terms is the lack of uniformity in defining them. To Tthing, who is medically well advised and recommended, the term "episodic" denotes a memory system for dating personal experiences and their temporal relationships; semantic memory is one's repository of perceptual and factual knowledge, which make it possible to comprehend language and make inferences. The latter hardly constitutes a novel concept; Korsakoff himself clearly recognized that certain aspects of mental function (among them the ones now being defined as semantic memory) remain intact, despite the profound impairment of retentive (episodic) memory. Gaden and colleagues have discussed five patients with Korsakoff syndrome with relative preservation of semantic memory, attributable to hypoxic-ischemic injury (bilateral hippocampal atrophy) sustained early in life.

Damasio has introduced yet another set of terms—generic, in place of semantic and contextual, for episodic. To Damasio, generic memory denotes the basic properties of acquired information, such as its class membership and function; he makes the point that in the amnesic syndrome, this component of declarative memory remains intact and only the contextual component is impaired.

The full significance of these categorizations is still being explored. The categorical purity of semantic memory is open to question, as is the notion of a strict dichotomy between semantic and episodic memory. Most importantly, a separate anatomic basis for these systems of memory has not been established (see below).

Anatomic Basis of the Amnesic Syndrome

The anatomic structures of particular importance in memory function are the diencephalon (specifically the medial portions of the dorsomedial and adjacent midline nuclei of the thalamus) and the hippocampal formations (dentate gyrus, hippocampus, parahippocampal gyrus, subiculum, and entorhinal cortex). Discrete bilateral lesions in these regions derange memory and learning out of all proportion to other cognitive functions, and a unilateral lesion of these structures, especially of the dominant hemisphere, can produce a lesser degree of the same effect. A severe but less enduring defect in retentive memory has also been observed with infarction lesions in these regions derange memory and learning out of all proportion to other cognitive functions, and a unilateral lesion of these structures, especially of the dominant hemisphere, can produce a lesser degree of the same effect. A severe but less enduring defect in retentive memory has also been observed with infarction of the septal gray matter, a cluster of midline nuclei at the base of the frontal lobes, just below the interventricular septum and including the septal nucleus, nucleus accumbens, diagonal band of Broca, and paraventricular hypothalamic gray matter (Phillips et al.). These septal nuclei have connections with the hippocampus through the precommissural fornix and with the amygdala through the diagonal band. The amnesic syndrome that follows ruptured anterior communicating aneurysm is caused by an associated lesion in the frontal lobes (Brocine). Other cognitive functions are sensitive to human amnesia, Zola-Morgan and colleagues have shown that bilateral lesions of the hippocampal formation cause an enduring impairment of memory function. Lesions confined to the fornices or mammillary bodies and stereotaxic lesions of the amygdala that spared the adjacent cortical regions (entorhinal and perirhinal cortices) failed to produce a memory defect. However, lesions that were confined to the perirhinal and entorhinal cortex (Brodmann areas 35 and 36) and the closely associated parahippocampal cortex did cause a persistent memory defect, presumably by interrupting major afferent pathways conveying cortical information to the hippocampus. Lesions of the anteromedial parts of the diencephalon, which receive and send fibers to the amygdala and...
hippocampus, similarly abolished memory function.

These observations indicate that integrity of the hippocampal formations and the mediadorsal nuclei of the thalamus are essential for normal memory and learning. Interestingly, there are only sparse direct anatomic connections between these two regions. The importance assigned to the hippocampal formations and medial thamic nuclei in memory function does not mean that the mechanisms governing this function are confined to these structures or that these parts of the brain form a “memory center.” It means only that these are the sites where the smallest lesions have the most devastating effects on memory and learning. Normal memory function involves many parts of the brain in addition to diencephalic-hippocampal structures. It is also clear that extensive lesions of the neocortex may cause impairment of retentive memory and learning and that this effect is probably more dependent upon the size of the lesion than upon its locus. Of particular importance are the circumscribed areas of the cerebellar cortex that are related to special forms of learning and memory (so-called modality-based memory), a subject that is considered in detail in the next chapter. Thus, a lesion of the dominant temporal lobe impairs the ability to remember words (loss of explicit semantic memory), and a lesion of the inferior parietal lobule undermines the recognition of written or printed words as well as the ability to relearn them. The dominant parietal lobe is related to recognition of geometric figures and numbers; the nondominant parietal lobe, to visuospatial relations; the inferoposterior temporal lobes, to the recognition of faces; and the dominant posterofrontal region, to acquiring and remembering motor skills and their affective associations.

Any hypothesis concerning the anatomic substratum of learning and retentive memory must therefore include not only the diencephalic-hippocampal structures but also special parts of the neocortex and midbrain reticular formation (for maintaining alertness). We would suggest that the diencephalic-hippocampal structures are involved in all active phases of learning and integration of new information, regardless of the sense avenue through which this information reaches the organism in order to be assimilated or of the final pathway of its expression, and it seems to make little difference whether the newly acquired information involves functions clearly cognitive or as emotional. This general aspect of memory function may suitably be designated as the “universal” or “U” factor of memory. Restricted regions of the temporal, parietal, and occipital cortex have particular relationships to the several special (modality-specific) memories, which may be designated as the “S” factors of memory.

It is a remarkable feature of the Korsakoff amnesic state that no matter how severe the defect in retentive memory may be, it is never complete. Certain past memories can be recalled, but imperfectly and with no regard for their normal temporal relationships, giving them a fictional quality and explaining many instances of confabulation. Another noteworthy fact is that long-standing social habits, automatic motor skills, and memory for words (language) and visual impressions (visual or pictorial attributes of persons, objects, and places) are unimpaired. Long periods of repetition and usage have made these implicit or procedural memories virtually automatic; they no longer require the participation of the diencephalic-hippocampal structures that were necessary to learn them originally. All of this suggests that these special memories, or coded forms of them, through a process of rehearsing and habituation, come to be stored or filed in other regions of the brain; i.e., they acquire a separate and autonomous anatomy.

Several fundamental questions concerning the amnesic syndrome remain unanswered. Not known is how a disease process, acting over a brief period of time, not only Impair all future learning but also wipes out a vast reservoir of past memories that had been firmly established for many years before the onset of the illness. Also unknown are the anatomic and physiologic mechanisms that govern immediate registration, which remains intact in even the most severely damaged patients with the Korsakoff amnesic syndrome. Equally obscure are the anatomic arrangements that enable the patient with virtually no capacity to retain any newly presented factual information to still learn some simple perceptual-motor and cognitive skills, even though there may be no memory of having been taught these skills in the first place. Other psychologic features of human memory that must be accounted for by any model purporting to explain this function are the importance of cueing in eliciting learned material and the impression of past memories, allowing for unwitting embellishment and false recollection, to the point of fabrication. The latter aspect has been a topic of considerable importance in children who have (or have not) been subjected to sexual abuse and in adults and children whose memories of past abuse have been suggested by the examiners (see Schacter).

The cellular mechanisms that are involved in learning and the formation of memories are only beginning to be understood. Kandel has provided a detailed review of current information on this subject (see references). Classification of Diseases Characterized by an Amnesic Syndrome

The amnesic (Korsakoff) syndrome, as defined above, may be a manifestation of several neurologic disorders, identified by their mode of onset and clinical course, the associated neurologic signs, and ancillary findings (see Table 21-4). Each of the amnesic states listed in this table is considered at an appropriate point in subsequent chapters of this book. The only exception is so-called transient global amnesia, the nature of which is not entirely certain. It cannot with assurance be included with the epilepsies or the cerebrovascular diseases or any other category of disease and is therefore considered here.

![Table 21-4 Classification of the amnesic states](image)

**Table 21-4** Classification of the amnesic states

**Transitory Global Amnesia**

This is the name applied by Fisher and Adams to a particular type of memory disorder that occurs not infrequently in middle-aged and elderly persons and is characterized by a period of amnesia and bewilderment lasting for several hours. The symptoms have their basis in an amnesia for events of the present and the recent past coupled with an ongoing anterograde amnesia. During the attack, there is no impairment in the state of consciousness and no overt sign of seizure activity; personal identification is intact, as are motor, sensory, and reflex functions. The patient’s behavior is normal except for incessant, repetitive questioning about his immediate circumstances (e.g., “What am I doing here?”; “How did we get here?”). Unlike those with psychomotor epilepsy, the patient is alert, in contact with his surroundings, and capable of high-level intellectual activity and language function during the attack. As soon as the attack has ended, no abnormality of mental activity; personal identification is intact, as are motor, sensory, and reflex functions.
No consistent antecedent events have been identified, but certain ones—such as a highly emotional experience, pain, exposure to cold water, sexual intercourse, and mild head trauma—have been reported in some cases (Haas and Ross; Fisher). We have also seen several patients in whom the attacks appeared after minor diagnostic procedures such as colonoscopy, but the residual effects of sedation are suspect in some of these instances. Several cases have been reported in high-altitude climbers and created difficulty in distinguishing TGA from altitude sickness. One of the difficulties in judging the accuracy of the many published reports of TGA is whether, during the attack, the patient was or was not in contact with the environment and capable of high-level mental performance and whether a retrograde amnesia was present—important features in differentiating the attack from a partial complex seizure.

The pathogenesis of TGA has not been settled. It has been suggested that it represents an unusual form of temporal lobe epilepsy, but this seems unlikely. A large number of patients have been studied with EEGs during an attack or shortly thereafter and have not shown seizure activity (Miller et al). Moreover, amnesic episodes due to seizures are usually much briefer than those of TGA, and most or all temporal lobe seizures are associated with impairment of consciousness and an inability to interact fully with the social and physical environment. Using EEG and nasopharyngeal leads, Rowan and Protass found mesiotemporal spike discharges in 5 of 7 patients. They attributed the discharges to ischemic lesions during drug-induced sleep. Paimini and coworkers cite exceptional cases of pure amnestic seizures in temporal lobe epilepsy, but even in their best examples, icctal and postictal function was not normal. More likely, transient global amnesia is ischemic in nature, though not atherosclerotic-thrombotic. Rarely do the attacks progress to stroke. In the series of Hinge and associates, the observed rates of death and stroke were similar to the expected rates in the Danish population matched for age and sex. Hodges and Warlow, in a case-control study of 114 patients with transient global amnesia, also found no evidence of an association with cerebrovascular disease; there was, however, a significantly increased history of migraine in this group of patients, as there was in the series of Miller and coworkers (14 percent) and of Caplan and colleagues. The most compelling case for an ischemic basis, perhaps related in some way to migraine, comes from Stillhard and colleagues, who demonstrated bipotential hyperperfusion during an attack of TGA, and from Strupp et al, who demonstrated left mediotemporal changes (interpreted as cellular edema) with diffusion-weighted MRI in 7 of 10 patients. The precipitation of identical attacks by vertebrobasilar and coronary angiography is also suggestive of an ischemic causation.

The benignity of episodic global amnesia in most patients is noteworthy. Once the history and examination have excluded vertebrobasilar ischemia and temporal lobe epilepsy, no treatment is required other than an explanation of the nature of the attack and reassurance, although we often hospitalize such patients briefly to be certain that the episode clears without further incident.

APPROACH TO THE PATIENT WITH DEMENTIA AND THE AMNESIC STATE

The physician presented with a patient suffering from dementia and amnesia must adopt an examination technique designed to expose the intellectual defect fully. Abnormalities of posture, movement, sensation, and reflexes cannot be relied upon to disclose the disease process, since the association areas of the brain may be severely affected and the more discrete and careful neurologic signs of these types. Susception of a dementiam demonstrable arose when the patient presents multiple complaints that seem totally unrelated to one another and to any known syndrome; when symptoms of irritability, nervousness, and anxiety are vaguely described and do not fit exactly into one of the major psychiatric syndromes; and when the patient is incoherent in describing the illness and the reasons for consulting a physician.

Three categories of data are required for the recognition and differential diagnosis of dementing brain disease:

1. A reliable history of the illness
2. Findings on mental examination, i.e., the mental status, as well as on the rest of the neurologic examination
3. Ancillary examinations: CT, MRI, sometimes lumbar puncture, EEG, and appropriate laboratory procedures, as described in Chap. 2

The history should generally be supplemented by information obtained from a person other than the patient, because, through lack of insight, the patient will have no grasp of his illness or its gravity; indeed, he may be ignorant even of his chief complaint. Special inquiry should be made about the patient's general behavior, capacity for work, personality changes, language, mood, special preoccupations and concerns, delusional ideas, hallucinatory experiences, personal habits, and such faculties as memory and judgment.

The examination of the mental status must be systematic and should include most of the following categories:

1. Insight (patient's replies to questions about the chief symptoms): What is your difficulty? Are you ill? When did your illness begin? a. Place: What is the name of the place where you are now (building, city, state)? How did you get here? What floor is it on? Where is the bathroom? b. Time: What is the date today (day of week and of month, month, year)? What time of the day is it? What meals have you had? When was the last holiday? c. Memory. d. Remote: Tell me the names of your children and their birth dates. When were you married? What was your father's maiden name? What was the name of your first schoolteacher? What jobs have you held? We find it useful to quiz the patient about cultural icons of the past that are appropriate to his age. Most patients should be able to name the presidents in reverse order dating to their twenties. d. Recent: Ask about your plans for the next day. (compare with present day.) f. What is my name (or the nurse's name)? When did you see me for the first time? What tests were done yesterday? What were the headlines of the newspaper today? I. Immediate recall—"(short-term memory)" Repeat these numbers after me (give series of 3, 4, 5, 6, 7, 8 digits at a speed of one per second). Now when I give a series of numbers, repeat them in reverse order.
2. Orientation (knowledge of personal identity and present situation): What is your name, address, telephone number? What is your occupation? Are you married? a. Place: What is the name of the building, city, state? How did you get here? What floor is it on? Where is the bathroom? b. Time: What is the date today (day of week and of month, month, year)? What time of the day is it? What meals have you had? When was the last holiday? c. Memory. d. Remote: Tell me the names of your children and their birth dates. When were you married? What was your father's maiden name? What was the name of your first schoolteacher? What jobs have you held? We find it useful to quiz the patient about cultural icons of the past that are appropriate to his age. Most patients should be able to name the presidents in reverse order dating to their twenties. d. Recent: Ask about your plans for the next day. (compare with present day.) f. What is my name (or the nurse's name)? When did you see me for the first time? What tests were done yesterday? What were the headlines of the newspaper today? I. Immediate recall—"(short-term memory)" Repeat these numbers after me (give series of 3, 4, 5, 6, 7, 8 digits at a speed of one per second). Now when I give a series of numbers, repeat them in reverse order.
3. Memorization (learning): The patient is given four simple data (examiner's name, date, time of day, and a fruit, structure, or trait, such as honesty) or a brief story containing several facts and is asked to repeat them. The capacity to reproduce them at intervals after committing them to memory is a test of retentive memory span. e. Another test of memory and verbal fluency we have found useful is to ask the patient to give the names of animals, vegetables, or makes of cars, as many as come to mind; most individuals can list at least 12 items in each category.
4. Capacity for sustained mental activity and working memory: Crossing out all the a's on a printed page; counting forward and backward; saying the months of the year forward and backward; spelling the alphabet forward and then backward. a. Calculation: Test ability to add, subtract, multiply, and divide. Subtraction of serial 3's and 7's from 100 is a good test of calculation as well as concentration. b. Construction: Ask the patient to draw a clock and place the hands at 7:45, a map of the United States, a floor plan of his house; ask him to copy a cube and other figures. c. Abstract thinking: See if the patient can describe the similarities and differences between classes of objects (orange and apple, horse and dog, desk and bookcase, newspaper and radio) or explain a proverb or fable.
5. General behavior: Attitudes, general bearing, evidence of hallucinosis, stream of coherent thought and attentiveness (ability to maintain a sequence of mental operations), mood, manner of dress, etc.
6. Special tests of localized cerebral functions: Grasping, sucking, aphasia battery, praxis with both hands, and cortical sensory function.

In order to enlist the full cooperation of the patient, the physician must prepare him for questions of this type. Otherwise, the patient's first reaction will be one of embarrassment or anger because of the implication that his mind is unsound. It should be pointed out to the patient that some individuals are rather forgetful or have difficulty in concentrating, or that it is necessary to ask specific questions in order to form some impression about his degree of nervousness when being examined. It should be explained in an acceptable manner that the information will be used for the patient's treatment and not to embarrass or anger because of the implication that his mind is unsound. It should be pointed out to the patient that some individuals are rather forgetful or have difficulty in concentrating, or that it is necessary to ask specific questions in order to form some impression about his degree of nervousness when being examined.

Reassurance that these are not tests of intelligence or of sanity is helpful. If the patient is extremely agitated, suspicious, or belligerent, intellectual functions must be inferred from his remarks and from information supplied by the family.

This type of mental status survey can be accomplished in about 10 min. In our experience, a high level of performance on all tests eliminates the possibility of dementia in 95 percent of cases. It may fail to identify a dementing patient and in a highly intelligent individual in the earliest stages of disease.

The question of whether to resort to formal psychologic tests is certain to arise. Such tests yield quantitative data of comparative value but cannot of themselves be used for diagnostic purposes. A number of tests that measure the degree of dementia (Roth, Pfeiffer, Blessed, Mattis) rely essentially on the points mentioned above...
and a brief assessment of the patient's ability to accomplish the activities of daily living, which is lost in the later stages of disease. Probably the Wechsler Adult Intelligence Scale (WAIS) is the most useful. In this test, an index of deterioration is provided by the discrepancy between the vocabulary, picture-completion, and object-assembly tests as a group (these correlate well with premorbid intelligence and are relatively insensitive to dementing brain disease) and other measures of general performance, namely arithmetic, block-design, digit-span, and digit-symbol tests. The Wechsler Memory Scale estimates the degree of memory failure and can be used to distinguish the amnesic state from a more general dementia (discrepancy of more than 25 points between the WAIS and the memory scale). The Mini-Mental Status examination of Folstein and coworkers and the Short Test of Mental Status of Kokmen and colleagues are useful bedside methods of scoring cognitive impairment and following its progress. Questions that measure spatial and temporal orientation and retentive memory are the key items in most of these abbreviated scales of dementia. All of the aforementioned clinical and psychologic tests, and others as well, measure the same aspects of behavior and intellectual function. The WAIS and the Mini-Mental Status examination of Folstein and associates are the most widely used clinically.

Management of the Demented Patient

Dementia is a clinical state of the most serious nature; though now sometimes impractical, it is usually worthwhile to admit patients to the hospital for a period of observation. Alternatively, the physician can see the patient serially over a period of weeks, during which time the appropriate laboratory tests (blood, cerebrospinal fluid analysis, and CT or MRI) can be carried out. The management of demented patients in the hospital may be relatively simple if they are quiet and cooperative. If the disorder of mental function is severe, it is helpful if a nurse, attendant, or member of the family can stay with the patient at all times.

The primary responsibility of the physician is to diagnose the treatable forms of dementia and to institute appropriate methods of therapy. Once it is established that the patient has an untreatable dementing brain disease and the diagnosis is sufficiently certain, a responsible member of the family should be informed of the medical facts and prognosis and assisted in the initiation of social and support services. Patients themselves need be told only that they have a nervous condition for which they are to be given rest and treatment. Little is accomplished by telling them more. If the dementia is slight and circumstances are suitable, patients should remain at home, continuing the activities of which they are capable. They should be spared responsibility and guarded against injury that might result from imprudent action. If they are still at work, plans for occupational retirement should be carried out. In more advanced stages of the disease, when mental and physical enfeeblement become pronounced, nursing home or institutional care should be arranged. So-called nerve tonics, vitamins, vasodilators, and hormones are of no value in checking the course of the illness or in regenerating atrophic tissue. The value of newer, centrally acting cholinergic agents in the treatment of Alzheimer disease is questionable and should be weighed against the need for repeated blood testing. They may, however, offer some psychologic support to the patient and family.

Undesirable restlessness, nocturnal wandering, and belligerency may be reduced by administration of one of the antipsychotic or benzodiazepine drugs (see Chap. 20, Chap. 43 and Chap. 48). Emotional lability and paranoid tendencies may be managed by the judicious use of olanzapine, risperidone, or haloperidol. Some patients are helped by short-acting sedatives such as lorazepam without worsening the mental condition, but all these drugs must be given with caution.

Questions asked by the patient's family must be answered patiently and sensitively by the physician. Common questions are: "Should I correct or argue with the patient?" (No.) "Can the patient be left alone?" "Must I be there constantly?" (Depends on specific circumstances and the severity of dementia.) "Should the patient manage his own money?" (Generally not.) "Will a change of environment or a trip help?" (Generally not—often the disruption in daily routine worsens behavior and orientation.) "Can he drive?" (Best to advise against driving in most instances.) "What shall we do about the patient's fears at night and his hallucinations?" (Medication under supervision may help.) "When is a nursing home appropriate?" "How will the condition worsen? What should the family expect, and when?" (Uncertain, but guided by one's understanding of the natural history of the disease.)

Visiting nurses, social agencies, live-in health care aides, day care settings, and respite care to relieve families from the constant burden of caring for the patient should all be offered to advantage. Some of the inevitable practical problems accompanying the dissolution of personal life caused by dementia can be ameliorated by judicious use of powers of attorney, guardianship, and similar legal vehicles.

CHAPTER REFERENCES

The age-old controversy about cerebral functions—whether they are diffusely represented in the cerebrum, with all parts roughly equivalent, or localized to certain lobes or regions—was resolved long ago. Clinicians and physiologists have demonstrated beyond doubt that particular cortical regions are related to certain functions. For example, the pre- and postrolandic zones are motor and sensory, the striate-parastriate occipital zones are visual, the superior temporal and transverse gyri of Heschl are auditory. Beyond these broad correlations, however, there is a notable lack of precision in the cortical localization of many of the behavioral and mental operations described in Chap. 20 and Chap. 21. As to the higher-order physiologic and psychologic functions—such as attention, vigilance, apperception, thinking, etc. —virtually none has been assigned a precise and predictable anatomy; or, more accurately, the neural systems on which they depend are widely distributed.

One may suitably pause and inquire into what precisely is meant by cerebral localization. Does it refer to the physiologic function of a circumscribed aggregate of neurons in the cerebral cortex, indicated clinically by a loss of that function (negative symptom) when the neurons in question are paralyzed or destroyed? From what we know of the rich connectivity of all parts of the so-called cortical centers, one must assume that this is not the case, but only that a lesion in a particular part or in the fiber systems with which it is connected is most consistently associated with certain impairments of function. It is therefore appropriate for the clinician to operate on the principle of correlation between certain neurologic signs or syndromes and damage (lesion) in particular regions of the brain. Nevertheless, it must be readily apparent, but is worth repeating, that certain positive symptoms resulting from the lesion—e.g., the grasping and sucking responses—cannot arise from destroyed neurons but are attributable to the now deranged or disinhibited functions of closely related intact parts of the cerebrum. And how is one to interpret the seeming inconsistencies from one case report to another, in which several different functions have been assigned to the same region of the brain and any one region appears to be the anatomic substratum of multiple functions? Most modern theorists who deal with this subject believe that the organization of cerebral function is based on discrete networks of closely interconnected afferent and efferent neurons in each region of the brain. These networks must be linked by both regional and more widespread systems of fibers.

Pertinent to this topic are a number of morphologic and physiologic data. Along strictly histologic lines, Brodmann distinguished 47 different areas of cerebral cortex (Fig. 22-1, and Fig. 22-2), and von Economo identified more than twice this number. Although this parceling was criticized by Bailey and von Bonin, it is still used by physiologists and clinicians, who find that Brodmann’s areas do indeed approximate certain functional zones of the cerebral cortex (Fig. 22-3). Also, the cortex has been shown to differ in its various parts by virtue of its particular connections with other areas of the cortex and with the thalamic nuclei and other lower centers. Hence, one must regard the cortex as a heterogeneous array of many anatomic systems, each with highly organized intercortical and central (thalamic) connections.
Some general aspects of cerebrocortical anatomy are noteworthy. The sheer size of the cortex is remarkable. Unfolded, it has a surface extent of about 4000 cm²—about the size of a full sheet of newsprint (right and left pages). Contained in the cortex are many billions of neurons (estimated at 10 to 30 billion) and five times this number of glial cells. The intercellular synaptic connections number in the trillions. Since nerve cells look alike and presumably function alike, the remarkable diversity in human intelligence, store of knowledge, and behavior must depend on infinite variations in neuronal interconnectivity.

Most of the human cerebral cortex is phylogenetically recent, hence the term neocortex. It has also been referred to as isocortex (Vogt) because of its uniform embryogenesis and morphology. These latter features distinguish the neocortex from the older and less uniform cortex, which comprises mainly the hippocampus and olfactory cortex and is referred to as the allocortex (“other cortex”).

Concerning the detailed histology of the neocortex, six layers (laminae) can be distinguished, from the pial surface to the underlying white matter: molecular (or plexiform) external granular, external pyramidal, internal granular, ganglionic (or internal pyramidal), and multiform (or fusiform). These are illustrated in Fig. 22-4. Two cell types—relatively large pyramidal cells and smaller, more numerous rounded (granular) cells—predominate, and variations in the lamination of the neocortex are largely determined by variations in the size and density of these neuronal types. Many variations in lamination have been described by the cortical mapmakers, but two main types of neocortex are recognized: (1) the homotypical cortex, in which the six-layered arrangement is readily discerned, and (2) the heterotypical cortex, in which the layers are less distinct. The association cortex—the large areas (75 percent of the surface) that are not obviously committed to primary motor or sensory functions—is generally of this latter type. The homotypical cortex is characterized by either granular or agranular nerve cells. The precentral cortex (Brodmann’s areas 4 and 6, mainly motor region) is dominated by pyramidal rather than granular cells, especially in layer V; hence the term agranular (Fig. 22-5). In contrast, primary sensory cortex—postcentral gyrus (areas 3, 1, 2), banks of the calcarine sulcus (area 17), and the transverse gyri of Heschl (areas 41 and 42)—where layers II and IV are strongly developed for the receipt of afferent impulses, has been termed granular cortex (koniocortex in older nomenclature) because of the marked predominance of granular cells (Fig. 22-5).

The intrinsic organization of the neocortex follows the pattern elucidated by Lorente de Nó. He described vertical chains of neurons that are arranged in cylindrical modules or columns, each containing 100 to 300 neurons and heavily interconnected up and down between cortical layers and to a lesser extent horizontally. Figure 22-6 illustrates the fundamental vertical (columnar) organization of these neuronal systems. Afferent fibers activated by various sensory stimuli terminate in layers IV and II. These impulses are then transmitted by internuncial neurons (interneurons) to adjacent superficial and deep layers and then to appropriate efferent neurons in layer V. Neurons of lamina III send axons to other parts of the association cortex in the same and opposite hemisphere. Neurons of layer VI project mainly to the thalamus. In the macaque brain, each pyramidal neuron in layer V has about 60,000 synapses, and one afferent axon may synapse with dendrites of as many as 5000 neurons; these figures convey some idea of the wealth and complexity of cortical connections. These columnar ensembles of neurons, on both the sensory and motor sides, function as the elementary working units of the cortex, in a manner indicated in Chap. 3, Chap. 8, and Chap. 9.
Whereas certain regions of the cerebrum are committed to special perceptual, motor, sensory, mnemonic, and linguistic activities, the intricacy of the anatomy and psychophysical mechanisms in each region are just beginning to be envisioned. The lateral geniculate-occipital organization in relation to color vision and recognition of form, stemming from the work of Hubel and Wiesel, may be taken as an example. In area 17, the polar region of the occipital lobe, there are discrete, highly specialized groups of neurons, each of which is activated in a small area of lamina 4 by spots of light or lines and transmitted via particular cells in the lateral geniculate bodies; other groups of adjacent cortical neurons are essential for the perception of color (see also page 487). Preparedness for all types of visual stimulation and recognition of objects, faces, and verbal and mathematical symbols also involves these areas but is integrated with other cortical regions. Lying between the main unimodal receptive areas for vision, audition, and somesthetic perception are zones of integration called heteromodal cortices. In the latter regions, neurons respond to more than one sensory modality or neurons responsive to one sense are interspersed with neurons responsive to another sense.

Cortical-subcortical integrations are reflected in volitional or commanded movements. A simple movement of the hand, for example, requires activation of the premotor cortex (also called accessory motor cortex), which projects to the striatum and cerebellum and back to the motor cortex via a complex thalamic circuitry before the direct and indirect corticospinal pathways can activate certain combinations of spinal motor neurons (see Chap. 3 and Chap. 4).

Interregional connections of the cerebrum are required for all natural sensorimotor functions; moreover, as indicated above, their destruction disinhibits or releases other areas. Denny-Brown has referred to these as cortical tropisms. Thus, destruction of the premotor areas, leaving precentral and parietal lobes intact, results in release of the sensorimotor automatons of groping, grasping, and sucking. Parietal lesions result in complex avoidance movements to contactual stimuli. Temporal lesions lead to a visually activated reaction to every observed object and its oral exploration, and limbic sexual mechanisms are rendered hyperactive.

Some of the aforementioned disorders and others known simplistically as disconnection syndromes depend not merely on involvement of certain cortical regions but also on the interruption of inter- and intrahemispheric fiber tracts. Some of these disconnections are indicated in Fig. 22-7; the involved fiber systems include the corpus callosum, anterior commissure, uncinate temporofrontal fasciculus, occipito- and temporoparietal tracts, etc. Extensive white matter lesions may virtually isolate certain cortical zones. Another example is the isolation of the perisylvian language areas from the rest of the cortex, as occurs with anoxic-ischemic infarction of border zones between major cerebral arteries.

These aspects of cerebral localization—brought out so clearly in the writings of Wernicke, Dejerine, and Liepmann and resurrected more recently by Geschwind—have been elaborated by the Russian school of physiologists and psychologists. They view function not as the direct property of a particular, highly specialized group of cells in one region of the cerebrum but as the product of complex, diffusely distributed activity by which sensory stimuli are analyzed and integrated at various levels of the nervous system and are united, through a system of temporarily acquired (experientially derived) connections, into a working mosaic adapted to accomplish a particular task. To some extent, this model has been corroborated by functional imaging studies (positron emission tomography (PET) and functional magnetic resonance imaging (fMRI)), which show increased metabolic activity in several cortical regions during any human behavior, including willed motor acts, language tasks, and perceptive and apperceptive sensory experiences. Within such a functional system, the initial and final links (the task and the effect) remain unchanged, but the intermediate links (the means of performance of a given task) may be modified within wide limits and will never be exactly the same on two consecutive occasions. Thus, when a certain act is called for by a spoken command, the dominant temporal lobe must receive the message and transmit it to the premotor areas. Or it may be initiated by the intention of the individual, in which case the first measurable cerebral activity (a negative readiness potential) occurs anterior to the premotor cortex. The motor cortex is always under the dynamic control of the proprioceptive, visual, and vestibular systems. These are some of the recognizable elements in motor performance; loss of a skilled act may be caused by a lesion that affects any one of several elements in the act, either the motor centers themselves or their connections with the other elements.

This concept of cerebral function and localization, which applies to all mental activities, contradicts both the concept that postulates the functional equivalence of all cerebral regions and also the one that assumes strict localization of any given activity within one part of the brain. It is open to neuropsychologic analyses, which has been the approach of A. R. Luria and others of the Russian school and of behavioral psychologists of the Skinner school.

Another theoretical scheme of cerebral anatomy and function systematizes cortices of similar overall structure and divides the cerebral mantle into three longitudinally oriented zones. The central vegetative neuronal system (allo-cortex and hypothalamus) provides the mechanisms for all internal functions—the milieu interieur of Bernard and Cannon. The outer zone, comprising the sensorimotor and association cortices and their projections, provides the mechanisms for perceiving the external world and interacting with it. The region between (limbic-paralimbic cortices) provides the bridges that permit the adaptation of organismal needs to the external environment. This concept of central nervous system function, first proposed by Broca, was elaborated by Yekovoy and has been adopted more recently by Mesulam and by Benson. Such a model retains to a large degree the cytoarchitectural similarities among areas that serve similar functions (i.e., the scheme of Brodmann) and also respects the sequence of maturation (myelination) of connecting pathways proposed by Flechsig (Fig. 28-3), which corresponds to the functional development of the primary, secondary, and tertiary associative cortical regions. In this way, localization may be viewed as the product of genetic patterns of structure, which mature during development, and their synaptic formations, which permit the development of complex circuits during lifelong learning and experience.

From these remarks it follows that subdivision of the cerebrum into frontal, temporal, parietal, and occipital lobes is somewhat of an anachronism and has a limited
functional validity (although, in clinical work, it still serves a practical purpose as a shorthand way of localizing a lesion). These delineations were made long before our first glimmer of knowledge about the function of the cerebrum. Even when the neurohistologists began parceling the neocortex, they found that their areas did not fall within zones bounded by sulci and fissures. Therefore, when the terms frontal, parietal, temporal, and occipital are used in the text below, it is mainly to provide the reader with familiar anatomic landmarks.

SYNDROMES CAUSED BY LESIONS OF THE FRONTAL LOBES

Anatomic and Physiologic Considerations

The frontal lobes lie anterior to the central, or rolandic, sulcus and superior to the sylvian fissure (Fig. 22-8). They are larger in humans (30 percent of the cerebrum) than in any other primate (9 percent in the macaque). Several different systems of neurons are located here, and they subserve different functions. Brodmann's areas 4, 6, 8, and 44 relate specifically to motor activities. The primary motor cortex, i.e., area 4, is directly connected with somatosensory neurons of the anterior part of the postcentral gyrus as well as with other parietal areas, thalamic and red nuclei, and the reticular formation of the brainstem. The supplementary motor cortex, a portion of area 6, shares most of these connections. As pointed out in earlier chapters, all motor activity needs sensory guidance, and this comes from the somesthetic, visual, and auditory cortices and from the cerebellum via the ventral tier of thalamic nuclei.

Area 8 is concerned with turning the eyes and head contralaterally. Area 44 of the dominant hemisphere (Broca's area) and the contiguous part of area 4 are "centers" of motor speech and related functions of the lips, tongue, larynx, and pharynx; bilateral lesions in these areas cause paralysis of articulation, phonation, and deglutition. The medial-orbital gyrus and anterior part of the cingulate gyrus, which are frontal components of the limbic system, take part in the control of respiration, blood pressure, peristalsis, and other autonomic functions. The most anterior parts of the frontal lobes (areas 9 to 12 and 45 to 47), sometimes referred to as the prefrontal areas, are particularly well developed in human beings but have imprecisely determined functions. They are not, strictly speaking, parts of the motor cortex, in the sense that electrical stimulation evokes no direct movement; the prefrontal cortex is said to be inexcitable. Yet these areas are involved in the initiation of planned action and executive control of all mental operations, including emotional expression.

The frontal agranular cortex (areas 4 and 6) and, more specifically, pyramidal cells of layer V of the pre- and postcentral convolutions provide most of the cerebral efferent motor system known as the pyramidal, or corticospinal, tract (see Fig. 3-3 and Fig. 3-3). Another massive projection from these regions is the frontopontocerebellar tract. In addition, there are other fiber systems that pass from frontal cortex to the caudate and putamen, subthalamic and red nuclei, brainstem reticular formation, substantia nigra, and inferior olive as well as to the ventrolateral, mediodorsal, and dorsolateral nuclei of the thalamus. Areas 8 and 6 are connected with the oculomotor brainstem nuclei motor nuclei and with identical areas of the other cerebral hemisphere through the corpus callosum. A massive bundle connects the frontal with the occipital lobe, and an uncinate bundle connects the orbital part of the frontal lobe with the temporal lobe.

The granular frontal cortex has a rich system of connections both with lower levels of the brain (medial and ventral nuclei and pulvinar of the thalamus) and with virtually all other parts of the cerebral cortex, including its limbic and paralimbic parts. As to its limbic connections, the frontal lobe is unique among cerebrocortical areas. Electrical stimulation of the orbitofrontal cortex and cingulate gyrus has manifest effects on respiratory, circulatory, and other vegetative functions. These parts of the frontal cortex also receive major afferent projections from other parts of the limbic system, presumably to mediate the emotional responses to sensory experiences, and they project to other parts of the limbic and paralimbic cortices (hippocampus, parahippocampus, anterior pole of the temporal lobe), amygdala, and midbrain reticular formation. The frontal-limbic connections are described in greater detail in Chap. 25.

Blood is supplied to the medial parts of the frontal lobes by the anterior cerebral artery and to the convexity and deep regions by the superior (rolandic) division of the middle cerebral artery.

With respect to the physiology of the frontal lobes, the literature is replete with unsubstantiated claims. Here are presumed to reside the mechanisms that govern personality, character, motivation, and our unique capacities for abstract thinking, introspection, and planning. These qualities and traits do not lend themselves to easy definition and study or to discrete localization. Most of them are too subtle to isolate and measure. Except for the more posterior frontal mechanisms subserving motor speech and motility and certain behaviors relating to impulse, neurologists have had great difficulty in delineating a group of symptoms indicative of frontal lobe disease, as will be evident in further discussion.

Clinical Effects of Frontal Lobe Lesions

In a general sense, the anterior half of the brain is committed to the monitoring and execution of all cerebral activity. This means that all activities—be they motor, cognitive, or emotional—are planned and initiated here. Of necessity in such a scheme, there must also be inhibitory mechanisms that control or modulate behavior. Thus, aside from the overt abnormalities of motor, speech, and voluntary movement, lesions of the frontal lobes give rise to a loss of drive, impairment of consecutive planning, inability to maintain serial relationships of events and to shift easily from one mental activity to another—at times in combination with the release (dissociation) of sucking, grasping, and groping reflexes and other so-called utilization behaviors. Furthermore, in the emotional sphere, frontal lobe lesions may cause anhedonia, apathy, loss of self-control, disinhibited social behavior, and euphoria.

For descriptive purposes, the clinical effects of frontal lobe lesions can be grouped under the following categories: (1) motor abnormalities related to the prerolandic motor cortex; (2) speech and language disorders related to the dominant hemisphere; (3) impairment of certain cognitive functions, especially attention, concentration, capacity for sustained mental activity, and ability to shift from one line of thought or action to another—i.e., both impersistence and perseveration; (4) akinesia and lack of initiative and spontaneity (apathy and abulia); (5) other changes in personality, particularly in mood and self-control (dissociation of behavior); (6) incontinence of bladder and bowel; and (7) a distinctive abnormality of gait (page 128).

Motor Abnormalities Of the various effects of frontal lobe lesions, most is known about the motor abnormalities. Electrical stimulation of the motor cortex elicits contraction of corresponding muscle groups, and focal seizure activity has a similar effect. Stimulation of Brodmann area 4 produces movement of discrete muscle groups or, if sufficiently refined, of individual muscles. Repertoires of larger coordinated movements are evoked by stimulation of area 6, the premotor cortex. Voluntary movement involves the motor cortex in its entirety. Lesions in the posterior part of the frontal lobe cause spastic paralysis of the contralateral face, arm, and leg. Involved are the direct corticospinal tract and other indirect tracts that descend from the motor, premotor, supplementary motor, and anterior parietal cortex to the spinal cord, either directly or via the red and pontomedullary reticular nuclei in the brainstem. Lesions of the more anterior and medial parts of the motor cortex (area 6 and supplementary motor area of 6—the premotor cortex) result in less paralysis and more spasticity as well as a release of sucking, grasping, and grasping reflexes, the mechanisms of which reside in the parietal lobe and which, according to Denny-Brown, are tropisms, or automatisms, that are normally inhibited by the frontal cortex.

Mutism, contralateral motor neglect, and impairment of bibrachial coordination were found by Laplane and his colleagues to follow ablation of the right or left...
supplementary motor area. On the basis of radioactive blood flow studies, Roland and colleagues and Fuster have suggested that an important function of the supplementary motor area is the ordering of motor tasks or the recall of memorized motor sequences—further evidence of the executive functions of the frontal lobes. Temporary paralysies of contralateral eye turning and sometimes head turning follow a destructive lesion in area 8, on the dorsolateral aspect (convexity) of the cerebral cortex, often referred to as the frontal eye field (see Fig. 22-1). Seizure activity in this area causes a tonic deviation of the head and eyes to the opposite side.

Other Alterations of Behavior and Personality

The effects of lesions of the frontal lobes were first divulged by the famous case of Harlow, published in 1868. His patient, Phineas Gage, was a capable, God-fearing foreman of a railroad gang who became inreverent, dissipated, irresponsible, and vacillating (he also confabulated freely) following an injury in which an explosion drove a large iron tamping bar into his frontal lobes. In Harlow’s words, “he was no longer Gage.” Another similarly dramatic example was Dandy’s patient (the subject of a monograph by Bricker), who underwent a bilateral frontal lobotomy during the removal of a meningioma. Feuchtwanger, in a clinical study of 200 cases of frontal lobe injury, was impressed with the lack of initiative, vacillation, changes in mood (euphoria), and inattentiveness, without intellectual and memory deficits; and Rylander, in a classic monograph, described similar changes in patients with unilateral and bilateral frontal lobeictomies (see below). Kleist, under the caption of “alogia,” stressed the importance of loss of capacity for abstract thought, as shown in tests of analogies, proverbs, definitions, etc. In chimpanzees, Jacobsen observed a decrease of premonitory apprehension, motor perseveration, indecisiveness, and difficulties in planning and solving—findings that led Edg Moniz, in 1936, to perform prefrontal lobotomies on psychotic patients (see Damasio). This operation and its successor, prefrontal leukotomy (undercutting of the prefrontal white matter), reached their height of popularity in the 1940s and provided the opportunity to study the effects of a wide range of frontal lobe lesions in a large number of patients.

The findings in patients subjected to frontal leukotomy have been the subject of endless controversy. Some workers claimed that there were few or no discernible effects of the operation, even with bilateral lesions. Others insisted that if the proper tests were used, a series of predictable and diagnostic changes in cognition and behavior could be demonstrated. The arguments pro and con and the inadequacies of many of the studies, both in methods of testing and in anatomic verification of the lesions (the extent and location of the lesions varied considerably, and this influenced the clinical effects), have been well summarized by Walsh. Admittedly, in patients who underwent bilateral frontal lobotomy, there was little if any impairment of memory function or of cognitive function as measured by intelligence tests and certain no loss of alertness and orientation. And some patients who had been disabled by schizophrenia, anxious depression, obsessive-compulsive neurosis, or a chronic pain syndrome did improve in respect to their psychiatric and pain symptoms. However, many patients were left with changes in personality, much to the distress of their families. These patients were indifferent to the problems of others; gave no thought to the effects of their conduct; were tactless, distractible, and socially inept; and were given to euphoria and emotional outbursts.

Incontinence is another manifestation of frontal lobe disease. Right- or left-sided lesions involving the posterior part of the superior frontal gyrus, the anterior cingulate gyrus, and the intervening white matter result in a loss of control of micturition and defecation (Andrew and Nathan). There is no warning of fullness of the bladder and imperious urination and bowel evacuation, and the patient is surprised and embarrassed at suddenly being wet or soiled. Less complete forms of the syndrome are associated with frequency and urgency of urination during waking hours. An element of indifference to being incontinent is added when the more anterior (nonmotor) parts of the frontal lobes are the sites of disease.

In the spheres of speech and language, a number of abnormalities other than Broca’s aphasia appear in conjunction with disease of the frontal lobes—incoercible speech, loss of spontaneity of speech, telegraphic speech (agrammatism), loss of fluency, perseveration of speech, tendency to whisper instead of speaking aloud, and dysarthria. These are more prominent with left-sided lesions and are fully described in Chap. 7.

Cognitive and Intellectual Changes

In general, when one speaks of cognitive and behavioral aspects of frontal lobe function, reference is made to the more anterior (prefrontal) parts rather than the motor and linguistic parts. Here one faces a paradox. These most recently developed parts of the human brain, sometimes called the “organ of civilization,” have the most elusive functions.
hypochondriasis, complaints of chronic pain, and depression are all reduced by frontal lobe disease, as they are by frontal lobotomy.

Extensive bilateral disease is accompanied by a quantitative reduction in all psychomotor activity. The number of movements, spoken words, and thoughts per unit of time diminish. Relatively mild degrees of this state, associated with a delay in responses, are called abulia; the most severe degrees take the form of akinetic mutism (page 371), wherein a nonparalyzed patient, alert and capable of movement and speech, lies or sits motionless and silent for days or weeks on end. The localization of this condition is quite imprecise. It has been attributed to bilateral lesions in the ventromedial frontal regions or frontal-diencephalic connections. Laplane finds the lack of motivation of the patient with bifrontal lesions and bifrontal lesions to be the same, though one would expect the latter to be manifest more as a bradykinesthesia than as a bradykinesia (slowness of thinking). Benson (and Kleist and others before him) related the syndrome of apathy and lack of initiative to lesions in the sagittal or midtdorsolateral convexities, and the faceticus, unguarded, and socially inappropriate state (see below) to orbital and dorsolateral frontal lesions.

The opposite state, in a sense, is the hyperactivity syndrome or “organic driverness” described by von Economo in children who had survived an attack of encephalitis lethargica. In our patients, the latter syndrome has been associated with combined frontal and temporal lobe lesions, usually traumatic but also encephalitic, although exact clinico-pathologic correlations could not be made. Such patients may also exhibit brief but intense involvement with some meaningless activity, such as sorting papers in an attic or hoarding objects or food. Combativeness and extreme insomnia or an otherwise disrupted sleep cycle are often part of the syndrome. The hyperactivity of young boys and the mania or hypomania of manic-depressive disease, despite similar symptoms, also lack a known anatomic basis.

In addition to the disorders of initiative and spontaneity, frontal lobe lesions result in a number of other changes in personality and behavior. These, too, are easier to observe in the patient’s natural environment, by his family, than to measure by psychologic tests. It has been difficult to find a term for all these personality changes. Analytical psychiatrists have referred to them as a loss of ego strength—a lessening of the integrative and constructive forces within the personality. Some patients, particularly those with inferiorfrontal lesions, feel compelled to make silly jokes that are inappropriate to the situation—so-called Witzelsucht or moria; they are socially uninhibited and lack awareness of their abnormal behavior. The patient is no longer the sensitive, compassionate, effective human being that he once was, having lost his usual ways of reacting with affection to family and friends. In more advanced instances, there is a reduced regard for social conventions and an interest only in immediate personal gratification. These changes, observed characteristiclly in lobotomized patients, came to be recognized as too great a price to pay for the loss of neurotic traits, pain, depression, and “tortured self-concern,” for which reasons lobotomies were done; hence the procedure became obsolete.

The effect of unilateral prefrontal lesions is a question that continues to vex clinicians. If the lesions are small, their effects are undetectable; even a large lesion, such as a tumor, may long escape detection. Rylander, by careful psychologic testing, has shown that patients with lesions of either frontal lobe manifest a slight elevation of mood, with increased talkativeness and a tendency to joke, lack of tact, inability to adapt to a new situation, instability of mood, and loss of initiative—changes that are more readily recognized if the frontal lobe lesions are bilateral.

Our experience with frontal lobe lesions, derived mainly from patients with trauma or ruptured anterior communicating aneurysms, affirms most of the statements above. Most apparent is the abulic-hypokinetic disorder that seems to slow the mental processes involved in all forms of cerebral performance. Inattentiveness, impersistence in all assigned tasks, and sometimes perseveration are the major features of this disorder. Such a state cannot be specifically ascribed to prefrontal lesions, since it may be a reflection of a more general impairment of the thalamolimbic or reticular activating thalamocortical system. Indeed, bilateral medial thalamic lesions may give rise to the same syndrome, and Degos and colleagues have described a severe “frontal lobe syndrome” in association with bilateral lesions of the anterior cingulate gyrus. It is noteworthy that these structures have close connections with the prefrontal cortices.

In general, we agree that the greatest cognitive-intellectual deficits relate to lesions in the dorsolateral parts of the prefrontal lobes and the personality, mood, and behavioral changes to lesions of the medial-orbital parts, although the two types of disorder often merge with one another. The diagnosis of lesions in the orbital regions is facilitated by the finding of unilateral anosmia or optic atrophy, as occurs with a meningioma of the olfactory groove.

Although frontal lobe function is the subject of a vast literature and endless speculation (see reviews of Stuss and Benson and of Damasio), a unified concept of this function has not emerged—probably because the frontal lobes are so large and include several heterogeneous systems. There is no doubt that the mind is changed by disease of the prefrontal parts of the frontal lobes, but often it is difficult to say exactly how it is changed. Perhaps at present it is best to regard the frontal lobes as the part of the brain that quickly and effectively orients and drives the individual, with all the percepts and concepts formed from past life experiences, toward action.

Psychologic tests of particular value are the card-sorting test, proverb interpretation, sequencing of pictures, and the three-step hand posture test of Luria. The last test is a popular part of the bedside neurolologic evaluation of patients with suspected frontal lobe lesions. The patient is asked to imitate, then reproduce on his own, a sequence of three hand gestures, typically performed by slapping the opposite outstretched palm, followed by hitting the palm with a closed fist, and then by striking it with the side of the open hand. Patients with frontal lesions on either or both sides have difficulty performing the test in correct sequence, often perseverating, blinking, or making unwanted gestures, but it should be kept in mind that similar impairments of performance may occur with all manner of confusional and inattentive states and apraxias.

Effects of frontal lobe disease may be summarized as follows:

I. Effects of unilateral frontal disease, either left or right
   A. Contralateral spastic hemiplegia
   B. Slight elevation of mood, increased talkativeness, tendency to joke (Witzelsucht), lack of tact, difficulty in adaptation, loss of initiative
   C. If entirely prefrontal, no hemiplegia; grasp and suck reflexes or instinctive grasping may be released
   D. Anosmia with involvement of orbital parts
II. Effects of right frontal disease
   A. Left hemiplegia
   B. Changes as in I.B, C, and D
III. Effects of left frontal disease
   A. Right hemiplegia
   B. Motor speech disorder with agrapnia, with or without apraxia of the lips and tongue (see Chap. 23)
   C. Sym pathetic apraxia of left hand (see page 60)
   D. Loss of verbal associative fluency; perseveration
   E. Changes as in I.B, C, and D
IV. Effects of bifrontal disease
   A. Bilaterally paralyzed patient
   B. Spastic bulbar (pseudobulbar) palsy
   C. If prefrontal, abulia or akinetic mutism, lack of ability to sustain attention and solve complex problems, rigidity of thinking, bland affect, social inaptitude, behavioral disinhibition, inability to anticipate, table mood, and varying combinations of grasping, sucking, decomposition of gait, and sphincteric incontinence

SYNDROMES CAUSED BY LESIONS OF THE TEMPORAL LOBES

Anatomic and Physiologic Considerations

The boundaries of the temporal lobes are indicated in Fig. 22-8. The sylvian fissure separates the superior surface of each temporal lobe from the frontal lobe and anterior parts of the parietal lobe. There is no definite anatomic boundary between the temporal lobe and the occipital or posterior part of the parietal lobe, but the angular gyrus serves as a landmark for the latter.

The inferior branch of the middle cerebral artery supplies the convexity of the lobe, and the temporal branch of the posterior cerebral artery supplies the medial and inferior aspects, including the hippocampus.

The temporal lobe includes the superior, middle, and inferior temporal, lateral occipitotemporal, fusiform, lingual, parahippocampal, and hippocampal convolutions
and the transverse gyri of Heschl; the last of these constitute the primary auditory receptive area and are located within the sylvian fissure. This area has a tonotopic arrangement: fibers carrying high tones terminate in the medial portion of the gyrus and those carrying low tones, in the lateral and more rostral portions (Merzenich and Bruege). The planum temporale (area 22), an integral part of the auditory cortex, lies immediately posterior to Heschl's convolutions, on the superior surface of the temporal lobe. The left planum is larger in right-handed individuals. There are rich reciprocal connections between the medial geniculate bodies and Heschl's gyr.

The latter project to the unimodal association cortex of the superior temporal gyrus, which, in turn, projects to the paralimbic and limbic regions of the temporal lobe and to temporal and frontal heteromodal association cortices and the inferior parietal lobe. There is also a system of fibers that projects back to the medial geniculate body and to lower auditory centers. The cortical receptive zone for labyrinthine impulses is less well demarcated than the one for hearing but is probably situated on the inferior bank of the sylvian fissure, just posterior to the auditory cortex. The lateral extent is well described as the medial parts of the temporal lobe in infarction and gustatory perception, although seizure-foci in the region of the uncus (uncinate seizures) will excite hallucinations of olfaction and occasionally of taste.

The middle and inferior temporal gyri (areas 21 and 37) receive a massive contingent of fibers from the striate cortex (area 17) and the parastriate visual association areas (areas 18 and 19). These temporal visual areas make abundant connections with the medial limbic, rhinencephalic (olfactory brain), orbitofrontal, parietal, and occipital cortices. Here the cortices subserving vision and hearing are intimately interconnected.

The superior part of the dominant temporal lobe is concerned with the acoustic or receptive aspects of language (page 500) and the middle and inferior convolutions, with the stream of parastriate auditory and fiber systems and, in turn, project to the contralateral visual association cortex, to the prefrontal heteromodal cortex, to the superior temporal cortex, and to the limbic and paralimbic cortex. Presumably these systems subserve visual discriminative functions such as spatial orientation, estimation of depth and distance, stereoscopic vision, and hue perception. Similarly, the unimodal auditory cortex is connected with a series of auditory association area that are situated in the superolateral temporal and parietal temporal-parietal heteromodal areas and the limbic areas (Mesulam). Most of these auditory systems have been worked out in the macaque, but they are probably involved in complex verbal and nonverbal auditory discriminations in humans.

The hippocampus was formerly thought to be related to the olfactory system, but now it is known that lesions here do not alter the sense of smell. Most important is the role of the hippocampus and other structures of the hippocampal formation (dentate gyrus, subiculum, entorhinal cortex, and parahippocampal gyrus) in learning and memory functions, already discussed in Chap. 21. There is an abundance of connections between the temporal medial lobe and the entire limbic system. For this reason MacLean referred to these parts as the "visceral brain," and Williams, as the "emotional brain." Included in this anatomic concept are the hippocampus, the amygdaloid nuclei, the fornix and limbic portions of the inferior and medial frontal regions, the cingulate cortices, and the septal and associated subcortical nuclei (see Chap. 25).

Most of the temporal lobe cortex, including Heschl's gyri, has fairly equally developed pyramidal and granular layers. In this respect, it resembles more the granular cortex of the frontal and prefrontal regions and inferior parts of the parietal lobes (see Fig. 22-5). Unlike the six-layered neocortex, the hippocampus and dentate gyri are typical of the phylogenetically older three-layered allocortex.

A massive fiber system projects from the striate and parastriate zones of the occipital lobes to the inferior and medial parts of the temporal lobes. The temporal lobes are connected to one another through the anterior commissure and middle part of the corpus callosum; the inferior, or uncinate, fasciculus connects the anterior temporal and orbital frontal regions. The arcuate fasciculus connects the posterosuperior temporal lobe to the motor cortex and Broca's area (see page 501). The medial parts of the temporal lobes are supplied by the posterior cerebral artery and the superior and lateral parts by the temporal branches of the middle cerebral artery.

Physiologically, two ideas stand out—that the temporal lobe is the great integrator of "sensations, emotions, and behavior" (Williams) and that it is continuously active through the entire waking and sleeping period. It seems to be the site where sensory modalities are integrated into ultimate self-awareness (the cartesian view of consciousness of one's self as a person with a mind). Similar suprasensory integrative mechanisms are operative in the parietal lobe, but only in the temporal lobe are they brought into close relationship to one's instinctive and emotional life. Probably self-awareness also requires a coherent and sequential stream of thought. Where precisely the inner stream of consciousness is perceived is still an open question, but given the requirement that it be close to other integrated sensory experiences, the main locus is likely to be in the temporal lobes. Also, the stream of thinking (the internal conversation that is constant in the waking state—James's "stream of consciousness") requires both language and memory function (inner language comprises thought and memories); both these functions involve the temporal lobe.

During the middle years of the twentieth century, the temporal lobe was the principal focus of studies of cerebral function. Some hint of its role in our personal and emotional life had been suggested by Hughlings Jackson, in the nineteenth century, derived from his insightful analysis of the psychic states accompanying temporal lobe seizures. Later, the observations of Penfield and his collaborators on the effects of stimulating the temporal lobes in the conscious epileptic patient revealed something of its complex functions. There followed a large volume of writings on its anatomy, the neuronal networks and circuits by which it was connected to other cortical and subcortical structures, and the effects of ablation on emotion, behavior, and sensory perception. The classic writings on this subject include Williams's chapter on temporal lobe syndromes in the Handbook of Clinical Neurology and the monographs by Penfield and Rasmussen (The Cerebral Cortex of Man) and by Alajouanine and colleagues (Les Grandes Activités du Lobe Temporal). Clinical Effects of Temporal Lobe Lesions

The symptoms consequent to disease of the temporal lobes may, for convenience of exposition, be divided into disorders of the special senses (visual, auditory, olfactory, and gustatory), time perception, language, memory, emotion, and behavior. Of central importance are the roles of the superior part of the dominant lobe and its connections in language in defining the emotional life of the individual; the functional roles of these function and their disturbances and derangements are of such scope and importance that they have been accorded separate chapters. Language is discussed in Chap. 23, memory in Chap. 21, and the neurology of emotion and behavior in Chap. 25; these subjects are omitted from further discussion here.

Visual Disorders Already in Chap. 13 (on vision) it was pointed out that lesions of the white matter of the central and posterior parts of the temporal lobe characteristically involve the lower arching fibers of the geniculocalcarine pathway (Meyer's loop). This results in an upper homonymous quadrantanopia, usually not completely congruent. There is considerable variability in the arrangement of visual fibers as they pass around the temporal horn of the lateral ventricle; this accounts for the smallness of the field defect in some patients after temporal lobectomy or stroke and extension into the inferior field in others. Quadrantanopia from a dominant temporal lobe seizure. Later, the observations of Penfield and his collaborators on the effects of stimulating the temporal lobes in the conscious epileptic patient revealed something of its complex functions. There followed a large volume of writings on its anatomy, the neuronal networks and circuits by which it was connected to other cortical and subcortical structures, and the effects of ablation on emotion, behavior, and sensory perception. The classic writings on this subject include Williams's chapter on temporal lobe syndromes in the Handbook of Clinical Neurology and the monographs by Penfield and Rasmussen (The Cerebral Cortex of Man) and by Alajouanine and colleagues (Les Grandes Activités du Lobe Temporal). Clinical Effects of Temporal Lobe Lesions

The symptoms consequent to disease of the temporal lobes may, for convenience of exposition, be divided into disorders of the special senses (visual, auditory, olfactory, and gustatory), time perception, language, memory, emotion, and behavior. Of central importance are the roles of the superior part of the dominant lobe and its connections in language in defining the emotional life of the individual; the functional roles of these function and their disturbances and derangements are of such scope and importance that they have been accorded separate chapters. Language is discussed in Chap. 23, memory in Chap. 21, and the neurology of emotion and behavior in Chap. 25; these subjects are omitted from further discussion here.

Visual Disorders Already in Chap. 13 (on vision) it was pointed out that lesions of the white matter of the central and posterior parts of the temporal lobe characteristically involve the lower arching fibers of the geniculocalcarine pathway (Meyer's loop). This results in an upper homonymous quadrantanopia, usually not completely congruent. There is considerable variability in the arrangement of visual fibers as they pass around the temporal horn of the lateral ventricle; this accounts for the smallness of the field defect in some patients after temporal lobectomy or stroke and extension into the inferior field in others. Quadrantanopia from a dominant lesion is often combined with aphasia.

Bilateral lesions of the temporal lobes render a monkey psychically blind. He can see and pick up objects but does not recognize them until they are explored orally. Natural emotional reactions such as fear are lost. This syndrome, named for Klüver and Bucy, has been identified in partial form in humans (page 545). Lesser degrees of visual impairment have been uncovered by Milner and by McFie and colleagues, using special tests.

Visual hallucinations of complex form, including ones of the patient himself (autoscopy), appear during temporal lobe seizures. In stimulation studies, Penfield was able to induce what he called "interpretive illusions" (altered impressions of the present) and to reactivate past experiences quite completely and vividly in association with their original emotions. Temporal lobe abnormalities may also distort visual perception; seen objects may appear too large (macropsia) or small (micropsia), too close or far away, or unreal. Some visual hallucinations have an auditory component: an imaginary figure may speak and move and, at the same time, arouse intense emotional reactions. The entire experience may seem unnatural and unreal but is unlike the visuospatial disorders of the body schema, which are considered with disorders of the parietal lobe, further on.

Cortical Deafness Bilateral lesions of the transverse gyri of Heschl are known to cause deafness. Hersen, in his famous review of 1337 cases of aphasia that had been reported up to 1922, found 3 in which these parts were destroyed by restricted vascular lesions, with resulting deafness. There are now many more cases of this type in the medical literature; lesions in other parts of the temporal lobes have no effect on hearing. These observations are the basis for the localization of the primary auditory receptive area in the cortex of the transverse gyr (chiefly the first), on the posterior-superior surface of the temporal lobe, deep within the sylvian fissure (areas 41 and 42). Subcortical lesions, which interrupt the fibers from both medial geniculate bodies to the transverse gyr (as in the two cases of Tanaka and colleagues, have the same effect. With left-sided supratemporal lesions, there is usually an aphasia as well, because of the proximity of the transverse gyr to the supratemporal association cortex. Hecaen has remarked that cortical deaf patients may seem to be unaware of their deafness, a state similar to that of blind persons who act as though they could see (Anton syndrome, see further on).
unilateral lesions do not diminish the perception of pure tones or clearly spoken words, the ear contralateral to a temporal lesion is less efficient if the conditions of hearing are rendered more difficult (binaural test). For example, if words are slightly distorted (electronically filtered to alter consonants), they are heard less well in the ear contralateral to the lesion. In addition, the patient has more difficulty in equalizing the volume of sounds that are presented to both ears and in perceiving rapidly spoken numbers or different words presented to the two ears (dichotic listening).

**Auditory Agnosias** Lesions of the secondary (unimodal association) zones of the auditory cortex—area 22 and part of area 21—have no effect on the perception of sounds and pure tones. However, the perception of complex combinations of sounds is severely impaired. This impairment, or auditory agnosia, takes several forms—incapability to recognize sounds, different musical notes (amusia), or words—and presumably each has a slightly different anatomic basis.

In agnosia for sounds, auditory sensations cannot be distinguished from one another. Such varied sounds as the tinkling of a bell, the rustling of paper, running water, and a siren all sound alike. The condition is usually associated with word deafness (page 510 and below) or with amusia. Hecaen observed an agnosia for sounds alone in only two cases; one patient could identify only half of 26 familiar sounds, and the other could recognize no sound other than the ticking of a watch. Yet in both patients the audiogram was normal, and neither had trouble understanding spoken words. In both, the lesion involved the right temporal lobe and the corpus callosum was intact.

Amusia proves to be more complicated, for the appreciation of music has several aspects: the recognition of a familiar melody and the ability to name it; the perception of pitch and timbre; and the ability to produce, read, and write music. There are many reports of musicians who became word-deaf with lesions of the dominant temporal lobe but retained their recognition of music and their skill in producing it. Others became agnostic for music but not for words, and still others were agnostic for both words and music. According to Segarra and Quadfasel, impaired recognition of music results from lesions in the middle temporal gyrus and not from lesions at the pole of the temporal lobe, as had been postulated by Hensch.

The appreciation of music is impaired by lesions of the nondominant temporal lobe finds support in Milner's studies of patients who had undergone temporal lobectomy. She found a statistically significant lowering of the patient's appreciation of the duration of notes, timbre, intensity of sounds, and memory of melodies following right temporal lobectomy; these abilities were preserved in patients with left temporal lobectomies, regardless of whether Heschl's gyr were included. Similar observations had been made by Shankweiler, but in addition he found that patients had difficulty in denoting a note or naming a melody following left temporal lobectomies.

More recent observations permit somewhat different interpretations. Tramo and Bharucha examined the mechanisms mediating the recognition and discrimination of timbre (the distinctive tonal quality produced by a particular musical instrument) in patients whose right and left hemispheres had been separated by callosotomy. They found that timbre could be recognized by each hemisphere—somewhat better by the left hemisphere than by the right. Also, it was observed that lesions of the right hemisphere (quadrants of pitch) and of the left hemisphere (the recognition of simultaneous pitches). However, if words are added to the melody, then either a left- or right-sided lesion impairs its recognition (Samson and Zatorre). From functional imaging studies, it appears that the left inferior frontal region is activated by tasks that involve the identification of familiar music (Platel et al.), as if this were a semantic test, but passively listening to melodies activates the right superior temporal and occipital regions (Zatorre et al.).

Taken together, these data suggest that the nondominant hemisphere is important for the recognition of harmony and melody (in the absence of words), but that the naming of musical scores and all the semantic (writing and reading) aspects of music require integrity of the dominant temporal and probably the frontal lobes as well.

**Word Deafness (Auditory Verbal Agnosia)** In essence, word deafness is a failure of the left temporal lobe function in decoding the acoustic signals of speech and converting them into understandable words. This is the essential element in Wernicke's aphasia and is discussed in Chap. 23. However, word deafness can occur by itself, without other features of Wernicke's aphasia. Also, verbal agnosia may be combined with agnosia for sounds and music, or the two may occur separately.

**Auditory Illusions** Temporal lobe lesions that leave hearing intact may cause a hearing disorder in which sounds are perceived as being louder or less loud than normal. Sounds or words may seem strange or disagreeable, or they may seem to be repeated, a kind of sensory perseveration. If auditory hallucinations are also present, they may undergo similar alterations. Such paracusias may last indefinitely and, by changing timbre or tonality, alter musical appreciation as well.

**Auditory Hallucinations** These may be elementary (murmurs, blowing, sound of running water or motors, whistles, clangs, sirens, etc.), or they may be complex (musical themes, choruses, voices). Usually sounds and musical themes are heard more clearly than voices. Patients may recognize the illusions and hallucinations for what they are, or they may be convinced that the voices are real and respond to them with intense emotion. Hearing may fade before or during the hallucination.

In temporal lobe epilepsy, the auditory hallucinations may occur alone or in combination with visual or gustatory hallucinations, visual distortions, dizziness, and aphasia. There may be hallucinations based on remembered experiences (experiential hallucinations, in the terminology of Penfield and Rasmussen).

The anatomy of lesions underlying auditory illusions and hallucinations has been incompletely studied. In some instances these sensory phenomena have been combined with auditory verbal (or nonverbal) agnosia; the superior and posterior parts of the dominant or both temporal lobes were then involved. Clinicoanatomic correlation is difficult in cases of tumors that distort the brain without completely destroying it and also cause edema of the surrounding tissue. Moreover, it is often unclear whether symptoms have been produced by destruction of tissue or by excitation, i.e., by way of seizure discharges, which act in a fashion similar to electrical stimulation of the auditory cortical areas. Elementary hallucinations and dreamy states have been reported with lesions of either temporal lobe, whereas the more complex auditory hallucinations and particularly polymodal ones (visual plus auditory) occur more often with left-sided lesions. Also, it should be noted that elementary or unformed auditory hallucinations (e.g., the sound of an orchestra tuning up) as well as entire strains of music and singing, occur with lesions that appear to be restricted to the pons ("pontine auditory hallucinations").

It is tempting to relate complex auditory hallucinations to disorders in the auditory association areas surrounding Heschl's gyr, but the data do not fully justify such an assumption. In schizophrenic patients, the areas activated during a period of active auditory hallucinosis include not only Heschl's gyr but also the hippocampus and other widely distributed structures in the dominant hemisphere (see Chap. 58).

**Vestibular Disturbances** In the superior and posterior part of the temporal lob (posterior to the primary auditory cortex), there is an area that responds to vestibular stimulation by altering one's sense of verticality in relation to the environment. If this area is destroyed on one side, the only clinical effect may be a subtle change in eye movements on optokinetic stimulation (more often a result of parietal damage). Epileptic activation of this area may occur, inducing vertigo or a sense of disorientation. If this area is destroyed on one side, the only clinical effect may be a subtle change in eye movements on optokinetic stimulation (more often a result of parietal damage). Epileptic activation of this area may occur, inducing vertigo or a sense of disorientation. As pointed out on page 338, pure vertiginous epilepsy does occur but is a rarity, and if vertigo does precede a seizure, it is usually momentary and is quickly submerged in other components of the seizure.

**Disurbances of Time Perception** These may occur with lesions of either temporal lobe. In a temporal lobe seizure, time may seem to stand still or to pass with great speed. On recovery from such a seizure, the patient, having lost all sense of time, may repeatedly look at the clock. Amnestias (mental retardation) and dementias prevent or abolish the capacity to reckon personal events in terms of a subjective time scale. The patient with a Korsakoff amnestic state is unable to place events in their proper time relationships, presumably because of failure of retentive memory. Assal and Bindschaedler have reported an extraordinary abnormality of time sense following right temporal lobe damage, where the patient was unable to judge the duration of notes, the relative intensity of sounds, or the time of events, as is characteristic of patients with auditory hallucinations.

Certainly the most common disruptions of the sense of time are part of confusional states of any type. The usual tendency is for the patient to report the current date as an earlier one, much less often as a later one. Characteristically, in this situation the responses vary from one examination to the next.

**Smell and Taste** The central anatomy and physiology of these two senses have been elusive. Brodal concluded that the hippocampus was not involved. However, seizure foci in the medial part of the temporal lobe (in the region of the uncus) may evoke olfactory hallucinations. This "uncinate fit," as originally pointed out by Jackson and Stewart, was often accompanied by a dreamy state, or, in the words of Penfield, an "intellectual aura." The central areas identified physiologically with olfaction are the posterior orbitofrontal, subcallosal, anterior temporal, and insular cortices, i.e., the areas that mediate visceral functions.

In comparison, hallucinations of taste are rare. Stimulation of the posterior inferior sacral area elicited a sensation of taste along with disturbances of alimentary function (Penfield and Faulk). There are cases in which a lesion in the medial temporal lobe caused both gustatory and olfactory hallucinations. Sometimes the patient cannot decide whether he experienced an abnormal odor, taste, or both. The anatomy and physiology of smell and taste are discussed further in Chap. 12.
Other (Nonauditory) Syndromes Between the hippocampal formation (on the inferomedial surface of the temporal lobe) and the primary and secondary auditory areas (Heschl's transverse gyril and superior temporal convolution, respectively), there is a large inferolateral expanse of temporal lobe that has only vaguely assignable integrative functions. With lesions in these parts of the dominant temporal lobe, a defect in the retrieval of words (amnestic dysnomia) has been a frequently observed abnormality. Stimulation of the posterior parts of the first and second temporal convolutions of fully conscious epileptic patients can arouse complex memories and visual and auditory images, some with strong emotional content (Penfield and Roberts).

Careful psychologic studies have disclosed a difference between the effects of dominant and nondominant partial temporal lobectomy (Miner). With the former, there was dysnomia and impairment in the learning of material presented through the auditory sense; with the latter, there was impairment in the learning of visually presented material. In addition, about 20 percent of patients who had undergone temporal lobectomy, left or right, showed a syndrome similar to that which results from lesions of the prefrontal regions. Perhaps more significant is the observation that the remainder of the cases showed little or no defect in personality or behavior.

Disorders of Memory, Emotion, and Behavior Finally, attention must be drawn to the central role of the temporal lobe, notably its hippocampal and limbic parts, in memory and learning and in the emotional life of the individual. As indicated earlier, these functions and their derangements have been accorded separate chapters. Memory is discussed in Chap. 21 and the neurology of emotion and behavior in Chap. 25.

To summarize, human temporal lobe syndromes include the following:

I. Effects of unilateral disease of the dominant temporal lobe
   A. Homonymous upper quadrantagnosia
   B. Wernicke's aphasia (word deafness—auditory verbal agnosia)
   C. Amusia (some types)
   D. Impairment in tests of verbal material presented through the auditory sense
   E. Dysnomia or amnesic aphasia
   F. Visual agnosia
   G. Occasionally amnestic (Korsakoff) syndrome

II. Effects of disease of the nondominant temporal lobe
   A. Homonymous upper quadrantagnosia
   B. Inability to judge spatial relationships in some cases
   C. Impairment in tests of visually presented nonverbal material
   D. Agnosia for sounds and some qualities of music

III. Effects of disease of either temporal lobe
   A. Auditory, visual, olfactory, and gustatory hallucinations
   B. Dreamy states with uncinate seizures
   C. Emotional and behavioral changes
   D. Delirium (usually nondominant)
   E. Disturbances of time perception

IV. Effects of bilateral disease
   A. Korsakoff amnesic defect (hippocampal formations)
   B. Apathy and placidity
   C. Hypermimicnia (compulsion to attend to all visual stimuli), hyperorality, hypersexuality, blunted emotional reactivity (Kübler-Blumberg syndrome; the full syndrome is rarely seen in man)

SYNDROMES CAUSED BY LESIONS OF THE PARIETAL LOBES

Anatomic and Physiologic Considerations This part of the cerebrum, lying behind the central sulcus and above the Sylvian fissure, is the least well demarcated (Fig. 22-8). Its posterior boundary, where it merges with the occipital lobe, is obscure, as is part of the inferior boundary, where it merges with the temporal lobe. On its medial side, the parieto-occipital sulcus marks the posterior border, which is completed by extending the line of the sulcus downward to the precereopial notch on the inferior border of the hemisphere. Within the parietal lobe, there are two important sulci: the postcentral sulcus, which forms the posterior boundary of the somesthetic cortex, and the interparietal sulcus, which runs anteroposteriorly from the middle of the posteroinferior central sulcus and separates the mass of the parietal lobe into superior and inferior lobules (Fig. 22-3 and Fig. 22-9). The inferior parietal lobule (Edinger's lobule in older terminology) is composed of the supramarginal gyrus (Brodmann's area 40) and the angular gyrus (area 39). These two gyri and the posterior third of the first temporal gyrus make up what has been called Wernicke's language area.

The architecture of the postcentral convolution is typical of all primary receptive areas (homotypical granular cortex). The rest of the parietal lobe resembles the association cortex, both unimodal and heteromodal, of the frontal and temporal lobes. The superior and inferior parietal lobules and adjacent parts of the temporal and occipital lobes are relatively much larger in humans than in any of the other primates and are relatively slow in attaining their fully functional state (beyond the seventh year of age). This area of heteromodal cortex has large fiber connections with the frontal, occipital, and temporal lobes of the same hemisphere and, through the middle part of the corpus callosum, with corresponding parts of the opposite hemisphere.

The postcentral gyrus or primary somatosensory cortex receives most of its afferent projections from the ventroposterior thalamic nucleus, which is the terminus of the ascending somatosensory pathways. The contralateral half of the body is represented somatotopically on the posterior bank of the Rolandic sulcus. It has been shown in the macaque that spindle afferent project to area 3a, cutaneous afferents to areas 3b and 1, and joint afferents to area 2 (Kappers). Stimulation of the posterior bank of the Rolandic sulcus elicits a numb, tingling sensation and sense of movement. Penfield remarked that rarely are these tactile illusions accompanied by pain, warmth, or cold. Stimulation of the motor cortex may produce similar sensations, as do discharging seizure foci from these regions. The primary sensory cortex projects to the superior parietal lobe (area 5), which is the somatosensory association cortex. Some parts of areas 1, 3, and 5 (except the hand and foot representations) probably connect, via the corpus callosum, with the opposite somatosensory cortex. There is some uncertainty as to whether area 7 (which lies posterior to area 5) is unimodal somatosensory or heteromodal visual and somatosensory; certainly it receives a large contingent of fibers from the occipital lobe.

In humans, electrical stimulation of the cortex of the superior and inferior parietal lobules evokes no specific motor or sensory effects. Overlapping here, however, are the tertiary zones for vision, hearing, and somatic sensation, the supramodal integration of which is essential to our awareness of space and person and certain aspects of language and calculation, as mentioned below.

The parietal lobe is supplied by the middle cerebral artery, the inferior and superior divisions supplying the inferior and superior lobules, respectively, although the vascular distribution in this area is variable.

Despite Critchley's pessimistic prediction that to establish a formula of normal parietal function will prove to be a "vain and meaningless pursuit," our concepts of the activities of this part of the brain are now assuming some degree of order. There is little doubt that the anterior parietal cortex contains the mechanisms for tactile percepts. Discriminative tactile functions, listed below, are organized in the more posterior, secondary sensory areas. But the greater part of the parietal lobe functions as a center for integrating somatosensory with visual and auditory information in order to construct an awareness of one's own body (bodily schema) and its relation to extrapersonal space. Connections between the parietal and occipital lobes provide the necessary proprioceptive and visual information for movement of the body and manipulation of objects and for certain constructive activities. Impairment of these functions implicates the parietal lobes, more clearly the one on the right. The understanding of spoken and written words is a function of the supramarginal and angular gyri of the dominant parietal lobe, as elaborated in Chap. 23. The recognition and utilization of numbers, arithmetic principles, and calculation, which have important spatial attributes, are other functions integrated primarily through these structures.

Clinical Effects of Parietal Lobe Lesions

Within the brain, no other territory surpasses the parietal lobes in the rich variety of clinical phenomena that are exposed under conditions of disease. Our current understanding of the effects of parietal lobe disease contrasts sharply with that of the late nineteenth century, when these lobes, in the classic textbooks of
Cortical Sensory Syndromes

The effects of a parietal lobe lesion on somatic sensation were first described by Verger and then more completely by Déjerine, in his monograph *L'agnosie corticale*, and by Head and Holmes. The latter, in their important paper of 1911, noted the close interrelationships between the thalamus and the sensory cortex. As pointed out on page 172, the defect is essentially one of sensory discrimination, i.e., an impairment or loss of the sense of position and passive movement and the ability to localize tactile, thermal, and noxious stimuli applied to the body surface; to distinguish objects by their size, shape, and texture (astereognosis); to recognize figures written on the skin; to distinguish between single and double contacts (two-point discrimination); and to detect the direction of movement of a tactile stimulus. In contrast, the perception of pain, touch, pressure, vibratory stimuli, and thermal stimuli is relatively intact. This type of sensory defect is sometimes referred to as “cortical,” although it can be produced just as well by lesions of the subcortical connections. Clinicanoatomic studies indicate that parietocortical lesions that spare the postcentral gyrus produce only transient somatosensory changes or none at all (Corkin et al; Carmon and Benton).

The question of bilateral sensory deficits with lesions in only one postcentral convolution was raised by the studies of Sommers and of Corkin and their associates. In tests of pressure sensitivity, two-point discrimination, point localization, position sense, and tactile object recognition, they found bilateral disturbances in nearly half of their patients with unilateral lesions, and the deficits were always more severe contralaterally and mainly in the hand. These disturbances of discriminative sensation and the subject of tactile agnosia are discussed more fully in Chap. 8.

Déjerine and Mouzon described another parietal sensory syndrome in which touch, pressure, pain, thermal, vibratory, and position sense are all lost on one side of the body or in a limb. This syndrome, usually associated with a thalamic lesion, may also occur with large, acute lesions (infarcts, hemorrhages) in the central and subcortical white matter of the contralateral parietal lobe; in the latter case these symptoms recede in time, leaving more subtle defects in sensory discrimination. As indicated in Chap. 8, smaller lesions, particularly ones that result from a glancing blow to the skull or a small infarct or hemorrhage, may cause a defect in cutaneous-kinesiesthetic function in a discrete part of a limb, e.g., the ulnar or radial half of the hand and forearm; these cerebral lesions may mimic a peripheral nerve or root lesion (Dodge and Mowinckel). Also, a pseudothalamic pain syndrome on the side deprived of sensation has been described (Biemond). In a series of 12 such patients described by Michel and colleagues, burning or constractive pain, identical to the thalamic pain syndrome (page 172), resulted from vascular lesions restricted to the cortex. The discomfort involved the entire half of the body or matched the region of cortical hypoplasia; in a few cases it was paroxysmal.

Head and Holmes drew attention to a number of interesting points about patients with parietal sensory defects—the easy fatigability of their sensory perceptions; the inconsistency of responses to painful and tactile stimuli; the difficulty in distinguishing more than one at a time; the disregard of stimuli on the affected side when the healthy side is stimulated simultaneously (tactile inattentiveness or extinction); the tendency of superficial pain sensations to outlast the stimulus and to be hyporeactive or even to occur out of phase with the stimulus; the occurrence of hallucinations or delusions for which there is no corroborative evidence; an intarresting elimination of hemineglect in patients with right parietal infarcts by caloric or electrical stimulation of the ipsilateral vestibular apparatus.

With anterior parietal lobe lesions there is often an associated hemiparesis, since this portion of the parietal lobe contributes a considerable number of fibers to the corticospinal tract. There is, however, only a very small area on the opposite side in the absence of somatic neglect. The affected limbs, if involved with this apparent weakness solely from a parietal lesion, tend to remain hypotonic and the musculature may undergo atrrophy of a degree not explained by inactivity alone. In some cases, as noted below, there is clumsiness in reaching for and grasping an object under visual guidance (optic ataxia), and exceptionally, at some phase in recovery from the hemisensory deficit, there is incoordinate movement and intention tremor of the contralateral arm and leg, simulating a cerebellar deficit (parietocerebellar syndrome). While relatively rare, it is authenticated by our own case studies. With parietal lesions, the arm and hand may sometimes be held in a fixed dystonic posture.

The Asomatognosias

This term denotes the inability to recognize part of one's body. The idea that visual and tactile sensory information is synthesized during development into a body schema or image (perception of one's body and the relations of bodily parts to one another) was first clearly formulated by Pick and extensively elaborated by Brain. Long before today, however, it was suggested that such information was the basis of our emerging awareness of ourselves as persons, and philosophers had assumed that this comes about by the constant interplay between percepts of ourselves and of the surrounding world.

The formation of the body schema is thought to be based on the constant influx and storage of sensations from our bodies as we move about: hence, motor activity is important in its development. Always, however, a sense of extrasensory space is involved as well, and this depends upon visual and labyrinthism stimulation. The mechanisms upon which these perceptions depend are best appreciated by studying their derangements in the course of neurologic disease.

Anosognosia (Unilateral Anosognosia; Anton-Babinski Syndrome) The observation that a patient with a dense hemiplegia, usually of the left side, may be indifferent to, or unaware of, the paralysis was first made by Anton; later, Babinski named this disorder anosognosia. It may express itself in several ways: The patient may act as if nothing were the matter. If asked to raise the paralyzed arm, he may raise the intact one or do nothing at all. If asked whether the paralyzed arm has been moved, the patient may say yes. If the failure to do so is pointed out, the patient may admit that the arm is slightly weak. If told it is paralyzed, the patient may deny that this is so or offer an excuse: “My shoulder hurts.” If asked why the paralysis went unnoticed, the response may be, “I’m not a doctor.” Some patients report that they feel as though their left side had disappeared, and when shown the paralyzed arm, they may deny it is theirs and assert that it belongs to someone else or even hold it of and fling it aside. This mental derangement, which Hughlings Jackson referred to as “a kind of imbecility,” obviously includes a somatosensory defect and loss of the stored images of the body schema as well as a conceptual negation of paralysis and even a disturbed visual perception and neglect of half of the body.

Anosognosia is unusual associated with a number of additional abnormalities. Often, in this state, there is a blurred emotional tone. The patient looks dull, is indifferent, and apathetic, and shows varying degrees of general confusion. There may be an indifference to failure, a feeling that something is missing, visual and tactile illusions when sensing the paralyzed part, hallucinations of movement, and alochorea (one-sided stimuli are felt on the other side).

A particularly common group of parietal symptoms, easily tested at the bedside, consists of neglect of one side of the body in dressing and grooming (“dressing apraxia”), recognition only on the intact side of bilaterally and simultaneously presented stimuli (“sensory extinction”), deviation of head and eyes to the side of the lesions and of the body in the same direction (failure of directed attention to the body and to extrapersonal space on the side opposite the lesion). The patient may fail to shave one side of the face, apply lipstick or comb the hair only on one side, or find it impossible to put on eyeglasses, insert dentures, or put on a dressing gown, or turn the head or eyes to the side of the lesion and of the objects in the room. Homonymous hemianopsia and varying degrees of hemiparesis may or may not be present. Unilateral spatial neglect is further reflected in the patient's inability to reproduce geometric figures (“construction apraxia”). A number of tests have been designed to elicit these disturbances, such as indicating the time by placement of the hands on a clock, drawing a map, copying a complex figure, reproducing stick-pattern constructions and block designs, making the movements in front of the patient, and contrasting perception of a right and left stimuli.

According to Denny-Brown and coworkers, the basic disturbance in such cases is an inability to summate a series of “spatial impressions”—tactile, kinesiesthetic, visual, or auditory—a defect they refer to as amorphosynthesis. In their view, impairment or neglect of one side of the body and of extrapersonal space represents the full extent of the lesion and is in a lesser degree the result of a primary lesion of the primary somatic sensory cortex, which is strictly contralateral to the damaged parietal lobe, right or left, and must be distinguished from a true agnosia, which is a conceptual disorder and involves both sides of the body and extrapersonal space as a result of damage to one (the dominant) hemisphere. More recent observations indicate that patients with right parietal lesions show variable but lessor elements of ipsilateral neglect in addition to the striking degree of contralateral neglect, suggesting that, in respect to spatial attention, the right parietal lobe is truly dominant (Weintraub and Mesulam).

An interesting observation of Bisach and Luzzatti suggests that the loss of attention to one side of the environment extends to the mental representation of space. They describe a patient who was able to describe the Piazza del Duomo of Florence, first as if seen from the other side of the piazza and then from the opposite corner. In each instance the description omitted the left side of the piazza. We have been unable to elicit this effect in our patients.
Bilateral Asematognosia (Gerstmann Syndrome) This syndrome provides the most striking example of bilateral asematognosia and is due to a left, or dominant, parietal lesion. The characteristic features are inability to designate or name the different fingers of the two hands (finger agnosia), confusion of the right and left sides of the body, and inability to calculate (dyscalculia) and to write (dysgraphia). One or more of these manifestations may be associated with word blindness (alexia) and homonymous hemianopia or a lower quadrantanopia, of which the patient is usually unaware. The lesion can then be placed in the angular gyrus or subjacent white matter of the left hemisphere ("angular gyrus syndrome").

Lesions of the superior parietal lobule may interfere with voluntary movement of the opposite limbs, particularly the arm, as pointed out by Holmes. In reaching for a visually presented target in the contralateral visual field and to a lesser extent in the ipsilateral field, the movement is misdirected and dysmetric (the distance to the target is misjudged). This disorder of movement, alluded to above in the general discussion of parietal signs and sometimes referred to as optic ataxia, resembles cerebellar ataxia and is explained by the fact that cortical areas 7 and 5 receive visual projections from the parastratified areas and proprioceptive ones from the cerebellum, both of which are integrated in the multimodal parietal cortex. Areas 5 and 7, in turn, project to frontal areas 6, 8, and 9, where ocular scanning and reaching are coordinated.

Discalculia has attracted little critical attention, perhaps because it occurs most often as a byproduct of aphasia and an inability of the patient to appreciate numerical language. The loss of the use form, usually associated in other elements of the Gerstmann syndrome. Computational difficulty may also be part of the more complex visuo-spatial abnormality of the nondominant parietal lobe; there is then difficulty in the placing of numbers in specific spatial relationships while calculating. In such cases, there is no difficulty in reading or writing the numbers and the rules governing the calculation can be described, but the computation cannot be accomplished correctly with pencil and paper. Hecaen has made a distinction between dyscalculia and anarthriesthesia; in the former, the process of calculation alone has been disturbed; in the latter, there is an inability to manipulate numbers. Recognition and reproduction of numbers are intact in both. An analysis of how the computation goes awry in each individual case is therefore required.

Ideomotor and Ideational Apraxia As discussed in Chap. 3, patients with dominant parietal lesions who exhibit no defects in motor or sensory function lose the ability to perform learned motor skills on command or by imitation. Common implements and tools can no longer be used, either in relation to the patient’s body (e.g., comb or brush) or in relation to objects in the environment. It is as though the patient had forgotten the sequences of learned movements. The effects are bilateral. It is of interest that, in both aggraphia and acalculia, the motor defect appears to be intertwined with agnostic defects; hence the term apragnosia seems appropriate.

From the above descriptions it is evident that the left and right parietal lobes function differently. The most obvious difference, of course, is that language and arithmetical functions are centered in the left hemisphere. It is hardly surprising, therefore, that verbally mediated or verbally associated spatial functions are more affected with left-sided than with right-sided lesions. It must also be realized that language function involves cross-modal connections and is central to all cognitive functions. Hence cross-modal matching tasks (auditory-visual, visual-auditory, visual-tactile, tactile-visual, auditory-tactile, etc.) are most clearly impaired with lesions of the dominant hemisphere. Such patients can read and understand spoken words but cannot grasp the meaning of a sentence if it contains elements of relationship (e.g., “the mother’s daughter” versus “the daughter’s mother,” “the father’s brother’s son.” “Jane’s complexion is lighter than Marjorie’s but darker than her sister’s”).

Thus, there are common difficulties with calculation, as just described. The recognition and naming of parts of the body and the distinction of right from left and up from down are other learned, verbally mediated spatial concepts that are disturbed by lesions in the dominant parietal lobe.

Visual Disorders with Parietal Lesions A lesion deep to the inferior part of the parietal lobe, at its junction with the temporal lobe, may involve the genticulocalcarine radiations and result in an incongruous homonymous hemianopia; but just as often, in practice, the defect is complete or almost complete and congruous. If the lesion is incomplete, the lower quadrants of the visual fields are affected predominantly (quadrantanopia). An alexia or components of the Gerstmann syndrome may be associated. If the lesion is predominantly cortical, optokineti nystagmus is usually retained; with deep lesions, it is abolished, with the target moving ipsilaterally (Chap. 14). With posterior parietal lesions, as noted by Holmes and Horrax, there are deficits in locali zation of visual stimuli, inability to compare the sizes of objects, failure to judge vertical objects, failure of the eyes to deviate away from the lesion on forced lid closure, a “spasticity of conjugate gaze.”

Visual Disorientation and Disorders of Spatial (Topographic) Localization Spatial orientation depends upon visual, tactile, and kinesthetic perceptions, but there are instances in which the defect in visual perception predominates. Patients with this disorder are unable to orient themselves in an abstract spatial setting (topographagnosia). Such patients cannot sight the floor plan of their house or a map of their town or the United States and cannot describe a familiar route—from their home to their place of work, for example—or find their way in familiar surroundings. In brief, they have lost topographic memory. This disorder is almost invariably caused by lesions in the dorsal convexity of the right parietal lobe.

A common and striking disorder of motor behavior of the eyelids is seen in most patients with large acute lesions of the right parietal lobe. Its mildest form is a disinclination to open the lids when spoken to. This gives the erroneous impression that a patient is drowsy or stuporous, but it will be found that a quick reply can be given to whispered questions. In more severe cases, the lids are held shut and opening is strongly resisted, to the point of making an examination of the globes impossible.

The effects of disease of the parietal lobes may be summarized as follows:

I. Effects of unilateral disease of the parietal lobe, right or left
   A. Corticosemy syndrome and sensory extinction (or total hemihemiasis with large acute lesions of white matter)
   B. Mild hemiparesis, unilateral muscular atrophy in children, hypotonia, poverty of movement, hemiataxia
   C. Homonymous hemianopia or inferior quadrantanopia (incongruent or congruent) or visual inattention, and sometimes anosognosia, neglect of one-half of the body and of extrapersonal space (amorphosynthesis, observed more frequently with right than with left parietal lesions)
   D. Abolition of optokinetic nystagmus with target moving toward side of the lesion

II. Effects of unilateral disease of the dominant parietal lobe (left hemisphere in right-handed patients)—additional phenomena include
   A. Disorders of language (Chap. 14)
   B. Gerstmann syndrome (dysgraphia, dyscalculia, finger agnosia, right-left confusion)
   C. Tactile agnosia (bimanual astereognosis)
   D. Bilateral ideomotor and ideational apraxia
   E. Ideomotor and Ideational Apraxia
   F. Disconnection of right and left hemisphere
   G. Visuospatial disorders
   H. Topographic memory loss
   I. Anosognosia, dressing and constructional apraxias. (These disorders may occur with lesions of either hemisphere but have been observed more frequently with lesions of the nondominant one.)
   J. Confusion
   K. Tendency to keep the eyes closed, resist opening, and blepharospasm

IV. Effects of bilateral disease of the parietal lobes
   A. Visual spatial imperception, spatial disorientation, and complete or partial Balint syndrome
In all these lesions, if the disease is sufficiently extensive, there may be a reduction in the capacity to think clearly, as well as inattentiveness and impaired memory.

It is still not possible to present an all-embracing formula of parietal lobe function. It does seem reasonably certain that, in addition to the perception of somatosensory impulses (postcentral gyrus), the parietal lobe participates in the integration of all sensory data, especially those that provide an awareness of one's body as well as a perception of one's surroundings and of the relation of one's body to extrapersonal space and of objects in the environment to one another. In this respect, the parietal lobe may be regarded as a special, high-order sensory organ—the locus of transmodal (intersensory) integrations, particularly tactile and visual ones, which are the basis of our concepts of spatial relations.

Useful references on parietal function include Critchley's monograph on the parietal lobes and the chapter by Botetz et al in the *Handbook of Clinical Neurology*.

**SYNDROMES CAUSED BY LESIONS OF THE OCCIPITAL LOBES**

Anatomic and Physiologic Considerations

The occipital lobes are the terminus of the geniculo-cortical pathways and are essential for visual perception and recognition. This part of the brain has a large medial surface and somewhat smaller lateral and inferior surfaces (Fig. 22.8). The parieto-occipital fissure is its obvious medial boundary with the parietal lobe, and laterally it merges with the parietal and temporal lobes. The large calcineurion fissure courses in an anteroposterior direction from the pole of the occipital lobe to the splenium of the corpus callosum; area 17, the primary idiothetic visual receptive cortex, lies on its banks (Fig. 22.9). It is typical homotypical cortex but is unique in that its fourth receptive layer is divided into two granular cell laminae by a greatly thickened band of myelinated fibers, the external band of B安全生产. This strip in area 17, also called the line or band of Genova, is grossly visible and has given this area its name—striate cortex. The largest part of area 17 is the terminus of the retinal macular fibers (see Fig. 13.2). The parastriate cortex (areas 18 and 19) lacks the line of Genova and resembles the granular unimodal association cortex of the rest of the cerebrum. Area 17 contains cells that are activated by the homolateral geniculo-cortical pathway; these cells are interconnected and project also to areas 18 and 19. The latter are connected with one another and with the angular gyrus, lateral and medial temporal gyri, frontal motor areas, limbic and paralimbic areas, and corresponding areas of the opposite hemisphere through the posterior third (splenium) of the corpus callosum.

The occipital lobes are supplied by the posterior cerebral arteries and their branches, either directly in most individuals or through an embryologically persistent branch of the internal carotid arteries in a few ("fetal" posterior cerebral artery).

The connections among these several areas in the occipital lobe are complicated, and the old idea that area 17 is activated by the lateral geniculate neurons and that this activity is then transferred and elaborated in areas 18 and 19 is surely not the complete story. Actually four or five occipital receptive fields are activated by the lateral geniculate neurons; fibers from area 17 project to approximately 20 other visual cortical areas, of which 5 are identified most clearly. These extrastriate visual areas lie in the lingula and posterior regions. Monkeys with bilateral lesions in the temporal visual zones lose the ability to identify objects; with posterior parietal lesions, there is loss of ability to locate objects. And, as Hubel and Wiesel have shown, the response patterns of neurons in both occipital lobes to edges and moving visual stimuli, to on-and-off effects of light, and to colors are much different from what was originally supposed. Hence, form, location, color, and movement each have separate localizable mechanisms. The monographs of Polvak and of Miller contain detailed information about the anatomy and physiology of this part of the brain.

**Clinical Effects of Occipital Lobe Lesions**

**Visual Field Defects**

The most familiar clinical abnormality resulting from a lesion of one occipital lobe, homonymous hemianopia, has already been discussed in Chap. 13. Extensive destruction abolishes all vision in the corresponding half of each visual field. With a neoplastic lesion that eventually involves the entire striate region, the field defect may extend from the periphery toward the center, and loss of color vision (hemiachromatopsia) precedes loss of black and white. Lesions that destroy only part of the striate cortex on one side yield characteristic field defects that accurately indicate the lobe of the lesions. A lesion confined to the pole of the occipital lobe results in a central hemianopic defect that splits the macula and leaves the peripheral fields intact. This observation indicates that half of each macula is unilaterally represented and that the maculae may be involved (split) in hemianopia. Bilateral lesions of the occipital poles, as in embolism of the posterior cerebral arteries, result in bilateral central hemianopias. Quadrant defects and altitudinal field defects due to striate lesions indicate that the cortex on one side, above or below the macula, is damaged. The cortex below the fissure is the terminus of fibers from the lower half of the retina, the part of the retina that projects to the upper half of the occipital lobe, so that a field defect in the upper quadrant of one eye may be accompanied by a field defect in the lower quadrant of the other eye. This fact is exploited in the diagnosis of certain lesions (see Fig. 13.3). Less complete lesions leave the patient with varying degrees of visual perception. There may also be visual hallucinations of either elementary or complex types. The visual agnosia and partially impaired perceptual function to recovery. Even with recovery, the patient may complain of visual fatigue (asthenopia) and difficulties in reading.

**Cortical Blindness**

With bilateral lesions of the occipital lobes (destruction of area 17 of both hemispheres), there is a loss of sight and a loss of reflex closure of the eyelids to a bright light or threat. The degree of blindness may be equivalent to that which follows encleavage of the eyes or severing of the optic nerves. The pupillary light reflexes are preserved, since they depend upon visual fibers that terminate in the midbrain, short of the geniculate bodies (see Fig. 14.6). Usually no changes are detectable in the retinas, though van Buren has described slight optic atrophy in monkeys long after occipital ablations. The eyes are still able to move through a full range, but optokinetic nystagmus cannot be elicited. Visual imagination and visual imagery in dreams are preserved. With very rare exceptions, no cortical visual function can be evoked in the occipital lobes by light flashes or pattern changes (visual evoked response), and the alpha rhythm is lost in the electroencephalogram (EEG) (see Chap. 2).

Less complete lesions leave the patient with varying degrees of visual perception. There may also be visual hallucinations of either elementary or complex types. The mode of recovery from cortical blindness has been studied carefully by Gloning and colleagues, who describe a regular progression from cortical blindness through partial visual agnosia and partially impaired perceptual function to recovery. Even with recovery, the patient may complain of visual fatigue (asthenopia) and difficulties in fixation and fusion.

The usual cause of cortical blindness is occlusion of the posterior cerebral arteries (embolic or thrombotic) or the equivalent, occlusion of the distal basilar artery. The infarct may also involve the medial temporal regions or thalami with a resulting Korsakoff amnesic defect and a variety of other neurologic deficits referable to the midbrain and diencephalon (see pages 838–842). Hypertensive, eclamptic, and hypoxic-ischemic encephalopathy, Schilder disease and other leukodystrophies, Creutzfeldt Jakob disease, progressive multifocal leukoencephalopathy, cerebral infections following cardiac arrest, and bilateral glommas are other causes of cortical blindness. A transitory form of cortical blindness may occur with head injury, migraine, or the antiphospholipid antibody syndrome of lupus erythematosus, and as a consequence of intravascular dye injection and administration of a number of drugs such as interferon-alpha or cyclosporine. In the case of the latter drugs, imaging studies have disclosed a reversible posteroior leukoencephalopathy, similar in appearance to what occurs in hypertensive encephalopathy.

**Visual Anosognosia (Anton Syndrome)**

The main characteristic is denial of blindness by a patient who obviously cannot see. The patient acts as though he can see, and when attempting to walk, collides with objects, even to the point of injury. He may offer excuses for his difficulties: “I lost my glasses,” “The light is dim,” etc., or there may be only an indifference to the loss of sight. The lesions in cases of negation of blindness extend beyond the striate cortex to involve the visual association areas.

Rarely, the opposite condition may arise: a patient can see small objects but claims to be blind. This individual walks about avoiding obstacles, picks up crumbs or pills from the table, and catches a small ball thrown from a distance. Damasio suggests that this might be a type of visual disinorientation but with sufficient residual visual information to guide the hand, and that the lesion will be in the visual association areas superior to the calcarine cortex.

**Visual Illusions (Metamorphopsias)**

These may present as distortions of form, size, movement, or color. In a group of 83 patients with visual perceptual abnormalities, Hécaen showed that 71 fell under one of four headings: deformation of the image, change in size, illusion of movement, or a combination of these. Illusions of these types have been reported with lesions confined to the occipital lobes but are more frequently due to shared occipitoparietal or occipitotemporal lesions, for which reason they are also considered in earlier sections of this chapter as well as in Chap. 13 and Chap. 16. The right hemisphere appears to be involved more often than the left. Illusions of movement occur more frequently with posterior temporal lesions, polyopia (one object appearing as two or more objects) more frequently with occipital lesions (although it may occur in hysteria), and patinaopsia (perservation of visual images) with both parietal and occipital lesions.
Visual field defects are present in many of the cases. In all these conditions the anatomic correlates are imprecise.

It is likely that an element of vestibular disorder underlies the metamorphopsias of parieto-occipital lesions (the vestibular and proprioceptive systems are represented in the parietal lobes of each side and the lesions are responsible for misperceptions of movement and spatial relations). The illusion of tilting of the environment or upside-down vision has been known to occur as a result of parieto-occipital lesions but occurs more often with abnormalities of the vestibular nuclei.

Pharmacologic agents may also alter visual experience, and one may surmise that occipital or temporoparietal regions are involved. Atropine, lysergic acid, and mescaline, but also other anticholinergic and dopaminergic drugs used for therapeutic purposes cause many of the aforementioned illusory and hallucinatory phenomena.

**Visual Hallucinations**

These phenomena may be elementary or complex, and both types have sensory as well as cognitive aspects. Elementary (or unformed) hallucinations include flashes of light, colors, luminous points, stars, multiple lights (like candles), and geometric forms (circles, squares, and hexagons). They may be stationary (rigid, occurring repeatedly, vibrating, and/or changing); complex hallucinations are obtained by stimulating the calcarine cortex in a conscious patient. Complex (formed) hallucinations include objects, persons, or animals. They are indicative of lesions in the visual association areas or their connections with the temporal lobes. They may be of natural size, illusory, or grossly enlarged. With hemianopia, they may appear in the defective field or move from the intact field toward the hemianopic one. The patient may realize that the hallucinations are false experiences or may be convinced of their reality. Since the patient's response is usually in accord with the nature of the hallucination, he may react with fear to a threatening vision or casually if its content is benign.

The clinical setting for the occurrence of visual hallucinations varies. The simplest black-and-white moving scintillations are part of migraine. Others, some colored, can occur as a seizure aura. Often they are associated with a homonymous hemianopia, as indicated earlier. Frequently they occur as part of a confusional state or delirium (Chap. 20). In the "peduncular hallucinosis" of hemiblaphse, the hallucinations are purely visual, appear natural in form and color—sometimes in pastels, move about as in an animated cartoon, and are usually considered by the patient to be unreal, abnormal phenomena (observed insight). Similar phenomena may occur as part of hypnic hallucinations in the narcolepsy-cataplexy syndrome. In our material, hallucinosis of this type (erroneously called "peduncular") has been associated mainly with high mesencephalic lesions. As indicated above, the hallucinations in this disorder are purely visual; if hallucinations are polymodal, the lesion is always in the occipitotemporal parts of the cerebrum.

A special syndrome of ophthalmopathic hallucinations occurs in the blind person. The visual images may be of elementary or complex type, usually of people or animals, and are polychromic (vivid colors). The hallucinations may occur in the visual field (in the totally blind person), the field of one eye, or corresponding blind fields in the patient with homonymous hemianopia. Moving the eyes or closing the affected eye has variable effects, sometimes abolishing the hallucinations.

A similar phenomenon in elderly patients with partially visualized vision has been called the syndrome of Charles Bonnet, following the report by this author of visual hallucinations occurring in a "sane" person. The topic of senile hallucinosis has been reviewed by Gold and Rabin and 60 such patients were reported in detail by Teachman and colleagues. The latter authors found that 11 percent of older persons with reduced vision experienced these phenomena at one time or another. In the majority of their cases the hallucinations lacked any personal meaning and were usually not distressing, but the patients were greatly relieved to hear that they did not have mental disease.

Traditionally it has been taught that the lesions responsible for visual hallucinations, if identifiable, are situated in the occipital lobe or posterior part of the temporal lobe, and that elementary hallucinations have their origin in the occipital cortex and complex ones, in the temporal cortex. However, the opposite may pertain; in some cases, formed hallucinations are related to lesions of the occipital lobe and undifferentioned ones to lesions of the temporal lobe (Weinberger and Grant). Also, as emphasized by these authors, lesions that give rise to visual hallucinations, simple or elaborate, need not be confined to central nervous structures but may be caused by lesions at every level of the neuro-optic apparatus (retina, optic nerve, chiasm, etc.).

The hallucinatory phenomena of delirium are nonlocalizable, as pointed out in Chap. 20, but sometimes the evidence points to an origin in the temporal lobe.

**The Visual Agnosias**

**Visual Object Agnosia**

This rare condition, first described by Lissauer in 1899, consists of a failure to name and indicate the use of a seen object by spoken or written word or by gesture. The patient cannot even tell the generic class of the seen object. Visual acuity is intact, the mind is clear, and the patient is not aphasic—conditions requisite for the diagnosis of agnosia. If the object is palpated, it is recognized at once, and it can also be identified by smell or sound if it has an odor or makes a noise. Moving the object or placing it in its customary surroundings facilitates recognition. In most reported instances of object agnosia, the patient retains normal visual acuity but cannot identify, match, or name objects presented in any part of the visual field; if misnamed, the object is used in a fashion that reflects the incorrect perception. Amazingly, one encounters patients who have lost the capacity to recognize only one class of objects, e.g., animals or vegetables, suggesting that, in the human, stored information is grouped and classified in a way that is necessary for visual perception. Lissauer conceived of visual object recognition as consisting of two distinct processes—the construction of a perceptual representation from vision (apprehension) and the mapping of this perceptual representation onto stored perceptual or engrams of the object's functions and associations. Lissauer proposed that impairment of either of these processes could give rise to a defect in visual object recognition.

As indicated in Chap. 13, visual object agnosia is usually associated with visual verbal agnosia (alexia) and homonymous hemianopia. Prosopagnosia (the inability to identify faces; see further on) is also present in most cases. The underlying lesions are usually bilateral, although McCarthy and Warrington have related an instance of visual object agnosia to a restricted lesion of the left occipitotemporal region (by MRI). Several of our patients with visual object agnosia had an incoordinate amnesic syndrome and a left-sided inferior occipital and medial temporal infarction, reflecting a proximal occlusion of the posterior cerebral artery.

**Simultagnosia**

Wolpert originally described a patient who demonstrated a "spelling dyslexia" (an inability to read all but the shortest words, spelled out letter by letter) and a failure to perceive simultaneously all the elements of a scene and to properly interpret the scene. In the framework of gestalt psychology, the patient could recognize the parts but not the whole. A cognitive defect of synthesis of the visual impressions was thought to be the basis of this condition, which Wolpert called simultagnosia. Some patients with this disorder have a right homonymous hemianopia; in others, the visual fields are full but there is one-sided extinction when tested with double simultaneous stimulation. This is part of the Balint syndrome (see below), the other components of which are faulty visual scanning (ocular apraxia) and visual reaching (optic ataxia), suggesting that a fault in ocular scanning might underlie all the defects. Through tachistoscopic testing, Kinsbourne and Warrington have noted that reducing the time of stimulus exposure permits single objects to be perceived in an instant, but not two objects. Rizzo and Robin have proposed that the primary defect is in sustained attention to incoming visual information; if attended, vision is not possible (appropriately called optic ataxia); and (3) visual inattention mainly to the periphery of the visual field, attention to other sensory stimuli being intact. Balint, a Hungarian neurologist, was the first to recognize this constellation of findings.

The psychic paralysis of gaze is apparent when the patient attempts to turn his eyes to fixate an object in the right or left visual field and to follow a moving object into all four quadrants of the field once the eyes are fixated on it. So-called optic ataxia is detected when the patient reaches for an object, either spontaneously or in response to verbal command. To reach the object, the patient engages in a tactile search with the palm and fingers, presumably using somatosensory cues to coordinate movements. Visual information is not used to give the erroneous impression that the patient is blind. In contrast, movements that do not require visual guidance, such as those directed to the body or movements of the body itself, are performed naturally. This disorder may involve one or both hands. The presence of visual inattention is tested by asking the patient to carry out tasks such as looking at a series of objects or connecting a series of dots by lines; often only one of a series of objects can be found, even though the visual fields seem to be full.

The essential feature of the Balint syndrome appears to be a failure to properly direct oculomotor function in the exploration of space. Thus it is closely related, to simultagnosia and to a disorder of spatial summation (amorphopsia). In all reported cases of the Balint syndrome, the lesions have been bilateral, often in the vascular border zones (areas 19 and 7) of the parieto-occipital regions, although instances of optic ataxia alone have been described within a single visual field, contralateral to a right or left parieto-occipital lesion.
Prospagnosia (Greek prosopos, “face,” and gnosia, “knowledge.”) This term was introduced by Bodamer for a type of visual defect in which the patient cannot identify a familiar face, by looking at either the person or a picture, even though he knows that a face is a face and can point out the features. Such patients cannot learn to recognize new faces. They may also be unable to interpret the meaning of facial expressions or to judge the ages or distinguish the genders of faces. In identifying persons, the patient depends on other data, such as the presence and type of spectacles or moustache, the type of gait, or sound of the voice. Similarly, species of animals and birds and specific models or types of cars cannot be distinguished from one another, but the patient can still recognize an animal, bird, or car as such. As a rule, other agnosias are present in such cases (color agnosia, simultanagnosia), and there may be topographic disorientation, disturbances of body schema, and constructional or dressing apraxia. Visual field defects are nearly always present, a left upper quadrantanopia being the most frequent. Some neurologists have interpreted this condition as a simultanagnosia involving facial features. Another interpretation is that the face, though satisfactorily perceived, cannot be matched to a memory store of faces. Levine has found a deficit in perception, characterized by insufficient feature analysis of visual stimuli. The small number of cases that have been studied anatomically and by computed tomography scanning and MRI indicate that prosopagnosia is associated with bilateral lesions of the ventromesial occipitotemporal regions (Damasio et al.).

A variant of this disorder is characterized by a specific difficulty with facial matching or discrimination from partial cues, such as portions of a face or a profile. The distinction between this deficit and the usual type of prosopagnosia rests on the use of tests that do not require memory of a specific face. This difficulty with facial matching and discrimination is more likely to be seen with lesions of the right than of the left posterior hemisphere.

Closely allied and often associated with prosopagnosia is the syndrome of color perception, in which the patient is unable to recognize familiar colors. The patient may be able to describe a familiar environment from memory and locate it on a map, but he experiences no sense of familiarity and gets lost when faced with new situations. In essence, this is an environmental agnosia. This syndrome is associated with right-sided, medial tempo-occipital lesions, although in some patients, as in those with prosopagnosia, the lesions are bilateral (Landis et al.).

To be distinguished from environmental agnosia is the visual disorientation and disorder of spatial (topographic) localization, already discussed under “Parietal Lobes” (page 486). Patients with the latter disorder, in distinction to those with environmental agnosia, are unable to orient themselves in an abstract spatial setting (topographagnosia or loss of topographic memory). Such patients cannot draw the floor plan of their house or a map of their town or the United States and cannot describe a familiar route, from their home to their place of work or find their way in familiar surroundings. This disorder is of interest insofar as it suggests that there are separate processes for spatial orientation—one for the actual space, i.e., environmental (temporo-occipital), and one for the abstract topography of space (parietal).

Visual Agnosia for Words (Alexia without Agraphia) See Chap. 23 and further on in the present chapter, under the “Disconnection Syndromes.”

Color Agnosia Here one must distinguish several different aspects of identification of colors, such as the correct perception of color (the loss of which is called color blindness) or the naming of a color. The common form of retinal color blindness is congenital and is readily tested by the use of Ishihara plates. Acquired color blindness often results from disease of the retina, due to a cerebral lesion, is referred to as central achromatopsia. Here the disturbance is one of hue discrimination; the patient cannot sort a series of colored woods according to hue (Holmgren test) and may complain that colors have lost their brightness or that everything looks gray. Achromatopsia is frequently associated with visual field defects and with prosopagnosia. Most often the field defects are bilateral and tend to affect the upper quadrants. However, full-field achromatopsia may exist with retention of visual acuity and form vision. There may also be a hemi- or quadrantanochromatopsia without other abnormalities. These features, together with the associated prosopagnosia, point to involvement of the inferotemporal occipital and temporal lobe(s) and the lower part of the striate cortex or optic radiation (Meadows; Damasio et al.). These clinical findings are not surprising in view of the animal studies of Hubel, which identified sets of cells in areas 17 and 18 that are activated only by color stimuli.

A second group of patients with color agnosia have no difficulty with color perception (i.e., they can match seen colors), but they cannot reliably name them or point out colors in response to their names. They have a color anomia, of which there are at least two varieties. One is typically associated with pure word blindness, i.e., alexia without agraphia, and is best explained by a disconnection of the primary visual areas from the language areas (see further on). In the second variety, the patient appears to have acquired tasks that require the patient to assign to color names but is also in purely spoken colors. Anomia also often occurs in patients with aphasias (e.g., color, banana). This latter disorder is probably best regarded as a form of anomic aphasia, in which the aphasia is more or less restricted to the naming of colors (Meadows). According to Damasio and associates, the lesion has invariably involved the mesial part of the left hemisphere at the junction of the occipital and temporal lobes, just below the splenium of the corpus callosum. All their patients also had a right homonymous hemianopia because of destruction of the left lateral geniculate body, optic radiation, or calcarine cortex.

The Theoretical Problem of Visual and Other Agnosias From the foregoing discussion, it is apparent that the term visual agnosia applies to a series of visual perceptual disorders that include, in varying combinations, faults of discrimination, identification, and recognition of faces, objects, pictures, colors, spatial arrangements, and words. The diagnosis of these states is predicated on the assumption that the failure in perception occurs in spite of intact visual acuity and adequate language and mental function. When examined carefully, agnostic patients usually do not satisfy all these criteria and instead have a number of other derangements that may at least in part explain their perceptual incompetence. Often there is a unisensory or polysensory disturbance, an inadequacy of memory or of naming, or an impairment of visual oculomotor or visuospatial control. Anatomical studies have established that disturbances of recognition of complex forms, human faces, and spatial arrangements accompany right (dominant) parieto-occipital lesions more often than left-sided ones. Disturbances of perception of graphic symbols of objects, of color discrimination and naming—in short, all of the lexical aspects of recognition—are virtually always associated with left parieto-occipital lesions. Variations in the clinical effects of such lesions are dependent not only on their location and size but also on the particular tests used to elicit these effects and whether they involve learning, recognition, and recall.

There have been many criticisms of the concept of agnosia as a higher-order perceptual disturbance that can be clearly separated from loss of elementary sensation. Such a division is said to perpetuate an archaic view of sensory reception in the brain as consisting of two separable functional attributes: elementary sensation and suprasensory zones of the parietal lobes, and the motor regions. Hécaen, Gassel, and McCarthy and Warrington have presented the evidence for and against these general defects such as confusion and mental deterioration. Others (Bay, for example) claimed that careful testing of patients with visual agnosia always brings to light some degree of diminished vision in combination with other derangements that may at least in part explain their perceptual incompetence. Often there is a unisensory or polysensory disturbance, an inadequacy of memory or of naming, or an impairment of visual oculomotor or visuospatial control. Anatomical studies have established that disturbances of recognition of complex forms, human faces, and spatial arrangements accompany right (dominant) parieto-occipital lesions more often than left-sided ones. Disturbances of perception of graphic symbols of objects, of color discrimination and naming—in short, all of the lexical aspects of recognition—are virtually always associated with left parieto-occipital lesions. Variations in the clinical effects of such lesions are dependent not only on their location and size but also on the particular tests used to elicit these effects and whether they involve learning, recognition, and recall.

The reported cases of visual agnosia emphasize the complexity of the perceptive process and the inadequacy of our knowledge of the physiology of the several receptive zones of the occipital lobes. The fact that in some cases there are impairments of primary sensation that can be elicited by careful testing of visual function—using tachistoscopic stimuli, visual adaptation, perception of pattern, flicker-fusion, etc.—cannot be disputed. However, even when present, such abnormalities would not fully explain the loss of discrimination and the inability to visualize or imagine the form and color of objects, their spatial arrangements, and their names. Failure of a sensation to activate these visual memories must involve a higher-order disturbance of cerebral function in the homotopical association areas. Here sensory and motor functions are always integrated, the latter being essential for proper scanning and exploring by the sense organs. To reduce the anosogias to a series of disconnections between the striate and parastriate cortex and other parts of the brain, although an interesting approach, leads to an overly simplified mechanistic view of cerebral activity, which probably will not be sustained as more knowledge of cerebral physiology is acquired. There is still a great need of unimpaired perception and memory to sustain thought and be able to act according to the memory store of faces. The lesion, in its clinical end stage, has been critically studied.

The effects of disease of the occipital lobes may be summarized as follows:

I. Effects of unilateral disease, either right or left
   A. Contralateral (congruent) homonymous hemianopia, which may be central (splitting the macula) or peripheral; also homonymous hemiacromatopsia
   B. Elementary (unformed) hallucinations—usually due to irritative lesions
II. Effects of left occipital disease
   A. Right homonymous hemianopia
   B. If deep white matter or splenium of corpus callosum is involved, alexia and color-naming defect
   C. Visual extinction
III. Effects of right occipital disease
   A. Left homonymous hemianopia

III.
Disturbances of the Nondominant Cerebral Hemisphere

A line of disagreement, as old as neurology itself, pertains to the relationship between the two cerebral hemispheres. Fechner, in 1860, speculated that since the two cerebral hemispheres, joined by the corpus callosum, were virtual mirror images of one another and functioned in totality in conscious life, separating them would result in two minds. William McDougall rejected this idea and said is said to have offered to have his own brain divided by Charles Sherrington should he have an incurable disease. He died of cancer and the callosotomy was considered unnecessary, for already there were indications that, when separated, the two hemispheres had different functions (Sperry and colleagues), as indicated in the next section, on "Disconnection Syndromes."

The practice of surgical sectioning of the corpus callosum for the control of epilepsy had greatly stimulated interest in the functions of the right cerebral hemisphere when isolated from the left. It is in the sphere of visuospatial perception that right hemispheric dominance is most convincing. Lesions of the right posterior cerebral region result in an inability to utilize information about spatial relationships in making perceptual judgments and in responding to objects in a spatial framework. This is manifest in constructing figures (constructional apraxia), in the spatial orientation of the patient (topographic agnosia), in identifying faces (prosopagnosia), and in relating to one another a scattering of visual stimuli (simultanagnosia). Also, there are claims that the right hemisphere is more important than the left in visual imagery, attention, emotion (both in feeling and in the perception of emotion in others), and manual drawing (but not writing); in respect to these functions, however, the evidence is less firm. The idea that attention is a function of the right hemisphere derives from the neglect of left visual space and of somatic sensation in the anosognosic syndrome and also from the apraxia that characterizes such patients. Certainly the popular notion of the right hemisphere as "emotional" in contrast to the left one as "logical" has no basis in fact and represents a gross oversimplification of brain function and localization.

Disconnection Syndromes

Following the insightful clinical observations and anatomic studies of Wernicke, Déjerine, and Liepmann, the concept of disconnection of parts of one or both cerebral hemispheres as a cause of neurologic syndromes was introduced to neurologic thinking. In more recent years, these ideas were resurrected and modernized by Geschwind. He called attention to several clinical syndromes resulting from interruption of the connections between the two cerebral hemispheres in the corpus callosum or adjacent white matter (commissural syndromes) or between different parts of one hemisphere (intrainhemispheric disconnection syndromes). Some of these are illustrated in Fig. 22-7.

When the entire corpus callosus has been destroyed by tumor or surgical section, the language and perception areas of the left hemisphere are isolated from the right. Patients with such lesions, if blindfolded, are unable to match an object held in one hand with that in the other. Objects placed in the right hand are named correctly, but not those in the left. Furthermore, if rapid presentation is used to avoid bilateral visual scanning, such patients cannot match an object seen in the right half of the visual field with one in the left half, and they cannot read words projected to the left visual field. They are alexic in the left visual fields, since the verbal symbols that are seen there have no access to the language areas of the left hemisphere. If given a verbal command, they execute it correctly with the right hand but not with the left. For example, if asked to write from dictation with the left hand, they produce only an illegible scrawl.

In most lesions confined to the posterior portion of the corpus callosum (splenium), only the visual part of the disconnection syndrome occurs. Occlusion of the left posterior cerebral artery provides the best examples. Since infarction of the left occipital lobe causes a right homonymous hemianopia, all visual information needed for activation of the speech areas of the left hemisphere must thereafter come from the right occipital lobe. The patient with a lesion of the splenium of the corpus callosum or the adjacent white matter cannot read or name colors because the visual information cannot reach the language areas. There is no difficulty in copying words; presumably the visual information for activating the left motor area crosses the corpus callosum more anteriorly. Spontaneous writing and writing to dictation are an intact because the language areas, including the angular gyrus, Wernicke's and Broca's areas, and the left motor cortex, are intact and connected. After a delay, the patient is unable to read what he has previously written unless it was memorized. This is the syndrome of alexia without agraphia alluded to earlier and is discussed further on page 511.

A lesion that is limited to the anterior third of the corpus callosum (or a surgical section of this part, as in patients with intractable epilepsy) does not result in an apraxia of the left hand, i.e., a failure of only the left hand to obey spoken commands, the right one performing normally. A section of the entire corpus callosum does result in such an apraxia, indicating that the fiber systems that connect the left to the right motor areas cross in the corpus callosum posterior to the genu (but anterior to the splenium). Object naming and matching of colors without naming them are done without error. Blinded, the patient cannot name a finger touched on the left hand or use it to touch a designated part of the body.

Of interest to the authors is the fact that one sometimes encounters patients with a lesion in all or some part of the corpus callosum without being able to demonstrate the above-mentioned disconnection syndromes. Is the lesion incomplete? Probably not in every case. Notable is the observation that in some patients with a congenital agenesis of the corpus callosum (a not uncommon developmental abnormality), none of the interhemispheric disconnection syndromes can be found. One can only suppose that in such patients information is transferred by another route—perhaps the anterior or posterior commissure—or that dual dominance for language was established during early development. (See review of this subject by Laszson and Jeeves.)

In addition to alexia without agraphia, the following intrainhemispheric disconnections have received the most attention. They are mentioned here only briefly and are considered in detail in the following chapter.

1. Conduction (also called "central") aphasia. The patient has fluent but paraphasic speech and writing, impaired repetition, but relatively intact comprehension of spoken and written language. Wernicke's area in the temporal lobe is separated from Broca's area, presumably by a lesion in the arcuate fasciculus or external capsule or subcortical white matter.

2. Ideomotor ("sympathetic") apraxia in Broca's aphasia. By destroying the origin of the fibers that connect the left and right motor association cortices, a lesion in the more anterior parts of the corpus callosum or the subcortical white matter underlying Broca's area and contiguous frontal cortex causes an apraxia of commanded movements of the left hand (see above).

3. Pure word deafness. Although the patient is able to hear and to identify nonverbal sounds, there is loss of ability to discriminate speech sounds, i.e., to comprehend spoken language. The patient's speech may be paraphasic, presumably because of the inability to monitor his own speech. This defect has been attributed to a subcortical lesion of the left temporal lobe, spanning Wernicke's area and interrupting also those auditory fibers that cross in the corpus callosum from the opposite side. Thus there is a failure to activate the left auditory language area (Wernicke's area). Bilateral lesions of the auditory cortex have the same effect.

Special Neuropsychologic Tests

In the study of focal cerebral disease, there are two approaches—the clinical-neurologic and the neuropsychologic. The first consists of the observation and recording of qualitative changes in behavior and performance and the identification of syndromes from which one may deduce the locus and nature of certain diseases. After reviewing the most important clinical syndromes, the second approach is considered. This approach involves the use of special tests and techniques designed to evaluate the abilities and functions of patients with cerebral dysfunction. The tests described in this section are not necessarily a complete listing of all available neuropsychologic tests, but they are selected as representative of the various methods by which specific neurologic impairments can be assessed.
particular psychologic abilities and skills:

I. Frontal lobe disorders
   A. Milan Sorting Test, Halstead Category Test, and Wisconsin Card-Sorting Test, as tests of ability to abstract
   B. The Porteus Maze Test, Reitan Trail Making Test, and the recognition of figures in the Figure of Rey as tests of planning, regulating, and checking programs of action
   C. Benton's Verbal Fluency Test for estimating verbal skill and verbal regulation of behavior

II. Temporal lobe disorders
   A. Figure of Rey, Benton Visual Retention Test, Illinois Nonverbal Sequential Memory Test, Recurring Nonsense Figures of Kimura, and Facial Recognition Test as modality-specific memory tests
   B. Milner's Maze Learning Task and Lhermitte-Signoret amnesic syndrome tests for general retentive memory
   C. Seashore Rhythm Test, Speech-Sound Perception Test from the Halstead-Reitan battery, Environmental Sounds Test, and Austin Meaningless Sounds Test as measures of auditory perception

III. Parietal lobe disorders
   A. Figure of Rey, Wechsler Block Design and Object Assembly, Benton Figure Copying Test, Halstead-Reitan Tactual Performance Test, and Fairfield Block Substitution Test as tests of constructional praxis
   B. Several mathematical and logigrammatical tests as tests of spatial synthesis
   C. Cross-modal association tests as tests of suprasensory integration
   D. Benton-Barton Sticks Test, Cattell's Pool Reflection Test, and Money's Road Map Test, as tests of spatial perception and memory

IV. Occipital lobe disorders
   A. Color naming, color form association, and visual inerminiscence, as tests of visual perception; recognition of faces of prominent people, map drawing

It is the authors' opinion that the data obtained from the above tests should supplement clinical observations. Taken alone, they cannot be depended upon for the localization of cerebral lesions.

Chapter 23

DISORDERS OF SPEECH AND LANGUAGE

Speech and language functions are of fundamental human significance, both in social interaction and in private intellectual life. When they are disturbed as a consequence of brain disease, the resultant functional loss exceeds all others in gravity—even blindness, deafness, and paralysis.

The neurologist is concerned with all derangements of speech and language, including those of reading and writing, because they are the source of great disability and are almost invariably manifestations of disease of the brain. Broadly viewed, language is the mirror of all higher mental activity. In a narrower context, language is the means whereby patients communicate their complaints and problems to the physician and at the same time the medium for all delicate interpersonal transactions. Therefore any disease process that interferes with speech or the understanding of spoken words touches the very core of the physician-patient relationship. Finally, the study of language disorders serves to illuminate the abstruse relationship between psychologic functions and the anatomy and physiology of the brain. Language mechanisms fall somewhere between the well-localized sensori-motor functions and the more widely distributed complex mental operations such as imagination and thinking, which cannot be localized.

General Considerations

It has been remarked that as human beings, we owe our commanding position in the animal world to two faculties: (1) the ability to develop and employ verbal symbols as a background for our own ideation and as a means of transmitting thoughts, by spoken and written word, to others of our kind and (2) the remarkable facility in the use of our hands. One curious and provocative fact is that both language and manual dexterity have evolved in relation to particular aggregates of neurons and pathways in one (the dominant) cerebral hemisphere. This is a departure from most other localized neurophysiologic activities, which are organized according to a contralateral or bilateral and symmetrical plan. The dominance of one hemisphere, usually the left, emerges together with speech and the preference for the right hand, especially for writing. A lack of development or loss of cerebral dominance as a result of disease deranges both these traits causing aphasia and apraxia.

There is abundant evidence that higher animals are able to communicate with one another by vocalization and gesture. However, the content of their communication is their feeling or reaction of the moment. This emotional language, as it is called, was studied by Charles Darwin, who noted that it undergoes increasing differentiation in the animal kingdom. Only in the chimpanzee do the first semblances of propositional language become recognizable.

Similar instinctive patterns of emotional expression are observed in human beings. They are the earliest modes of expression to appear (in infancy) and may have been the original forms of speech in primitive human beings. Moreover, the utterances we use to express joy, anger, and fear are retained even after destruction of all the language areas in the dominant cerebral hemisphere. The neural arrangement for this paralinguistic form of communication (intonation, exclamations, facial expressions, eye movements, body gestures), which subserves emotional expression, is bilateral and symmetrical and does not depend solely on the cerebrum. The experiments of Cannon and Bard demonstrated that emotional expression is possible in animals after removal of both cerebral hemispheres provided that the diencephalon, particularly its hypothalamic part, remains intact. In the human infant, emotional expression is well developed at a time when much of the cerebrum is still immature.

Propositional, or symbolic, language differs from emotional language in several ways. Instead of communicating feelings, it is the means of transferring ideas from one person to another. It requires the substitution of a series of sounds or marks for objects, persons, and concepts. This is the essence of language. It is not instinctive but learned and is therefore subject to all the modifying social and cultural influences of the environment. However, the learning process becomes possible only after the nervous system has attained a certain degree of maturation. Facility in symbolic language, which is acquired over a period of 15 to 20 years, depends then on maturation of the nervous system and on education.

Although speech and language are closely interwoven functions, they are not synonymous. A derangement of language function is always a reflection of an abnormality of the brain and, more specifically, of the dominant cerebral hemisphere. A disorder of speech may have a similar origin, but not necessarily; it may be due to abnormalities in different parts of the brain or to extracerebral mechanisms. Language function involves the comprehension, formulation, and transmission of ideas and feelings by the use of conventionalized verbal symbols, sounds, and gestures and their sequential ordering according to accepted rules of grammar. Speech, on the other hand, refers more to the articulatory and phonetic aspects of verbal expression.

The profound importance of language may not be fully appreciated unless one reflects on the proportion of our time devoted to purely verbal pursuits. "External" speech, or exophasy, by which is meant the expression of thought by spoken or written words and the comprehension of the spoken or written words of others, is an almost continuous activity when human beings gather together; "inner speech," or endophasy, i.e., the silent processes of thought and the formulation in our minds of unuttered words on which thought depends, is "the coin of mental commerce." The latter is almost incessant during our preoccupations, since we think always with inner speech. When people are together, i.e., they have a common purpose, they will discourse with each other. Written speech is in constant use. If the means whereby we communicate our thoughts and wishes to another are not used, we may just as well not exist. The functions of art and science are based on an understanding and use of language.

Anatomy of the Language Functions

The conventional teaching, based on correlations between various disorders of language and damage to particular areas of the brain, postulates four main language areas, situated, in most persons, in the left cerebral hemisphere. The entire language zone that encompasses these areas is perisylvian, i.e., it borders the sylvian fissure. Two language areas are receptive and two are expressive, i.e., concerned with the production (output) of language. The two receptive areas are closely related and embrace what has been referred to as the central language zone. One, subserving the perception of spoken language, occupies the posterior-posterior temporal area (the posterior portion of area 22) and Heschl's gyr (areas 41 and 42); the posterior part of area 22 in the planum temporale is referred to as Wernicke's area. A second area, subserving the perception of written language, occupies the angular gyrus (area 39) in the inferior parietal lobe, anterior to the visual receptive areas. The supramarginal gyrus, which lies between these auditory and visual language "centers," and the inferior temporal region, just anterior to the visual association cortex, are probably part of this central language zone as well. Here are located the integrative centers for cross-modal visual and
auditory language functions.

The main executive region, situated at the posterior end of the inferior frontal convolution (Brodmann areas 44 and 45), is referred to as Broca's area and is concerned with motor aspects of speech. Visually perceived words are given expression in writing through a fourth language area, the so-called Exner writing area in the posterior part of the second frontal convolution, a concept that is still controversial in view of the fact that widely separated parts of the language zone may cause a disproportionate disorder of writing. Thus there are two parallel systems for understanding the spoken word and producing speech and for the understanding of the written word and producing writing. They develop separately but are the integral components of the semantic system.

These sensory and motor areas are intricately connected with one another by a rich network of nerve fibers, one large bundle of which, the arcuate fasciculus, passes through the isthmus of the temporal lobe and around the superior part of the Sylvian fissure; other connections may traverse the external capsule of the lenticular nucleus (subcortical white matter of the insula). Many additional corticocortical connections and other fiber systems lead into the perisylvian zones and project from them to other parts of the brain. The visual receptive region is connected in the spatial lobe, and the auditory receptive zone, in the temporal lobe. Of special importance are the association fibers that join Broca's area with the lower Rolandic cortex, which, in turn, innervates the speech apparatus, i.e., the muscles of the lips, tongue, pharynx, and larynx. The Exner writing area is similarly integrated with the motor apparatus for the muscles of the hand. The perisylvian language areas are also connected with the striatum and thalamus and with corresponding areas in the minor (nondominant) cerebral hemisphere through the corpus callosum and anterior commissure (Figg. 22.7).

There has been much difference of opinion concerning the cortical language areas, and objection has been made to calling them "centers," for they do not represent histologically circumscribed structurally and functionally distinct structures. Moreover, a classical anatomist would not have been able to distinguish these areas on the basis of the nerve fibers alone; he would have to know the sensory and motor apparatus functionally, microscopically from the cerebral cortex that surrounds them. Some of the receptive areas are polymodal, i.e., they are activated by auditory, visual, and tactile stimuli. Presumably, their function is integrative. Electrical stimulation of the anterior cortical language areas while the patient is alert and talking (during craniotomy under local anesthésia) may induce a simple vocalization, usually a single-vowel monotone, but otherwise causes only an arrest of speech. Electrical stimulation of Wernicke's area causes errors of speech, such as stumbling over a word or saying the wrong word.

As indicated earlier, knowledge of the anatomy of language has come almost exclusively from the postmortem study of humans with focal brain diseases. Two major theories emerged from these studies. One subdivided the language zone into separate afferent (auditory and visual) and receptive parts, connected by identifiable tracts to the executive (efferent-expressive) centers. Depending on the exact anatomy of the lesions, a number of special syndromes are elicited. The other theory, advanced originally by Marie (he later changed his mind) and supported by Head, Wilson, Brain, and Goldstein, favored a single language mechanism, roughly localized in the opercular, or perisylvian, region of the dominant cerebral hemisphere. The aphasia in any particular case was presumably due to the summation of damage to input or output modalities consequent upon damage to this central language process. Undeniably, there is, within the language area, a recognizable afferent and efferent localization, as discussed above, but there is also an undifferentiated central integrative mass action, in which the degree of deficit is to a considerable extent influenced by the size of the lesion. Thus a strict division of aphasia into executive and receptive is not fully borne out by clinical observation.

Carl Wernicke, of Breslau, more than any other person, must be credited with the anatomical-psychologic scheme upon which many contemporary ideas of aphasia rest. Earlier, Paul Broca (1865), and, even before him, Dax (1836), had made the fundamental observations that a lesion of the insula and the overlying operculum deprived a person of speech and that such lesions were always in the left hemisphere. Wernicke's thesis was that there were two major anatomic loci for language: (1) an anterior focus, in the posterior part of the inferior frontal lobe (Broca's area), in which were contained the "memory images" of speech movements, and (2) the insular region and adjoining parts of the posterior perisylvian cortex, in which were contained the images of sounds (Meynert had already shown that aphasia could occur with lesions in the temporal lobe, Broca's area being intact). Wernicke believed that the fibers between these regions ran in the insula and mediated the psychic reflex arc between the heard and spoken word. Later, Wernicke came to accept von Monakow's view that the connecting fibers ran around the posterior end of the Sylvian fissure, in the arcuate fasciculus.

Wernicke gave a comprehensive description of the receptive or sensory aphasia that now bears his name. The four main features, he pointed out, were (1) a disturbance of comprehension of spoken language and (2) of written language (alexia), (3) agraphia, and (4) fluent paraphasic speech. In Broca's aphasia, by contrast, comprehension was intact, but the patient was mute or employed only a few simple words. Wernicke theorized that a lesion interrupting the connecting fibers between the two cortical speech areas would leave the patient's comprehension undisturbed but would prevent the intact sound images from exerting an influence on the choice of words. Wernicke proposed that this variety of aphasia be called Leitungsaphasie, or central aphasia (later called central aphasia by Kurt Goldstein and deep aphasia by Martin and Saffran).

Careful case analyses since the time of Broca and Wernicke have repeatedly borne out these associations between a receptive (Wernicke) type of aphasia and lesions in the posterior perisylvian region and between a predominantly (Broca) motor aphasia and lesions in the posterior part of the inferior frontal lobe and the adjacent, insular, and opercular regions of the cortex. The concept of a conduction aphasia, based upon an interruption of pathways between Wernicke's and Broca's areas, has been the most difficult to accept, because it presupposes a neat separation of sensory and motor functions, which is not in line with contemporary views of sensorimotor physiology of the rest of the nervous system or with the recent analyses of language by cognitive neuropsychologists (Margolin). Nevertheless, there are in the literature a number of cases that have certainly come very close to cases that conform to Wernicke's conduction aphasia—cases that conform to Wernicke's conduction aphasia—cases that conform to Wernicke's conduction aphasia—cases that conform to Wernicke's conduction aphasia—cases that conform to Wernicke's conduction aphasia—cases that conform to Wernicke's conduction aphasia—cases that conform to Wernicke's conduction aphasia—cases that conform to Wernicke's conduction aphasia—cases that conform to Wernicke's conduction aphasia—cases that conform to Wernicke's conduction aphasia—cases that conform to Wernicke's conduction aphasia—cases that conform to Wernicke's conduction aphasia—cases that conform to Wernicke's conduction aphasia—cases that conform to Wernicke's conduction aphasia—cases that conform to Wernicke's conduction aphasia. How these regions of the brain are organized into separable but interactive information processing modules and how they can be activated (controlled) by a variety of visual and auditory stimuli and bifrontal motivational mechanisms, resulting in the complex behavior of which we make casual daily use in interpersonal communication, is just beginning to be studied by linguists and cognitive neuropsychologists. They are dissecting language into its most basic elements—phonemes (the smallest units of sound recognizable as language), morphemes (the smallest meaningful units of a word), as well as the semantic elements (words and their meanings), and syntax (sentence structure). In general, as a restatement of the Wernicke-Broca scheme, phonologic difficulties correlate with left frontal lesions; semantic-comprehension difficulties, with left temporal lesions; and alexia and agraphia, with inferior perisylvian lesions. These elements, or modules, have been diagrammed as a series of boxes and are connected to one another by arrows, to indicate the flow of information and the manner in which it influences the spoken output of language. These "boxologies," as they are called, are not inconsistent with current psychologic theories that views language functions as the result of synchronized activity in vast neuronal networks made up of many cerebrocortical regions and their interconnecting pathways (Damasio and Damasio, 1989).

Despite this level of theoretical sophistication, attempts to delineate the anatomy of speech and language disorders by means of brain imaging techniques have been disappointing. Using computed tomography (CT) scanning, Roch-LeCours and Lhermitte were unable to establish a correspondence between the type of aphasia and the demonstrable lesion. Also, Willmes and Poeck, in a retrospective study of 221 aphasic patients, failed to demonstrate an unequivocal association between the type of aphasia and the CT localization of the lesion. This poor correlation may be related to the timing of the CT scan; images of infarcts may not be evident for several days and, when they do appear, the functional disorder at first extends beyond the margins of the visible anatomic lesion. Functional magnetic resonance
imaging may prove to be superior to conventional scanning for understanding the language process, but so far only the broadest rules of localization can be confirmed. Studies of blood flow and topographic physiology during the acts of reading and speaking have shown widespread activation of Wernicke's and Broca's areas as well as the supplementary motor area and even the opposite hemisphere.

Although localization of the lesion that produces aphasia is in most instances roughly predictable from the clinical deficit, there are wide variations in the degree of deficit that follows focal brain disease. Inconsistency of anatomic findings in certain types of aphasia has several explanations, the most popular being that the net effect of any lesion depends not only on its locus and extent but also on the degree of cerebral dominance, i.e., on the degree to which the minor hemisphere assumes language function after damage to the major one. According to this view, a left-sided lesion has less effect on language function if cerebral dominance is poorly established than if dominance is strong. Another explanation invokes the poorly understood concept that individuals differ in the ways in which they acquire language as children. This is believed to play a role in making available alternative means for accomplishing language tasks when the method initially learned has been impaired through brain disease. The extent to which improvement of aphasia represents “recovery” of function or generation of new response methods has not been settled to the present day.

**Cerebral Dominance and Its Relation to Language and Handedness**

The functional supremacy of one cerebral hemisphere is fundamental to language function. There are many ways of determining that the left side of the brain is dominant: (1) by the loss of speech that occurs with disease in certain parts of the left hemisphere and its preservation with lesions involving corresponding parts of the right hemisphere; (2) by preference for and greater facility in the use of the right hand, foot, and eye; (3) by the arrest of speech with magnetic cortical stimulation or a focal seizure or with electrical stimulation of the anterior language area during a surgical procedure; (4) by the injection of sodium amyntal into the left internal carotid artery (Wada test—a procedure that produces mutism for a minute or two, followed by misnaming, including perseveration and substitution; misreading; and paraphasic speech—effects lasting 8 to 9 min in all); (5) by the dichotic listening test, in which different words or phonemes are presented simultaneously to the two ears (yielding a right ear–left hemisphere advantage); (6) by observing increases in cerebral blood flow during language processing; and (7) by lateralization of speech and language functions following commissurotomy.

Approximately 90 to 95 percent of the general population is right-handed; i.e., they choose the right hand for intricate, complex acts and are more skillful with it. The preference is more complete in some persons than in others. Most individuals are neither completely right-handed nor completely left-handed but favor one hand for more complicated tasks.

The reason for hand preference is not fully understood. There is strong evidence of a hereditary factor, but the mode of inheritance is uncertain. Yakovlev and Rakic, in a study of infant brains, observed that the corticospinal tract coming from the left cerebral hemisphere contains more fibers and decussates higher than the tract from the right hemisphere. Learning is also a factor; many children are shifted from left to right at an early aperhre and is considered to be a handicap in a right-handed world. Most right-handed persons with the right eye, and it has been said that eye preference determines hand preference. Even if true, this still does not account for eye dominance. It is noteworthy that handedness develops simultaneously with language, and the most that can be said at present is that localization of language; preference for one eye, hand, and foot; and praxis of the right hand are all manifestations of some fundamental, inherited tendency not yet defined.

There are slight but definite anatomic differences between the dominant and the nondominant cerebral hemispheres. The planum temporale, on the superior surface of the temporal lobe, posterior to Heschl's gyr. and extending to the posterior end of the sylvian fissure, has been found to be slightly larger on the left in 65 percent of brains and larger on the right in only 11 percent (Geschwind and Levitsky). LeMay and Cubebras noted in cerebral angiograms that the left Sylvian fissure is longer and more horizontal than the right and that there is a greater mass of cerebral tissue in the area of the left temporo parietal junction. CT scanning has shown the right occipital horn to be smaller than the left, indicative perhaps of a greater right-sided development of visuospatial connections. Also, subtle cytoarchitectonic asymmetries of the auditory cortex and posterior thalamus have been described; these and other biologic aspects of cerebral dominance have been reviewed by Geschwind and Galaburda.

Left-handedness may result from disease of the left cerebral hemisphere in early life; this probably accounts for its higher incidence among the mentally retarded and brain-injured. Presumably the neural mechanisms for language then come to be represented in the right cerebral hemisphere. Handedness and cerebral dominance may fail to develop in some individuals, and this is particularly true in certain families. In these individuals, defects in reading, stuttering, mirror writing, and general clumsiness are much more frequent and persistent during development.

In right-handed individuals, aphasia is almost invariably related to a left cerebral lesion; aphasia in such individuals as a result of purely right cerebral lesions ("crosed aphasia") is very rare, occurring in only 1 percent of cases (Joanette et al). Cerebral dominance in ambidextrous and left-handed persons is not so uniform. In a large series of left-handed patients with aphasia, 60 percent had lesions confined to the left cerebral hemisphere (Goodglass and Quadfasel). In the relatively rare case of an aphasia due to a right cerebral lesion, the patient is nearly always left-handed; moreover, the language disorder in some such patients is less severe and enduring than in right-handed patients with comparable lesions in the left hemisphere (Gloning, Subirana). The latter findings suggest a bilateral albeit unequal representation of language functions in right-handed patients. Using the Wada test, Milner and colleagues found evidence of bilateral speech representation in about 15 percent of 212 consecutively studied left-handed patients.

The language capacities of the nondominant hemisphere have not been documented by careful anatomic studies. As mentioned above, there is always some uncertainty as to whether residual function after lesions of the dominant hemisphere can be traced to recovery of parts of its language zones or to activity of the minor hemisphere. The observations of Levine and Mohr suggest that the nondominant hemisphere has only a limited capacity to produce oral speech after extensive damage to the dominant hemisphere; their patient recovered the ability to sing, recite, curse, and utter one- or two-word phrases, all of which were abolished by a subminor hemisphere infarction. The fact that varying amounts of language function may remain after dominant hemispherectomy in adults with glioma also suggests some residual capacity for language. In most cases, the left hemisphere appears to have suffered the effect of amyntal injections into the right-hemispheral arteries of patients aphasic from left-sided lesions make the same point. However, congenital absence (or surgical section) of the corpus callosum, permitting the testing of each hemisphere, has shown virtually no language functions of the right hemisphere. Some of these differences are attributable to variations in the clinical state of the subjects being tested and in the methods of language testing.

Despite its minimal contribution to the purely linguistic or propositional aspects of language, the right hemisphere does have an important role in the communication of feelings and emotion. It has long been known that globally aphasic patients, when angered, can shout or curse. These aspects of language are subserved under the term prosody, by which is meant the melody of speech—its intonation, inflection, and pauses—all of which have emotional overtones. These prosodic components of speech and the gestures that accompany them enhance the meaning of the spoken word and endow language with its richness and vitality.

Many diseases and focal cerebral lesions mutate the prosody of speech, the most dramatic examples being the hypophonic monotone of Parkinson disease and the effortful speech of Broca's aphasia. But even the work of Rossa, it has been shown that this deficit in prosody is also present in patients with strokes involving the territory of the right middle cerebral artery, i.e., in portions of the nondominant hemisphere that mirror the language areas of the left hemisphere. There is an impairment both of comprehending and of producing the emotional content of speech and its accompanying gestures. A prospective study of middle cerebral artery infarctions by Darby has corroborated this view; aprosodia was present only in those patients with lesions in the territory of the inferior division of the right middle cerebral artery. This deficit was not present soon after the stroke and was not found in with individual lesions.

Interest has been expressed in a possible role for the cerebellum in language function, based partly on observations in the Williams syndrome, in which mental retardation is associated with preservation of language skills that is sometimes striking in degree. In this disease, the cerebellum is spared in the face of greatly diminished volume of the cerebral hemispheres (see also Leiner et al). Based on our clinical experience, we would judge any language (though not speech) deficits from cerebellar disease to be subtle or nonexistent.

**DISORDERS OF SPEECH AND LANGUAGE DUE TO DISEASE**

These may be divided into four categories:

1. A loss or impairment of the production and/or the comprehension of spoken or written language due to an acquired lesion of the brain. This condition is called aphasia or dysphasia.

2. Disturbances of speech and language with diseases that globally affect higher-order mental function, i.e., in confusion, delirium, mental retardation, and
dementia. Speech and language functions are seldom lost in these conditions but are deranged as part of a general impairment of perceptual and intellectual functions. In Alzheimer disease, for example, a gradual impairment of all elements of language without the emergence of any of the classic aphasic syndromes constitutes an important part of the clinical picture (Chap. 21). Common to this category are certain special disorders of speech such as extreme perseveration (pallilalia) and echolalia, in which the patient repeats, parrot-like, words and phrases that he hears (see further on). The odd constructs of language and other disorders of verbal communication of schizophrenics and some autistic individuals—extending to the production of meaningless phrases, neologisms or jargon—probably belong in this category as well.

3. A defect in articulation with intact mental functions and comprehension of spoken and written language and normal syntax (grammatical construction of sentences). This is a pure motor disorder of the muscles of articulation and may be due to flaccid or spastic paralysis, rigidity, repetitive spasms (stuttering), or ataxia. The terms dysarthria and anarthria are applied to this category of speech disorder.

4. An alteration or loss of voice due to a disorder of the larynx or its innervation—aphonia or dysphonia. Articulation and language are unaffected. The important category of developmental disorders of speech and language is considered fully in Chap. 28.

Clinical Varieties of Aphasia

Systematic examination will usually enable one to decide whether a patient has a predominantly motor, or Broca's, aphasia, sometimes called "expressive," "anterior," or "nonfluent" aphasia; a sensory, or Wernicke's, aphasia, referred to also as "receptive," "posterior," or "fluent" aphasia; a total, or global, aphasia, with loss of all or nearly all speech and language functions; or one of the dissociative language syndromes, such as conduction aphasia, word deafness (auditory verbal agnosia), word blindness (visual verbal agnosia or alexia), and several types of mutism. The last of these, mutism, does not permit one to predict the exact locus of the lesion. Anomia (also called nominal or amnesic aphasia) and the impaired ability to communicate by writing (agraphia) are found to some degree in practically all types of aphasia. Only rarely does agraphia exist alone. The main aphasic syndromes are summarized in Table 23-1.

Broca's Aphasia

Although the precise nature of Broca's aphasia remains somewhat in doubt, we have chosen to apply the term, as have others, to a primary deficit in language output or speech production, with relative preservation of comprehension. There is a wide range of variation in the motor speech deficit, from the mildest types of poverty of speech and so-called cortical dysarthria with intact comprehension and ability to write (Broca's area aphasia; "mini-Broca"), to a complete loss of all means of linguistic, phonetic, and gestural communication. Since the muscles that can no longer be used in speaking may still function in other learned acts, i.e., they are not paralyzed, the term apraxia seems applicable to certain elements of the deficit.

In the most advanced form of the syndrome, patients will have lost all power of speaking aloud. Not a word can be uttered in conversation, in attempting to read aloud, or in trying to repeat words that are heard. One might suspect that the lingual and phonatory apparatus is paralyzed, until patients are observed to have no difficulty chewing, swallowing, clearing the throat, crying or shouting, and even vocalizing without words. Occasionally, the words yes and no can be uttered, usually in the correct context. Or patients may repeat a few stereotyped utterances over and over again, as if compelled to do so—a disorder referred to as monophasia (Critchley), recurring utterance (Hughlings Jackson), verbal stereotypy, or verbal automatism. If speech is possible at all, certain habitual expressions, such as "hi," "fine, thank you," or "good morning," seem to be the easiest to elicit, and the words of well-known songs may be sung or counting by consecutive numbers may remain facile. When angered or excited, the patient may utter an expulsive, thus emphasizing the fundamental distinction between propositional and emotional speech (see above). The patient recognizes his ineptitude and mistakes. Repeated failures in speech may cause exasperation or despair. Often the arm and lower part of the face are weak on the right side, and occasionally the leg as well. The tongue may deviate away from the lesion, i.e., to the right, and be slow and awkward in rapid movements. For a time, despite the relative preservation of auditory comprehension and ability to read, commands to purse, smack, or lick the lips or to blow and whistle and make other purposeful movements are poorly executed, which means that an apraxia has extended to certain other learned acts involving the lips, tongue, and pharynx. In these circumstances, imitation of the examiner's actions is performed better than execution of acts on command. Self-initiated actions, by contrast, may be normal. By implication from CT and MRI findings in patients with apractic speech, the coordination of orobuccolingual movements, which are responsible for articulation, takes place in the left insular cortex (Dronkers). Scanning by positron emission tomography (PET) shows activation of the same insular region as well as of the lateral premotor cortex and the anterior pallidum during repetition of single words (Wise et al). It would be incorrect, however, to conclude from these studies that Broca's area itself does not participate in the composition of articulatory movements during natural speech.

In the milder form of Broca's aphasia and in the recovery phase of the severe form, patients are able to speak aloud to some degree, but the normal melody of speech is entirely lacking. Words are uttered slowly and laboriously and are enunciated poorly. Lacking is the normal inflection, intonation, phrasing of words in a series, and the pacing of word utterances. This labored, uninflected speech stands in contrast to the fluent speech of Wernicke's aphasia. Speech in Broca's aphasia is sparse (10 to 15 words per minute as compared with the normal 100 to 115 words per minute) and consists mainly of nouns, transitive verbs, or important adjectives; phrase length is abbreviated and many of the small words (articles, prepositions, conjunctions) are omitted, giving the speech a telegraphic character (so-called agrammatism). The substantive content of the patient's language permits the crude communication of ideas, despite the gross expressive difficulties. Repetition of the examiner's spoken language is as abnormal as the patient's own speech. If a patient with nonfluent aphasia has no difficulty in repetition, the condition is termed transcortical motor aphasia (see further on).

Most patients with Broca's aphasia have a correspondingly severe impairment in writing. Should the right hand be paralyzed, the patient cannot print with the left one, and if the right hand is spared, the patient fails as miserably in writing to request and replying to questions as in speaking them. Letters are malformed and words misspelled. While writing to dictate is impossible, letters and words can still be copied.

The comprehension of spoken and written language, though seemingly normal under many conditions of testing, is usually defective in Broca's aphasia and will break down under stringent testing, especially when novel or complicated material is introduced. The naming of objects and particularly parts of objects is usually faulty. These are the most variable and controversial aspects of Broca's aphasia. In some patients with a loss of motor speech and aphasia as a result of cerebral infarction, the understanding of spoken and written language may be virtually normal. Mohr has pointed out that in such patients an initial mutism is usually replaced by a rapidly improving dyspraxic and effortful articulation, leading to complete recovery (the above noted "mini-Broca's aphasia"); the lesion in such cases is restricted to a zone in and immediately around the posterior part of the inferior frontal convolution (Broca's area). Mohr has stressed the distinction between this relatively mild and restricted type of motor speech disorder and the more complex syndrome that is traditionally referred to as Broca's aphasia. The lesion in the major form of Broca's aphasia is much larger than originally described, involving not only the inferior frontal gyrus but also the subjacent white matter and even the head of the caudate nucleus and putamen (Fig. 23-2), the anterior insula, frontoparietal operculum, and adjacent cerebrum. In other words, the lesion in the usual form of Broca's aphasia extends well beyond the so-called Broca's area (Brodmann areas 44 and 45). The persistence of Broca's aphasia is associated with the type of extensive lesion illustrated in Fig. 23-2.)
It is noteworthy that in one of Broca's original patients, whose expressive language had been limited to a few verbal stereotypes for 10 years before his death, inspection of the surface of the brain (the brain was never cut, although CT scans have since been made) disclosed an extensive lesion encompassing the left insula; the frontal, central, and parietal operculum; and even part of the inferior parietal lobe posterior to the sylvian fissure. The Wernicke area was spared, refuting the prediction of Marie. Irreconcilably, Broca attributed the aphasic disorder to the lesion of the frontal operculum alone. (The term operculum refers to the cortex that borders the sylvian fissure and covers or forms a lid over the insula, or island of Reil.) Broca ignored the rest of the lesion, which he considered to be a later spreading effect of the stroke. Perhaps Broca was influenced by the prevailing opinion of the time (1861) that articulation was a function of the inferior parts of the frontal lobes. The fact that Broca's name later became attached to a discrete part of the inferior frontal cortex helped to entrench the idea that Broca's aphasia exemplifies the Wernicke area. However, as pointed out above, a lesion confined to the Broca's area gives rise to a relatively modest and transient motor speech disorder (Mohr et al) or to no disorder of speech at all (Goldstein).

Motor speech disorders, both severe Broca's aphasia and the more restricted and transient types, are most often due to a vascular lesion. Embolic infarction in the territory of the upper main (rolandic) division of the middle cerebral artery is probably the most frequent type of vascular lesion and results in the most abrupt onset and sometimes the most rapid regression (hours or days), depending on whether the ischemia proceeds to tissue necrosis. Even with the latter, however, transient ischemia around the zone of infarction causes a more extensive syndrome than one might expect from the infarct itself, i.e., the physiologic impairment exceeds the pathologic. Because of the distribution of the upper, or superior, branch of the middle cerebral artery, there are a frequently associated right-sided faciobrachial paresis and a left-sided brachial apraxia (so-called sympathetic apraxia), due probably to interruption of the fibers that connect the left and right motor cortices. Atherosclerotic thrombosis, tumor, subcortical hypertensive hemorrhage, traumatic hemorrhage, seizure, etc., should they involve the appropriate parts of the motor cortex, may also declare themselves by a Broca's aphasia.

A closely related syndrome, pure word mutism, also causes the patient to be wordless but leaves inner speech intact and writing undisturbed. Anatomically, this is believed to be in the nature of a disconnection of the motor cortex for speech from lower centers and is described with the dissociative speech syndromes discussed further on in this chapter.

Wernicke's Aphasia

This syndrome comprises two main elements: (1) an impairment in the comprehension of speech—basically an inability to differentiate word elements or phonemes, both spoken and written—which reflects involvement of auditory association areas or their separation from the primary auditory cortex (transverse gyri of Heschl) and (2) a relatively fluent but paraphasic speech, which reveals the major role of the auditory region in the regulation of language. The defect in language is manifest further by a varying inability to repeat spoken and written words. The involvement of visual association areas or their separation from the primary visual cortices is reflected in an inability to read (alexia).

In contrast to Broca's aphasia, the patient with Wernicke's aphasia talks volubly, gestures freely, and appears strangely unaware of his deficit. Speech is produced without effort, the phrases and sentences appear to be of normal length and are properly intoned and articulated. These attributes, in the context of aphasic disturbances, are referred to as "fluency" of speech. Despite the fluency and normal prosody, the patient's speech is remarkably devoid of meaning. The patient with Wernicke's aphasia produces many nonsensutable words, and the words themselves are often malformed or inappropriate, a disorder referred to as paraphasia. A phoneme (the minimum unit of sound recognizable as language) or a syllable may be substituted within a word (e.g., "The grass is green"); this is called literal paraphasia. The substitution of one word for another ("The grass is blue") is called semantic substitution. Neologisms—i.e., phonemes, syllables, or words that are not part of the language—may also appear ("The grass is grumps"). Fluent paraphasic speech may be entirely incomprehensible (gibberish or jargon aphasia). Fluency is not an invariable feature of Wernicke's aphasia. Speech may be hesitant, in which case the block tends to occur in part of the phrase that contains the central communicative (predicative) item, such as a key noun, verb, or descriptive phrase. The patient with such a disorder conveys the impression of constantly searching for the correct word and of having difficulty in finding it.

Although the motor apparatus required for the expression of language may be intact, patients with Wernicke's aphasia have great difficulty in functioning as social organisms because they are deprived of the main means of communication. They cannot understand fully what is said to them; a few simple commands may still be executed, but there is failure to carry out complex ones. They cannot read aloud or silently with comprehension, tell others what they want or think, or write spontaneously. Written letters are often combined into meaningless words, but there may be a scattering of correct words. In trying to designate an object that they see or feel, they cannot find the name, even though they can sometimes repeat it from dictation; nor can they write from dictation the very words that they can copy. The copying performance is notably slow and laborious and conforms to the contours of the model, including the examiner's handwriting style. All these defects, of course, may be present in varying degrees of severity. In general, the disturbances in reading, writing, naming, and repetition parallel in severity the impairment in comprehension. There are, however, exceptions in which either reading or the understanding of spoken language is disproportionately affected. Some aphasiologists thus speak of two Wernicke syndromes.

In terms of the Wernicke schema, the motor language areas are no longer under control of the auditory and visual areas. The disconnection of the motor speech areas from the auditory and visual ones accounts for the impairment of repetition and the inability to read aloud. Reading may remain fluent, but with the same paraphasic errors that mar conversational language. The occurrence of dyslexia (impaired visual perception of letters and words) with lesions in the temporal lobe is explained by the fact that most individuals learn to read by transforming the printed word into the auditory form before it can gain access to the integrative centers in the posterior perisylvian region. Only in the congenitally deaf is there thought to be a direct pathway between the visual and central integrative language centers.

Wernicke's aphasia that is due to stroke usually improves in time, sometimes to the point where the deficits can be detected only by asking the patient to repeat unfamiliar words, to name unusual objects or parts of objects, to spell difficult words, or to write complex self-generated sentences. A more favorable prognosis attends those forms of Wernicke's aphasia in which some of the elements, e.g., reading, are only slightly impaired.

As a rule, the lesion lies in the posterior perisylvian region (comprising posterosuperior temporal, opercular supramarginal, angular, and posterior insular gyri) and is usually due to embolic (less often thrombotic) occlusion of the lower (inferior) division of the left middle cerebral artery. A hemorrhage confined to the subcortex of the temporoparietal region or involvement of this area by tumor, abscess, or extension of a small putaminal or thalamic hemorrhage may have similar effects but a different prognosis. A lesion that involves structures deep to the posterior temporal cortex will cause an associated homonymous quadrantan- or hemianopia. Often there is no associated weakness of limbs or face and the aphasic patient may be misdiagnosed as psychotic, especially if there is jargon aphasia. According to Kertesz and Benson, persistence of Wernicke's aphasia is related to a lesion that involves both the supramarginal and angular gyri.

The posterior perisylvian region appears to encompass a variety of language functions, and seemingly minor changes in the size and locale of the lesion are associated with important variations in the elements of Wernicke's aphasia or lead to conduction aphasia or to pure word deafness (see below). The interesting theoretical problem is whether all the deficits observed are indicative of a unitary language function that resides in the posterior perisylvian region or, instead, of a series of separate sensorimotor activities whose anatomic pathways happen to be crowded together in a small region of the brain. In view of the multiple ways in
which language is learned and deteriorates in disease, the latter hypothesis seems more likely.

Total, or Global, Aphasia

This syndrome is due to destruction of a large part of the language zone, embracing both Broca's and Wernicke's areas and much of the territory between them. The lesion is usually due to occlusion of the left internal carotid artery or middle cerebral artery, but it may be caused by hemorrhage, tumor, or other lesions, and it may occur briefly as a postictal effect. The middle cerebral artery perfuses all of the language area, and nearly all the aphasic disorders due to vascular occlusion are caused by involvement of this artery or its branches.

All aspects of speech and language are affected. At most, the patients can say only a few words, usually some cliché or habitual phrase, and they can imitate single sounds. Or they can only emit a syllable, such as "ah," or cry, shout, or moan. In other words, they are not mute. They may understand a few words and phrases, but—because of rapid fatigue and verbal and motor perseveration (the obligate repetitive evocation of a word or motor act just after it has been employed)—they characteristically fail to carry out a series of simple commands or to name a series of objects. They cannot read a single word or repeat what is said to them. The patient may participate in common gestures of greeting, show modesty and avoidance reactions, and engage in self-help activities. With the passage of time, some degree of comprehension of language may return, and the clinical picture that is then most likely to emerge is closest to that of a severe Broca's aphasia.

Varying degrees of right hemiplegia, hemianesthesia, and homonymous hemianopia almost invariably accompany global aphasia of vascular origin. In such patients, language function rarely recovers to a significant degree. On the other hand, improvement frequently occurs when the main cause is cerebral trauma, compression from edema, postcommisurotomy paralysis, or a transient metabolic derangement such as hypoglycemia, hypotension, etc., which may worsen an old lesion that had involved language areas.

Disconnection (Dissociative) Syndromes

This term refers to certain disorders of language that result not from lesions of the cortical language areas themselves but from an apparent interruption of association pathways crossing the primary receptive (sensorimotor) areas to the language areas. Included also in this category are aphasia due to lesions that separate the more strictly receptive parts of the language mechanism itself from the purely motor ones (conduction aphasia—see below) and to lesions that isolate the perisylvian language areas, separating them from the other parts of the cerebral cortex ("transcortical aphasia").

The anatomic basis for most of these so-called disconnection syndromes is poorly defined. The concept, however, is an interesting one and emphasizes the importance of afferent, intercortical, and efferent connections of the language mechanisms. The weakness of the concept is that it may lead to premature acceptance of the hypothesis that logical mechanisms that cause loss of a language function does not localize the language function itself, a warning enunciated long ago by Hughlings Jackson. Nevertheless, the language disorders described below occur with sufficient regularity and clinical uniformity to be as useful as the more common types of aphasia in revealing the complexity of language functions.

Conduction Aphasia

As indicated earlier, Wernicke theorized that certain clinical symptoms would follow a lesion that effectively separated the auditory and motor language areas without directly damaging either of them. Since then, a number of well-studied cases have been described that conform to Wernicke's proposed model of Leitungstausch (conduction aphasia), which is the name he gave to it. Characteristically, repetition is severely affected both for single words and for nonwords in the face of relatively preserved comprehension. This dichotomy is said to be the essential feature of conduction aphasia.

In other respects, the features of conduction aphasia resemble those of Wernicke's aphasia. There is a similar fluency and paraphasia in self-initiated speech, in repeating what is heard, and in reading aloud; writing is invariably impaired. Dysarthria and dysprosody are usually lacking. Speech output is normal or somewhat reduced. But, compared with the one who has Wernicke's aphasia, the patient with conduction aphasia has relatively little difficulty in understanding words that are heard or seen and is aware of this deficit.

The lesion in autopsied cases has been located in the cortex and subcortical white matter in the upper bank of the left Sylvian fissure, sometimes involving the supramarginal gyrus and occasionally the most posterior part of the superior temporal region. According to Damasio and Geschwind, Wernicke's and Broca's areas are spared, and the critical structure involved is the arcuate fasciculus. This fiber tract streams from the temporal lobe, proceeding somewhat posteriorly, around the posterior end of the Sylvian fissure; there it joins the superior longitudinal fasciculus, deep in the anteroinferior parietal region, and proceeds forward, deep to the suprasylvian operculum, to the motor association cortex, including the Broca and Exner areas (Fig. 22-7). However, in most of the reported cases, such as those of the Damascos, the left auditory complex, insula, and supramarginal gyrus were also involved. The usual cause of conduction aphasia is an embolic occlusion of the ascending parietal or posterior temporal branch of the middle cerebral artery, but other forms of vascular disease, neoplasm, or trauma in this region may produce the same syndrome.

The concept of conduction aphasia, as outlined above, remains a useful theoretic construct, although not all authors are in agreement as to its purity as an aphasic syndrome. Mohr, in his analysis of the writings on this subject, found that the distinction between conduction aphasia and Wernicke's aphasia, mainly one degree of auditory comprehension, was ambiguous clinically and that the lesions in the two syndromes were much the same.

"Pure" Word Deafness

This uncommon disorder, originally described by Lichthein in 1885, is characterized by an impairment of auditory comprehension and repetition and an inability to write to dictation. Self-initiated utterances are usually correctly phrased but sometimes paraphasic; spontaneous writing and ability to comprehend written language are preserved, thus distinguishing this disorder from classic Wernicke's aphasia. Patients with pure word deafness may declare that they understand a text, but shouting does not help, formulas to their surprise. Audiometric testing and auditory evoked potentials disclose no hearing defect, and nonverbal sounds, such as a doorbell, can be heard without difficulty. The patient is forced to depend heavily on visual cues and frequently uses them well enough to understand most of what is said. However, tests that prevent the use of visual cues readily uncover the deficit. If able to describe the auditory experience, the patient says that words sound like a jumble of noises. As in the case of visual agnosia (see below), the syndrome of pure auditory verbal agnosia is not pure, particularly at its onset, and paraphasic and other elements of Wernicke's aphasia may be detected (Buchman et al). At times this syndrome is the result of resolution of a more typical Wernicke's aphasia, and it will be recognized that word deafness is an integral feature of all instances of Wernicke's aphasia. Conceptually it has been thought of as an exclusive injury of the auditory processing system.

In most recorded autopsy studies, the lesions have been bilateral, in the middle third of the superior temporal gyr, in a position to interrupt the connections between the primary auditory cortex in the transverse gyrus of Heschl and the association areas of the superoposterior cortex of the temporal lobe. In a few cases unilateral lesions have been localized in this part of the dominant temporal lobe (see page 490). Requirements of small size and superficiality of the lesion in the cortex and subcortical white matter are best fulfilled by an embolic occlusion of a small branch of the lower division of the middle cerebral artery.

"Pure" Word Blindness (Alexia without Agraphia, Visual Verbal Agnosia)

This is a not uncommon syndrome, in which a literate person loses the ability to read aloud, to understand written script, and, often, to name colors—i.e., to match a seen color to its spoken name—visual verbal color anomia. Such a person can no longer name or point on command to words, although he is sometimes able to read letters or numbers. Understanding spoken language, repetition of what is heard, writing spontaneously and to dictation, and conversation are all intact. The ability to copy words is impaired but is better preserved than reading, and the patient may even be able to spell a word or to identify a word by having it spelled to him or by reading one letter at a time (letter-by-letter reading). In some cases, the patient manages to read single letters but not to join them together (letter-by-letter reading). The most striking feature of this syndrome is the retained capacity to write fluently, after which the patient cannot read what has been written (alexia without agraphia). And when the patient with alexia or dyslexia also has difficulty in auditory comprehension and in repeating spoken words, the syndrome corresponds to Wernicke's aphasia.

Autopsies of such cases have usually demonstrated a lesion that destroys the left visual cortex and underlying white matter, particularly the geniculocarotin tract, as well as the connections of the right visual cortex with the intact language areas of the dominant hemisphere. In the case originally described by Déjerine (1892), the disconnection occurred in the posterior part (splenium) of the corpus callosum, wherein lie the connections between the visual association areas of the two hemispheres (Fig. 22-7). More often the callosal pathways are interrupted in the forceps major or in the paravenricular region (Damasio and Damasio). In either event, the patient is blind in the right half of each visual field by virtue of the left occipital lesion, and visual information reaches only the right occipital lobe; however, this information cannot be transferred, via the callosal pathways, to the angular gyrus of the left (dominant) hemisphere.

A rare variant of this syndrome takes the form of alexia without agraphia and without hemianopia. A lesion deep in the white matter of the left occipital lobe, at its junction with the parietal lobe, interrupts the projections from the intact (right) visual cortex to the language areas but spares the geniculocarotin pathway.
In yet other cases, the lesion is confined to the angular gyrus or the subjacent white matter. In such cases also, a right homonymous hemianopia will be absent, but the alexia may be compensated for by the contralateral reading or writing of Coons of syndactyly—i.e., left-right confusion, dyscalculia, and finger agnosia (page 485). This constellation of symptoms is sometimes referred to as the syndrome of the angular gyrus. Anomic aphasia may be added (see below).

"Pure" Word Mutism (Aphemia, Pure Motor Aphasia of Déjerine) Occasionally, as a result of a vascular lesion or other type of localized injury of the dominant hemisphere, there is a loss of capacity to repeat the spoken word (of the same reason. Several of our cases have resulted from infarctions in the watershed zone between the anterior and middle cerebral arteries, after cardiac arrest or shock.

Anomic (Amnesic, Nominal) Aphasia Some degree of word-finding difficulty is probably part of every type of language disorder, including that which occurs with the confusional states and dementia. In fact, without an element of anomia, a diagnosis of aphasia is usually incorrect. Only when this feature is the most notable aspect of language difficulty is the term amnic aphasia employed. In this latter condition, a relatively uncommon form of aphasia, the patient loses only the ability to name people and objects. There are typical pauses in speech, groping for words, circumlocution, and substitution of another word or phrase that is intended to convey the meaning. Or the patient may simply fail to name a shown object, in contrast to the usual aphasic patient, who produces a paraphasic error. Less frequently used words give more trouble. When shown a series of common objects, the patient may tell of their use instead of giving their names. The difficulty applies not only to objects seen but to the names of things heard or felt (Geschwind), but this is more difficult to demonstrate.

Anomic aphasia has been associated with lesions in different parts of the language area, classically in the temporal area. In these cases the lesion has been deep in the basolateral portion of the temporal lobe or in the middle temporal convolution, in position to interrupt connections between sensory language areas and the hippocampal regions concerned with learning and memory. Mass lesions—such as a tumor, herpes encephalitis, or an abscess—are the most frequent causes; as these lesions enlarge, a contralateral upper quadrantic visual field defect or a Wernicke's aphasia is added. Occasionally, anomia appears with lesions due to occlusion of the temporal branches of the posterior cerebral artery. Anomia may be a prominent manifestation of transcortical motor aphasia (see below) and may be associated with the Gerstmann syndrome, in which case the lesions are found in the frontal lobe and angular gyrus, respectively. An anomic type of aphasia is often an early sign of Alzheimer and Pick disease, and minor degrees of it are common in old age. Finally, anomia, anomic aphasia may be the only residual abnormality after partial recovery from Wernicke's, conduction, transcortical sensory, or (rarely) Broca's aphasia.

Isolation of the Language Areas (Transcortical Aphasia) Destruction of the border zones between anterior, middle, and posterior cerebral arteries—usually as a result of prolonged hypotension, carbon monoxide poisoning, or other forms of anoxic-ischemic injury—may effectively isolate the motor association and sensory association language areas, all or in part, from the rest of the cortex of the same hemisphere. In the case of Asall and colleagues, for example, multiple infarcts had isolated all of the language area.

In transcortical sensory aphasia, so named by Lichtheim and later defined by Goldstein, the patient suffers a deficit of auditory and visual word comprehension, and writing and reading are impossible. Speech remains fluent, with marked paraphasia, anomia, and empty circumlocutions. However, the central feature of transcortical aphasia is that repetition is remarkably preserved, unlike the deficit in Wernicke's and conduction aphasia, in which ability to repeat the spoken word is lost or severely impaired. Facility in repetition, in extreme degree, takes the form of echoing, parrot-like, word phrases and songs that he heard (echolia). In a series of 15 such patients, CT and isotope scans have uniformly disclosed a lesion in the posterior parieto-occipital region (Kertesz et al). This locates the frequent association with the Gerstmann syndrome, in which case the lesions are found in the frontal lobe and angular gyrus, respectively. An anomic type of aphasia is often an early sign of Alzheimer and Pick disease, and minor degrees of it are common in old age. Finally, anomia, anomic aphasia may be the only residual abnormality after partial recovery from Wernicke's, conduction, transcortical sensory, or (rarely) Broca's aphasia.

Presumably, in anomic aphasia, information from the nonlanguage areas of the cerebrum cannot be transferred to Wernicke's area for conversion into verbal form. The paraphasia is thought to result from the weakened control of the motor language areas by the auditory and visual areas, though the direct connection between them, presumably the arcuate fasciculus, is preserved. Preservation of this direct connection is said to account for the ability to repeat. Reading and auditory comprehension suffer because the sensory information does not reach the central integrative centers.

In transcortical motor aphasia ("anterior isolation syndrome," "dynamic aphasia" of Luria) the patient is unable to initiate conversational speech, producing only a few grunts or syllables. Comprehension is relatively preserved, but repetition is strikingly intact, distinguishing this syndrome from pure word mutism (see above).

Transcortical motor aphasia occurs in two clinical contexts: (1) in a mild or partially recovered Broca's aphasia in which repetition remains superior to conversational speech (repeating and reading aloud are generally easier than self-generated speech) and (2) in states of abulia and akinetic mutism with frontal lobe damage, for the same reason. Several of our cases have resulted from infarctions in the watershed zone between the anterior and middle cerebral arteries, after cardiac arrest or shock.

These transcortical syndromes are of great theoretical interest and are probably more common than is currently appreciated.

The Aphagrasia

Writing is, of course, an integral part of language function but a less essential and universal component, for a considerable segment of the world's population speaks but does not read or write. It might be supposed that all the rules of language derived from the study of motor aphasia would be applicable to agraphia. In part this is true. One must be able to formulate ideas in words and phrases in order to have something to write as well as to say; hence disorders of writing, like disorders of speech, may be basic defects of language rather than differences between these two expressive modes. In speech, only one final motor pathway coordinating the movements of lips, tongue, larynx, and respiratory muscles is available, whereas if the right hand is paralysed, one can still write with the left one, or with a foot, and even with the mouth by holding a pencil between the teeth.

The writing of a word can be accomplished either by the direct lexical method of recalling its spelling or by sounding out its phonemes and transforming them into learned graphemes (motor images)—i.e., the phonologic method. Some authors state that in agraphia there is a specific difficulty in transforming phonologic information, acquired through the auditory sense, into orthographic forms; others see it as a block between the visual form of phonemes and the cursive movements of the hand. In support of the latter idea is the fact that reading and writing usually develop together and are long preceded by the development and elaboration of auditory-articular mechanisms.

Pure agraphia as the initial and sole disturbance of language function is a rare entity, but such cases have been described (see the review of Rosati and de Bastiani). Pathologically verified cases are virtually nonexistent, but CT examination of the case of Rosati and de Bastiani disclosed a lesion of the posterior perisylvian area. This is in keeping with the observation that a lesion in or near the angular gyrus will occasionally cause a disproportionate disorder of writing as part...
of the Gerstmann syndrome. As mentioned earlier, the notion of a specific center for writing in the posterior part of the second frontal convolution ("Exner's writing area") has been questioned by some aphasiologists (see Leischner). However, Croisile and associates do cite cases of pure dysgraphia in which a lesion (in their case, a hemotoma) was located in the centrum semiovale beneath the motor parts of the frontal cortex.

Quite apart from these aphasic agraphias, in which spelling and grammatical errors abound, there are special forms of agraphia caused by abnormalities of spatial perception and praxis. Disturbances in the perception of spatial relationships appear to underlie constructive agraphia. In this circumstance, letters and words are formed clearly enough but are wrongly arranged on the page. Words may be superimposed, reversed, written diagonally or in haphazard arrangement, or from right to left; with right parietal lesions, only the right half of the page is used. Usually one finds other constructional difficulties as well, such as inability to copy geometric figures or to make drawings of clocks, flowers, and maps, etc.

A third group may be called the apraxic agraphias. Here language formulation is correct and the spatial arrangements of words are respected, but the hand has lost its skill in forming letters and words. Handwriting becomes a scrawl, losing all personal character. There may be an uncertainty as to how the pen should be held and applied to paper; apraxias (idiomotor and ideational) are present in the right-hander. As a rule, other learned manual skills are simultaneously disturbed.

Speculations as to the basic fault here are discussed in Chap. 3, under "Agraphia and Other Nonparalytic Disorders of Motor Functions," and in Chap. 22, in relation to functions of the frontal and parietal lobes.

In addition to the neurologic forms of agraphia, described above, psychologists have defined a group of linguistic agraphias, subdivided into phonologic, lexical, and semantic types (Roeltgen). These linguistic models are based on loss of the ability to write (and to spell) particular classes of words. For example, the patient may be unable to spell pronounceable nonsense words, with preserved ability to spell real words (phonologic agraphia); or there may be preserved ability to write nonsense words such as illogical words (semantic agraphia); or there may be difficulty in writing words such as "the moon comes out at night." For the most part these linguistic agraphias have no well-established cerebral localization and only tenuous associations with the classic agraphias, for which reason this subject is of greater interest to linguists and psychologists than to neurologists.

Subcortical Aphasia (Thalamic and Striatocapsular Aphasias)

A lesion of the dominant thalamus, usually vascular and involving the posterior nuclei, may cause an aphasia, the clinical features of which are not entirely uniform. Usually there is mutism initially and comprehension is impaired. With beginning recovery, spontaneous speech is reduced in amount; less often, speech is fluent and paraphasic to the point of jargon. Reading and writing may or may not be affected. Anomia has been described with a ventrolateral lesion (Ojemann).

Characteristically the patient’s ability to repeat dictated words and phrases is impaired, as in transcortical sensory aphasia. Complete recovery, in a matter of weeks, is the rule, often with persistence of the thalamic lesion.

Aphasia has also been described with dominant striatocapsular lesions, particularly if they extend laterally into the subcortical white matter of the temporal lobe and insula. The head of the caudate, anterior limb of the internal capsule, and the anterosep niorior aspect of the putamen appear to be the critically involved structures. The thalamus characterizes by nonfluent, dysarthric, paraphasic speech and varying degrees of difficulty with comprehension of language, naming, and repetition. The patient is possibly a right-handed as a rule, and a right hemiparesis is usually associated. In general, striatocapsular aphasia recovers more slowly and less completely than thalamic aphasia.

These two subcortical aphasias—thalamic and striatocapsular—resemble but are not identical to the Wernicke and Broca types of aphasia. For further discussion of the subcortical aphasias, the reader is directed to the articles of Naeser and of Alexander and their colleagues.

Other Cerebral Disorders of Language

It would be incorrect to conclude that the syndromes described above, all of which are related to perisylvian lesions of the dominant cerebral hemisphere, represent all the ways in which cerebral disease disturbs language. The effects on speech and language of diffuse cerebral disorders, such as delirium tremens and Alzheimer disease, have already been mentioned (see pages 505 and 512). Pathologic changes in parts of the cerebrum other than the perisylvian regions may secondarily affect speech and language. Examples of these changes are lesions that damage the border zones between major cerebral arteries and effectively isolate perisylvian areas from other parts of the cerebrum fall into this category (transcortical aphasias, see above). Other examples are the lesions in the medio-orbital or superior and lateral parts of the frontal lobes, which impair all motor activity, to the point of abulia or akinetic mutism (pages 369–370). The mute patient, in contrast to the aphasic one, emits no sounds. If the patient is less severely hypokinetic, his speech tends to be laconic, with long pauses and an inability to sustain a monologue. Extensive occipital lesions will, of course, impair reading, but they also reduce the utilization of all visual and textual stimuli. Deep cerebral lesions, by causing fluctuating states of inattention and disorientation, induce fragmentation of words and phrases and sometimes protracted, uncontrolled talking (logorhea). Strong stimulation, which momentarily stabilizes behavior and speech, proves the essential integrity of language mechanisms.

Severe mental retardation often results in failure to acquire even spoken language, as pointed out in Chap. 28 and Chap. 38. If there is any language skill, it consists only of the understanding of a few simple spoken commands. The subject of developmental dyslexia is discussed on page 628.

Approach to the Patient with Language Disorders

In the investigation of aphasia, it is first necessary to inquire into the patient’s native language, handedness, and previous level of literacy and education. For many years it has been taught that following the onset of aphasia, individuals who had been fluent in more than one language (polyglots) improved more quickly in their native language than in a subsequently acquired one (a derivative of Ribot’s law of retained distant memory). This rule seems to hold if the patient is not truly fluent in the more recently acquired language, or has not used it for a long time. More often, the language most used before the onset of the aphasia will recover first (Pitres’ law). Usually, if adequate testing is possible, more or less the same aphasic abnormalities are found in both the first and the more recently acquired language.

Many naturally left-handed children are trained to use the right hand for writing; therefore, in determining handedness, one must ask which hand is preferred for throwing a ball, threading a needle, sewing, or using a tennis racket or hammer, and which eye is used for sighting a target with a rifle or other instrument. It is important, before beginning the examination, to determine whether the patient is alert and can participate reliably in testing, since accurate assessment of language depends on these factors.

One should quickly ascertain whether the patient has other gross signs of a cerebral lesion such as hemiplegia, facial weakness, homonymous hemianopia, or corticospinal loss. When such a constellation of major neurologic signs is present, the aphasic disorder is usually of the total (global) type. Dyspraxia of limbs and spatially oriented gestures in response to spoken commands or to visual mimicry is generally associated with Broca’s aphasia and sometimes with Wernicke’s aphasia. Bilateral or unilateral homonymous hemianopia without motor weakness tends often to be linked to pure word blindness, to alexia with or without agraphia, and to anomic aphasia.

The bedside analysis of aphasic disorders entails the systematic testing of six aspects of language function: conversational speech (fluency), comprehension, repetition, reading, writing, and naming. Simply engaging the patient in conversation permits quick assessment of the motor aspects of speech (praxis and prosody), fluency, language formulation, and auditory comprehension. If the disability consists mainly of sparse, laborious speech, it suggests, of course, Broca’s aphasia, and this is confirmed further by tests of repeating from dictation and by special tests of praxis of the oropharyngeal muscles. Fluent but empty paraphasic speech with impaired comprehension is indicative of Wernicke’s aphasia. Impaired comprehension but perfectly normal formulated speech and intact ability to read suggest the rare syndrome of pure word deafness.

When conversation discloses virtually no abnormalities, other tests may still be revealing. The most important of these are reading, writing, repetition, and naming. Reading aloud single letters, words, and text may disclose the dissociative syndrome of pure word blindness. Except for this syndrome and pure word mutism (see above), writing is disturbed in all forms of aphasia. Literal and verbal paraphasic errors may appear in milder cases of Wernicke’s aphasia as the patient reads aloud from a text or from words in the examiner’s handwriting. Similar errors appear even more frequently when the patient is asked to explain the text, read aloud, or give an explanation in writing.

Testing the patient’s ability to repeat spoken language is a simple and important maneuver in the evaluation of aphasic disorders. As with other tests of aphasia, it may be necessary to increase the complexity of the test—from digits and simple words to complex words, phrases, and sentences—in order to disclose the full disability. Defective repetition occurs in all forms of aphasia (Broca’s, Wernicke’s, and global) due to lesions in the perisylvian language areas. The patient may be
lower motor neuron paralysis — the hallmark of conduction aphasia. Contrariwise, normal repetition in an aphasic patient indicates that the perisylvian area is intact (so-called transcoritical aphasia). In fact, the tendency to repeat may be excessive (echolalia). Preserved repetition is also characteristic of anomia and occurs occasionally with subcortical lesions. Disorders confined to naming, other language functions (reading, writing, spelling, etc.) being adequate, are diagnostic of anomic, or anomia, aphasia and referable usually to lower temporal lobe lesions.

These deficits can be quantitated by the use of any one of several examination procedures. Those of Gooodglass and Kaplan (Boston Diagnostic Aphasia Examination, or BDAE) and of Kertesz (Western Aphasia Battery, or WAB) are the most widely used in the United States. The use of these procedures will enable one to predict the type and localization of the lesion in approximately two-thirds of the patients, which is not much better than detailed bedside examination. Aphasia of the Broca, Wernicke, conduction, global, and anomia types accounted for 392 of 444 unselected cases studied by Benson and his group.

**Treatment** The sudden onset of aphasia would be expected to cause great apprehension, but except for cases of pure or almost pure motor disorders of speech, most patients show remarkably little concern. It appears that the very lesion that deprives them of speech also causes at least a partial loss of insight into their own disability. This reaches almost a ludicrous extremity in some cases of Wernicke's aphasia, in which the patient becomes indignant when others cannot understand his jargon. Nonetheless, as improvement occurs, many patients do become discouraged. Reassurance and a program of speech rehabilitation are the best ways of helping the patient at this stage.

Whether contemporary methods of speech therapy can more than can be accounted for by spontaneous recovery is still uncertain. Most aphasic disorders are due to vascular disease and trauma, and they are nearly always accompanied by some degree of spontaneous improvement in the days, weeks, and months that follow the stroke or accident. A Veterans Administration Cooperative Study (Wertz et al) has suggested that intensive therapy by a speech pathologist does hasten improvement. Also, Howard and colleagues have shown increased efficacy of word retrieval in a group of chronic stable aphasics treated by two different techniques. More studies of this type, which could control for the effects of the patient's motivation and the interest of family and therapist, are needed. In an interesting personal experiment by Wender, a classicist who had become aphasic, practice of Greek vocabulary and grammar led to recovery in that language, but there was little recovery of her facility with Latin, which was not similarly exercised.

One must decide for each patient when speech training should be started. As a rule, therapy is not advisable in the first few days of an aphasic illness, because one does not know how lasting it will be. Also, if the patient suffers a severe global aphasia and can neither understand spoken and written words, the speech therapist is virtually helpless. Under such circumstances, one does well to wait a few weeks until one of the language functions has begun to return. Then the physician and therapist can begin to help the patient to use that function to a maximum degree. In milder aphasic disorders, the patient may be sent to the speech therapist as soon as the illness has stabilized.

The methods of speech rehabilitation are specialized, and it is advisable to call in a person who has been trained in this field. However, insasmuch as the benefit is also largely psychologic, an interested family member or schoolteacher can be of help if a speech therapist is not available in the community.

Frustration, depression, and paranoia, which complicate some aphasias, may require psychiatric evaluation and treatment. The developmental language disorders of children pose special problems and are considered in Chap. 28.

**Prognosis and Recovery Patterns** Some aspects of prognosis have been discussed above. In general, recovery from aphasia due to cerebral trauma is usually faster and more complete than that from aphasia due to stroke. The type of aphasia and particularly its initial severity (extent of the lesion) clearly influence recovery: global aphasia usually improves very little, and the same is true of severe Broca's and Wernicke's aphasias (Kertesz and McCabe). The various dissociative speech syndromes and pure word mutism tend to improve rapidly and often completely. Also, in general, the outlook for recovery of any particular aphasia is more favorable in a left-handed person than in a right-handed one. Characteristically, in the course of recovery, one type of aphasia may evolve into another type (global into Broca's, Wernicke's, transcortical, and conduction aphasia) through transitional forms that may mistakenly be attributed to the effects of therapy. It is because so many factors may influence the mode of recovery from aphasia that the effectiveness of formal speech therapy has never been fully evaluated.

**DISORDERS OF ARTICULATION AND PHONATION**

The act of speaking involves a highly coordinated sequence of actions of the respiratory musculature, larynx, pharynx, palate, tongue, and lips. These structures are innervated by the vagal, hypoglossal, facial, and phrenic nerves, the nuclei of which are controlled by both motor cortices through the corticobulbar tracts. As with all movements, those involved in speech are subject to extrapyramidal influences from the cerebellum and basal ganglia. The act of speaking requires that air be expired in regulated bursts, and each expiration must be maintained long enough (by pressure mainly from the intercostal muscles) to permit the utterance of phrases and sentences. The current of expired air is then finely regulated by the activity of the various muscles engaged in speech.

Phonation, or the production of vocal sounds, is a function of the larynx, more particularly the vocal cords. The pitch of the speaking or singing voice depends upon the length and mass of the membranous parts of the vocal cords and can be varied by changing their tension; this is accomplished by means of the intrinsic laryngeal muscles, before any audible sound emerges. The controlled intratracheal pressure forces air past the glottis and separates the margins of the cords, setting up a series of vibrations and recolts. Sounds thus formed are modulated as they pass through the nasopharynx and mouth, which act as resonators. Articulation consists of controlling the pharynx, palate, tongue, and lips, which interlace with the phonatory sounds. Vowels are of long duration and consist of a series of vibrations and recoils. Sounds thus formed are modulated as they pass through the nasopharynx and mouth, which act as resonators.

Defective articulation and phonation are recognized at once by listening to the patient speak during ordinary conversation or read aloud from a newspaper. Test phrases or attempts at rapid repetition of lingual, labial, and guttural consonants (e.g., la-la-la, ma-ma-ma-ma, or k-k-k-k) bring out the particular abnormality. Disorders of phonation call for a precise analysis of the voice and its apparatus during speech and singing. The movements of the vocal cords should be inspected with a laryngoscope and those of the tongue, palate, and pharynx by direct observation.

**Dysarthria and Anarthria**

In pure dysarthria or anarthria, there is no abnormality of the cortical language mechanisms. The dysarthric patient is able to understand perfectly what is heard and, if the patient has normal hearing, can say or write things perfectly. But when it comes to spoken language, the patient has no control over the muscles of speech, and what he says is not what he means.

In pure dysarthria or anarthria, there is no abnormality of the cortical language mechanisms. The dysarthric patient is able to understand perfectly what is heard and, if the patient has normal hearing, can say or write things perfectly. But when it comes to spoken language, the patient has no control over the muscles of speech, and what he says is not what he means.

**Lower Motor Neuron (Neuromuscular) Dysarthria, Atrophic Bulbar Paralysis** This is due to weakness or paralysis of the articular muscles, the result of disease of the motor nuclei of the medulla and lower pons or their intramedullary or peripheral extensions (lower motor neuron paralysis). In advanced forms of this disorder, the shivered tongue lies inert and fasciculating on the floor of the mouth, and the lips are lax and tremulous. Saliva constantly collects in the mouth because of dysphagia, and drooling is troublesome. Dysphonia—alteration of the voice to a rasping monotone due to vocal cord paralysis—is often added. As this condition evolves, the patient has poverty of voice, nasal resonance, and hoarseness. In addition, there is special difficulty in the enunciation of vibrations, such as /r/ and /s/. As the paralysis becomes more complete, linguistic and labial consonants are finally not pronounced at all. In the past, bilateral paralysis of the palate, causing nasality of speech, often occurred with diphtheria and poliomyelitis, but now it occurs most often with progressive bulbar palsy, a form of motor neuron disease (page 1154), and with certain diseases that involve the corticobulbar tracts, usually due to vascular, demyelinative, or motor system disease (amyotrophic lateral sclerosis). The patient may have a clinically incoherent vascular lesion at some time in the past, affecting the corticobulbar fibers on one side; however, since the bulbar muscles on each side are innervated by both motor cortices, there may be little or no impairment in speech or swallowing by a unilateral corticobulbar tract lesion. Should another stroke then occur, involving the other corticobulbar tract at the pontine, medullary, or spinal level, the patient immediately becomes dysarthric, dysphonic, and anomic, often with paralysis of the tongue and facial muscles. This condition, unlike bulbar paralysis due to lower motor neuron involvement, entails no atrophy or fasciculations of the paralyzed muscles; the jaw jerk and other facial reflexes become exaggerated, the palatal reflexes are retained or increased, emotional control is impaired (spasmodyc crying and laughing—the pseudobulbar affective state described on page 541), and sometimes breathing becomes periodic (Cheyne-Stokes). Amyotrophic lateral sclerosis is the main condition in which the signs of spastic and atrophic bulbar palsy are combined.
When the dominant frontal operculum alone is involved, speech may be dysarthric, usually without impairment in emotional control. In the beginning, with vascular lesions, the patient may be mute; but with recovery or in mild degrees of the same condition, speech is notably slow, thick, and indistinct, much like that of partial bulbar paralysis. Magnetic stimulation of the cortex in these cases may reveal a delay in corticobulbar conduction. The terms cortical dysarthria and anarthria, among many others, have been applied to this disorder, which is more closely related to mild forms of Broca's aphasia than to the dysarthrias being considered in this section (see "Pure Word Mutism," page 511). Also, in many cases of partially recovered Broca's aphasia and in the "mini-Broca" syndrome, the patient is left with a dysarthria that may be difficult to distinguish from a pure articulatory defect. Careful testing of other language functions, especially writing, will in this instance reveal the aphasis aspect of the defect.

A severe dysarthria that is difficult to classify but resembles that of cerebellar disease may occur with a left hemiplegia, the result of capsular or right opercular infarction. It tends to improve over several weeks but initially may be so severe as to make speech incomprehensible (Ropper).

Rigid (Extrapyramidal) Dysarthria In Parkinson and other extrapyramidal disorders associated with rigidity of muscles, one observes a rather different disturbance of articulation, characterized by rapid utterance and slurring of words and syllables and trailing off in volume at the ends of sentences. The voice is low-pitched and monotonous, lacking both inflection and volume (hypophonia). The words are spoken hastily and run together in a pattern different from that of spastic dysarthria. In advanced cases, speech is almost unintelligible; only whispering is possible. It may happen that the patient finds it impossible to whisper, but he can speak a few words, or even longer sentences, without any effort, even while standing. Occasionally he can speak better if standing still, sitting, or lying down. The terms hypokinetic and festinating are aptly applied to these aspects of parkinsonian speech. Curiously, in the extrapyramidal disorder of progressive supranuclear palsy, the dysarthria and dysphonia tend to be staccato in nature.

With chorea and myoclonus, speech may also be affected in a highly characteristic manner. The speech is loud, harsh, improperly stressed, and poorly coordinated with breathing (hyperkinetic dysarthria). Unlike the defect of pseudobulbar palsy or Parkinson disease, chorea and myoclonus cause abrupt interruptions of the words by superimposition of involuntary movements of bulbar muscles. The latter abnormality is best described as "hiccup speech," in that the breaks are unexpected, as in singultus. Grimming and other characteristic movement abnormalities must be depended upon for diagnosis. The Tourette syndrome of multiple motor and vocal tics is characterized by starting vocalizations (barking noises, squeals, shrieks, grunting, sniffling, snorting) and by speech disturbances, notably stuttering and the involuntary utterance of obscenities (coprolalia).

Elements of both corticobulbar (spastic) and extrapyramidal speech disturbances may be combined in Wilson disease, in Hallervorden-Spatz disease, and in the form of cerebral palsy called double athetosis. The speech is loud, slow, and labored; it is poorly coordinated with breathing and accompanied by facial contortions and athetotic accesses of tone in other muscles. In diffuse cerebral diseases such as general paresis, strummed, tremulous speech is one of the cardinal signs.

Ataxic Dysarthria This is characteristic of acute and chronic cerebellar lesions. It may be observed in multiple sclerosis and various degenerative disorders involving the cerebellum or its peduncles, or as a sequel of anoxic encephalopathy and rarely of heat stroke. The principal abnormalities are slowness of speech, slurring, monotony, and unnatural separation of the syllables of words (scanning). Again, the coordination of speech and respiration is disordered. There may not be enough breath to utter other words or syllables, and others are expressed with an interval or an intended (explosive) sound. The dysarthria (see page 90) is less distinctive and is due most often to mesencephalic lesions involving the brachium conjunctivum. However, in some cases of cerebellar disease, especially if there is an element of spastic weakness of the tongue from corticobulbar tract involvement, there may be only a slurring dysarthria, and it is not possible to predict the anatomy of the lesions from analysis of speech alone. Myoclonic jerks involving the speech musculature may be superimposed on cerebellar ataxia in a number of diseases.

Acquired Stuttering This anomaly, characterized by interruptions of the normal rhythm of speech by involuntary repetition and prolongation or arrest of uttered letters or syllables, is a common developmental disorder, discussed in Chap. 36. But as pointed out by Rosenbek et al and by Helm and colleagues, it may appear in patients who are recovering from aphasic disorders and who had never stuttered in childhood. This acquired stuttering in adults resembles the developmental type in that the repetitions, prolongations, and blocks are restricted to the initial syllables of words, and there is no adaptation. However, it involves grammatical as well as substantive words and is generally unaccompanied by grimming and associated movements. In many instances, acquired stuttering is transitory; if it is permanent, among the sequelae are bilateral cerebral lesions, bilateral lesions in the thalamus, or specific lesions in the midbrain, such as those associated with bilateral cerebral lesions; present. Nevertheless we have observed some cases in which only a left-sided, predominantly motor aphasia provided the background for stuttering and others in which stuttering was an early sign of cerebral glioma originating in the parietal region. Benson also cites patients in whom stuttering accompanied fluent aphasia. Noteworthy is the fact that stuttering differs from palilalia, in which there is repetition of a word or phrase with increasing rapidity, and from echolalia, in which there is an obligate repetition of words or phrases. The treatment of Parkinson disease with L-dopa and occasionally an acquired cerebral lesion may reactivate developmental stuttering.

Aphonia and Dysphonia

Finally, a few points should be made concerning the fourth group of speech disorders, i.e., those due to disturbances of phonation. In adolescence there may be a persistence of the unstable "change of voice" normally seen in boys during puberty. As though by habit, the patient speaks part of the time in falsetto, and the condition may persist into adult life. Its basis is unknown. Probably the larynx is not masculinized, i.e., there is a failure in the spur of growth (length) of the vocal cords that ordinarily occurs in pubertal boys. Voice training has been helpful in the majority of patients.

Paresis of respiratory movements, as in myasthenia gravis, Guillain-Barré syndrome, and severe pulmonary disease, may affect the voice because insufficient air is provided for phonation. Also, disturbances in the rhythm of respiration may interfere with the fluency of speech. This is particularly noticeable in extrapyramidal disorders. One may observe that the patient tries to talk during part of inspiration. Another common feature of the latter diseases is the reduction in volume of the voice (hypophonia) due to limited excursion of the breathing muscles; the patient is unable to shout or to speak above a whisper. Whispering speech is also a feature of advanced Parkinson disease, stupor, and occasionally concussive brain injury and frontal lobe lesions, but strong stimulation may make the voice audible.

With paresis of both vocal cords, the patient can speak only in whispers. Since the vocal cords normally separate during inspiration, their failure to do so when paralyzed may result in an inspiratory stridor. If one vocal cord is paralyzed—as a result of involvement of the tenth cranial nerve by tumor, for example—the voice becomes hoarse, low-pitched, rasping, and somewhat nasal in quality, like cleft palate speech, because the posterior nares do not close during phonation. The pronunciation of certain consonants such as k, p, r, and l is followed by an escape of air into the nasal passages. The abnormality is sometimes less pronounced in recency and increased when the head is thrown forward.

Spasmodic Dysarthria This is a relatively common condition about which little is known. Spasmodic dysphonia is a better term than spastic dysphonia, since the former suggests corticospinal involvement, whereas the disorder is probably of extrapyramidal origin. The authors have seen many patients with middle-aged or elderly men and women, otherwise healthy, who lose the ability to speak quietly and fluently. Any attempt to speak results in explosive speech, articulation of words or syllables, and others are expressed with an interval or an intended (explosive) sound. Again, the coordination of speech and respiration is disordered. There may not be enough breath to utter other words or syllables, and others are expressed with an interval or an intended (explosive) sound. The speech is loud, slow, and labored; it is poorly coordinated with breathing and accompanied by facial contortions and athetotic accesses of tone in other muscles. In diffuse cerebral diseases such as general paresis, strummed, tremulous speech is one of the cardinal signs.

Spasmodic (Spastic) Dysphonia This is a relatively common condition about which little is known. Spasmodic dysphonia is a better term than spastic dysphonia, since the former suggests corticospinal involvement, whereas the disorder is probably of extrapyramidal origin. The authors have seen many patients with middle-aged or elderly men and women, otherwise healthy, who lose the ability to speak quietly and fluently. Any attempt to speak results in explosive speech, articulation of words or syllables, and others are expressed with an interval or an intended (explosive) sound. Again, the coordination of speech and respiration is disordered. There may not be enough breath to utter other words or syllables, and others are expressed with an interval or an intended (explosive) sound. The speech is loud, slow, and labored; it is poorly coordinated with breathing and accompanied by facial contortions and athetotic accesses of tone in other muscles. In diffuse cerebral diseases such as general paresis, strummed, tremulous speech is one of the cardinal signs.

Paresis of respiratory movements, as in myasthenia gravis, Guillain-Barré syndrome, and severe pulmonary disease, may affect the voice because insufficient air is provided for phonation. Also, disturbances in the rhythm of respiration may interfere with the fluency of speech. This is particularly noticeable in extrapyramidal disorders. One may observe that the patient tries to talk during part of inspiration. Another common feature of the latter diseases is the reduction in volume of the voice (hypophonia) due to limited excursion of the breathing muscles; the patient is unable to shout or to speak above a whisper. Whispering speech is also a feature of advanced Parkinson disease, stupor, and occasionally concussive brain injury and frontal lobe lesions, but strong stimulation may make the voice audible.

Spasmodic dysphonia is usually nonprogressive and occurs as an isolated phenomenon, but we have observed exceptions in which it occurs in various combinations with blepharospasm, spasmodic torticollis, writer's cramp, or some other type of segmental dystonia. The nature of spasmodic dysphonia suggests a localized lesion of the motor cortex or its descending pathways, perhaps a focal cortical lesion, as in a stroke or a parietal lobe tumor. As a neurologic disorder, it is akin to writer's cramp, i.e., a restricted dystonia (see Chap. 6). Speech therapists, observing such a patient strain to achieve vocalization, often assume that relief can be obtained by making the patient relax, and psychotherapists believed at first that a search of the patient's personal life around the time when the dysphonia began would enable the patient to understand the problem and regain a normal mode of speaking. But both these methods have failed without exception. Doctors useful in the treatment of Parkinson disease and other extrapyramidal disorders are practically never effective. Crushing of one recurrent laryngeal nerve can be beneficial, but recurrence is to be expected. The most effective treatment consists of the injection of 5 to 20 units of botulinum toxin, under laryngoscopic guidance, into each thyroarytenoid or cricothyroid muscle. Relief lasts for several months. An anatomic abnormality has not been demonstrated, but careful neuropathologic analysis will in this instance reveal the aphasis aspect of the defect.

Clinical References

In this chapter, we consider the clinical phenomena of lassitude, fatigue, nervousness, irritability, anxiety, and depression. These phenomena, though more abstruse than paralysis, sensory loss, seizures, or aphasia, are no less important, if for no other reason than their frequency in neurologic and general practice. In an audit of one neurologic outpatient department, anxiety-depression was the main preliminary diagnosis in 20 percent of the patients—second only to the complaint of headache (Digon et al.). And in two primary care clinics, in Boston and Houston, fatigue was the chief complaint in 21 and 24 percent, respectively. Some of these symptoms, acting through the autonomic nervous system, represent only slight aberrations of function or only a heightening or exaggeration of normal reactions to all manner of medical and neurologic diseases; others are integral features of the diseases themselves; and still others represent subtle and inchoate disturbances of psychiatric function, which are not yet sufficiently advanced to be readily identified as one of the diseases described in the section on psychiatry. It is because of their frequency and clinical significance that we have accorded them a chapter of their own among the cardinal manifestations of neurologic disease.

FATIGUE AND ASTHENIA

Of all the symptoms to be considered in this chapter, lassitude and fatigue are the most frequent and often the most vague. Fatigue refers to the universally familiar state of weakness or exhaustion resulting from physical or mental exertion. Lassitude has much the same meaning, although more strictly it connotes an inability or disinclination to be active, physically or mentally. More than half of all patients entering a general hospital register a complaint of fatigability or admit to it when questioned. During World War II, fatigue was such a prominent symptom in combat personnel as to be given a separate place in medical nosology, namely combat fatigue, a term that came to be applied to practically all acute psychiatric disorders occurring on the battlefield. In subsequent wars it was a key element in the posttraumatic stress and Gulf War syndromes. In civilian life, fatigue is, of course, the central feature of the chronic fatigue syndrome. The common clinical antecedents and accompaniments of fatigue, its significance, and its physiologic and psychologic bases should, therefore, be matters of interest to all physicians. These aspects of the subject will be better understood if we first consider the effects of fatigue on the normal individual.

Effects of Fatigue on the Normal Person

Fatigue has both explicit and implicit effects, grouped under (1) a series of biochemical and physiologic changes in muscles and a reduced capacity to generate force—manifest as weakness, or asthenia; (2) an overt disorder in behavior, taking the form of a reduced output of work (work decrement) or a lack of endurance; and (3) a subjective feeling of tiredness and discomfort.

As to the biochemical and physiologic changes, continuous muscular work leads to depletion of muscle adenosine triphosphate (ATP), the supply of which is derived from creatine phosphate via phosphorylation of adenosine diphosphate (ADP). With continued and more intense exercise, a further supply of ATP becomes available as a result of anaerobic breakdown of glycogen. When all the muscle glycogen has been consumed, exercise at a maximal level cannot be continued. However, mild to moderate exercise is still possible, since fatty acids provide an increasing share of muscle fuel. Gradually there is an accumulation of lactic acid and other metabolites, which in themselves reduce the power of muscular contraction and delay the recovery of muscle strength. Even in normal persons, extreme degrees of muscular effort, in which activity exceeds the provision of substrates, may result in necrosis of fibers and a rise in serum concentrations of creatine kinase (CK) and aldolase (this effect is much more evident in individuals with one of the hereditary metabolic diseases of muscle described in Chapter 51).

The decreased productivity and capacity for work, which is a direct consequence of fatigue, has been investigated by industrial psychologists. Their findings clearly demonstrate the importance of motivational factors on work output, whether the work be of physical or mental type. Also, individual differences in energy potential appear to be important, just as there are differences in physique, intelligence, and temperament. It should be emphasized that in majority of persons complaining of fatigue, one does not find true muscle weakness. This may be difficult to prove, for many such individuals are disinclined to exert full effort in tests of peak power of muscle contraction or endurance of muscular activity.

Aside from feeling weary and tired, the fatigued person is unable to deal effectively with complex problems and may behave unreasonably, often over trivialities. The number and quality of his associations in psychologic tests are reduced. The ability to deliberate and to make sound judgments is impaired. The worker, after a long, hard day, is unable to perform adequately the demanding duties of head of household; the tired business executive who becomes the tyrant of the family is proverbial. A disinclination to make an effort is another characteristics of the fatigued mind.

The Clinical Significance of Lassitude and Fatigue

Patients experiencing lassitude and fatigue have a more or less characteristic way of expressing their symptoms. They say that they are “all done in,” “tired all the time,” “weary,” “exhausted,” “tired out,” “fed up,” or “pooped out”—or that they have “no pep,” “no ambition,” or “no interest.” They manifest their condition by showing an indifference to the tasks at hand, by talking much about how hard they are working and how stressed they are by circumstances; they are inclined to sit around or lie down or to occupy themselves with trivial tasks. On closer analysis, one observes that they have difficulty in initiating activity and also in sustaining it—i.e., endurance is diminished. This condition, of course, is the familiar aftermath of sleeplessness or prolonged mental or physical effort, and under such circumstances it is accepted as a normal physiologic reaction. When, however, similar symptoms appear without relation to such antecedents, they should be suspected of being the manifestations of disease.

The physician's task begins, then, with an attempt to determine whether the patient is merely suffering from the physical and mental effects of overwork without realizing it. Overworked, overtaxed people are observable everywhere in our society. Their actions are both instructive and pitiful. Some constitutional inadequacy seems to prevent them from deriving pleasure from any activity except their work, in which they indulge themselves as a kind of defense mechanism. Their behavior is said to be irrational in that they will not listen to reason; they seem to be impelled by certain notions of duty and refuse to think of themselves. They work with great intensity and persistence, which reveals a high degree of emotional involvement. In addition to fatigue, such persons frequently show other symptoms, such as instability, restlessness, sleeplessness, and anxiety, sometimes to the point of panic attacks and a variety of somatic symptoms, particularly abdominal, thoracic, and cranial discomforts. Formerly, society accepted this state in responsible individuals and prescribed the obvious cure—a vacation. Even Charcot made time for regular “cures” during the year, in which he retired to a spa without family, colleagues, or the drain of work. Nowadays, the need to contain this type of stress, to which some individuals are more prone than others, has spawned a small industry of meditation, yoga, and similar “therapies.” Individuals with strong hobbies and athletic interests seem to be less subject to this problem.

Instances of fatigue and lassitude resulting from overwork are not difficult to recognize. A description of the patient’s daily routine and a talk with family members and associates will usually suffice. A common error in diagnosis, however, is to ascribe fatigue to overwork when actually it is a manifestation of a neurosis or depression.
Lassitude and Fatigue as Symptoms of Psychiatric Illness

The great majority of patients who seek medical help for unexplained chronic fatigue and lassitude are found to have some type of psychiatric illness. Formerly this state was called “neurasthenia,” but since lassitude and fatigue rarely exist as isolated phenomena, the current practice is to label such cases according to the total clinical picture. The usual associated symptoms are nervousness, irritability, anxiety, depression, associated head-aches, dizziness, difficulty in concentrating, reduced sexual impulse, and loss of appetite. In one series, 85 percent of persons admitted to a general hospital and seen in consultation by a psychiatrist for the chief complaint of chronic fatigue were diagnosed, finally, as having anxious depression or anxiety neurosis. In a subsequent study, Wessely and Powell found similarly that 72 percent of patients who presented to a neurologic center with unexplained chronic fatigue proved to have a psychiatric disorder, most often a depressive illness.

Several features are common to the psychiatric group. Tests of peak muscle power on command, with the patient exerting full effort, reveal no weakness. The muscles remain relaxed and tendon reflex activity. The fatigue may be worse in the morning. There is an inclination to lie down and rest, but sleep does not follow. The fatigue is worsened by mild exertion and relates more to some activities than to others. Inquiry may disclose that the fatigue was first experienced in temporal relation to a grief reaction, a surgical operation, physical trauma such as an automobile accident, or a medical illness such as myocardial infarction. The feeling of fatigue interferes with mental as well as physical activities; the patient is easily worried, is mentally inactive, is “full of complaints,” and finds it difficult to concentrate in attempting to solve a problem or to read a book, or in carrying on a complicated conversation. Also, sleep is disturbed, with a tendency to early-morning waking, so that such persons are at their worst in the morning, both in spirit and in energy output. Their tendency is to improve as the day wears on, and they may even feel fairly normal by evening. It may be difficult to decide whether the fatigue is a primary manifestation of the disease or secondary to a lack of interest.

Among chronically fatigued individuals without medical disease, not all deviate enough from normal to justify the diagnosis of neurosis or depression. Many persons, because of circumstances beyond their control, have little or no purpose in life and much idle time. They are bored with the monotony of their routine. Such circumstances are conducive to fatigue, just as the opposite, a strong emotion or a new enterprise that excites optimism and enthusiasm, will dispel fatigue. Also, as mentioned, one must be aware of striking individual differences in energy potential. Some persons are born low in impulse and energy and become more so at times of stress; they have a lifelong inability to play games vigorously, to compete successfully, to work hard without exhaustion, to withstand or recover quickly from illness, or to assume a dominant role in a social group—a constitutional asthenia (Kahn).

Lassitude and Fatigue with Medical Disease

Myopathic Fatigue
Not unexpectedly, fatigue and intolerance of exercise (i.e., fatigue with mild exertion) are prominent manifestations of myopathic disease, in which muscle weakness is an invariable feature. Even in a disease as benign as myasthenia gravis, the muscles exhibiting fatigue are usually weak even in the resting state. The classes of myopathic disease in which weakness, inability to sustain effort, and excessive fatigue are notable features include the following: the muscular dystrophies, congenital myopathies, disorders of neuromuscular transmission (myasthenia gravis, Lambert-Eaton syndrome), some of the glycogen storage myopathies, and mitochondrial myopathies. One type of glycogen storage disease—McArdle phosphofructokinase deficiency—is exceptional in that fatigue and weakness are accompanied by pain and sometimes by cramps and contracture. The first contractions after rest are of near normal strength, but after 20 to 30 contractions, there occurs a deep ache and an increasing firmness and shortening of the contracting muscles. The characteristics of these diseases are presented in the chapters on muscle disease.

Neurologic Diseases
Fatigue of varying degree is a regular feature of all diseases that are marked by denervation of muscle and loss of muscle fiber. Fatigue in these cases is due to the excessive work imposed on the intact muscle fibers (overwork fatigue). This is most characteristic of amyotrophic lateral sclerosis and the postpolio syndrome, but it also occurs in patients who are recovering from Guillain-Barre syndrome and in those with chronic polyneuropathy.

Not surprisingly, many neurologic diseases that are characterized by incessant muscular activity (Parkinson disease, double attherosclerosis, Huntingdon disease, hemiballismus) induce fatigue. In particular, muscles partially paralyzed by a stroke often feel tired (Brodal). Fatigue is often a major complaint of patients with multiple sclerosis, its cause is unknown, although the effect of CSF interleukins has been postulated. Also, the depression that follows stroke or myocardial infarction frequently presents with the complaint of fatigue rather than other signs of mood disorder. Inordinate fatigue is a common complaint among patients with posttraumatic neurologic disease (page 945). Severe degrees of fatigue that cause the patient consistently to get to bed after dinner and make all mental activity effortful should suggest an associated depression.

Systemic Diseases
A wide variety of medications and other therapeutic agents, particularly when first administered, commonly induce fatigue. The main offenders in this respect are anthihypertensive blocking agents, anticonvulsants, antipsychotics, drugs, anxiolytics, chemotheraphy and radiation therapy, and, paradoxically, many antidepressant and anxiolytic drugs. Introduction of these medications in gradually escalating doses may obviate the problem, but, just as often, an alternative medicine must be chosen. The administration of beta-interferon for the treatment of multiple sclerosis (and alpha-interferon for other diseases) induces fatigue of varying degree. Plasma exchange for the treatment of immune neuropathies and myasthenia gravis may be followed by fatigue for a day or so; this state should not be mistaken for a worsening of the underlying disease. Surgeons and nurses can testify to fatigue that comes with exposure to anesthetics in inadequately ventilated operating rooms. Similarly, fatigue and headache may result from exposure to carbon monoxide or natural gas in homes with furnaces in disrepair or from leaking gas pipes.

The sleep apnea syndrome is an important cause of fatigue and daytime drowsiness. In overweight men who snore loudly and need to nap frequently, testing for sleep apnea is indicated (page 419).

Acute or chronic infection is an important cause of fatigue. Everyone, of course, has at some time or other sensed the abrupt onset of exhaustion, a tired ache in the muscles, or an inexplicable listlessness, only to discover later that he was “coming down with the flu.” Chronic infections such as hepatitis, tuberculosis, brucellosis, infectious mononucleositis [Epstein-Barr virus (EBV) infection], subacute bacterial endocarditis, and Lyme disease may not be evident immediately but should always be suspected when fatigue is a new symptom and disproportionate to other symptoms such as mood change, nervousness, and anxiety. More often, the fatigue begins with an obvious infection (such as influenza, hepatitis, or infectious mononucleosis) but persists for several weeks after the overt manifestations of infection have subsided; it may then be difficult to decide whether the fatigue represents the lingering effects of the infection or the infection has been complicated by postviral fatigue syndrome.

Fatigue is often a major complaint of patients with viral hepatitis. The majority of patients are women between 20 and 35 years of age. Postviral fatigue occurs in a minority of patients and usually begins with an obvious infection (such as influenza, hepatitis, or infectious mononucleosis) but persists for several weeks after the overt manifestations of infection have subsided; it may then be difficult to decide whether the fatigue represents the lingering effects of the infection or the infection has been complicated by postviral fatigue syndrome.

Postviral and Chronic Fatigue Syndromes A particularly difficult problem is that of the patient who complains of severe fatigue for many months or even years after a bout of infectious mononucleosis or some other viral illness. This has been called the postviral fatigue syndrome. The majority of patients are women between 20...
and 40 years old. A few such patients were found to have unusually high titers of antibody to EBV, which suggested a causal relationship and gave rise to terms such as the chronic infectious mononucleosis or chronic EBV syndrome (Strauss). However, subsequent studies made it clear that a vast majority of patients with complaints of chronic fatigue have neither a clear-cut history of infectious mononucleosis nor serologic evidence of such an infection (Strauss; Holmes et al). In some of these patients the fatigue state has allegedly been associated with obscure immunologic abnormalities such as those attributed (spuriously) to silicone breast implants or meningitis. The currently fashionable designation for these and other abstruse states of persistent fatigue is the chronic fatigue syndrome, although a malady of this nature, under many different names, has long pervaded postindustrial Western society (Shorter). Its attribution to viral infection and ill-defined immune dysfunction are only the latest in a long line of putative explanations. At various times, colitis and other forms of bowel dysfunction, spiral irritation, hypoglycemia, brucellosis, and chronic mononucleosis, among others, have been proposed as causes.

The proposed criteria for the diagnosis of the chronic fatigue syndrome are the presence of persistent and disabling fatigue for at least 6 months, coupled with an arbitrary number (6 or 8) of persistent or recurrent somatic and neuropsychologic symptoms—including low-grade fever, cervical or axial lymphadenopathy, myalgias, malaise, dolichocephaly, arthralgias, scrotal discomfort, head and facial headaches, exacerbations in concentration and thinking, irritability, and sleep disturbances (Holmes et al). A number of such patients, in our experience, have also complained of paresthesias in the feet and hands, and an association is well recognized with a painful fibromyalgia state, consisting of neck, shoulder, and paraspinal pain and point tenderness (pages 231 and 1572). Despite these complaints, the patient may look surprisingly rested and robust and the neurologic examination is normal. Complaints of muscle weakness are frequent among such patients, but Lloyd and coworkers, who thoroughly performed a battery of motor performance tests, found no difference in maximal isometric strength or endurance in repetitive submaximal exercise and no change in intramuscular acidosis or serum CK levels, or depletion of energy substrates. These individuals share with depressed patients a subnormal response to cortical magnetic motor stimulation exercise (Samii et al), which can be said to match their symptoms of reduced endurance but otherwise is difficult to interpret. In a small number of persons, a chronic mild hypotension, elicited mainly with tilt-table testing, has been proposed as a cause of chronic fatigue (Rowe et al). Electrocardiography and nerve conduction studies are invariably normal, as is the spinal fluid, but the electroencephalogram (EEG) may be mildly and nonspecifically slowed. Batteries of psychologic tests have disclosed variable impairments of cognitive function, misinterpreted by advocates of the “organic” nature of the syndrome as proof of some type of encephalopathy.

In a large group of patients who were studied 6 months after viral infections, Cope and colleagues found that none of the features of the original illness was predictive of the development of chronic fatigue; however, a previous history of fatigue or psychologic morbidity and an indefinite illness often were associated with persistent disability. One thing is clear to the authors: that applying the label of “chronic fatigue syndrome in susceptible individuals almost always perpetuates this state.”

At the present time, the nature of the chronic fatigue syndrome is undecided. The possibility of some obscure metabolic or immunologic derangement secondary to a viral infection cannot be dismissed (Swartz), but it seems unlikely to us in the majority of cases that lack such a history. In one study of more than 1000 patients who were studied following an acute viral illness, the chronic fatigue syndrome was no more frequent than in the general population (Wessely et al). It is our impression that most such patients are depressed; they are best treated with exercises and antidepressant medication, although this regimen is not always successful. There are anecdotal reports of success in treating these patients with minocycline (predicated on the above-mentioned orthostatic intolerance), electroencephalographic feedback, and a variety of other medical and nonmedical treatments. Only a very few exhibit the special psychologic disorder related to litigation (compensation neurosis). Noteworthy is the frequency with which the syndrome has become the basis of court action against employers, as in the “sick-building syndrome” or claims against the government.

**Differential Diagnosis of Fatigue**

If one looks critically at patients who seek medical help because of incapacitating exhaustion, lassitude, and fatigability (sometimes incorrectly called “weakness”), it is evident that the most commonly overlooked diagnoses are anxiety and depression. The correct conclusion can usually be reached by keeping these illnesses in mind as one elicits the history from patient and family. Difficulty arises when symptoms of the psychiatric illness are so inconspicuous as not to be appreciated; one comes then to suspect the diagnosis only by having eliminated the common medical causes. Repeated observation may bear out the existence of an anxiety state or gloomy mood, as the patient resists rehabilitation. Strong reassurance in combination with a therapeutic trial of antianxiety or antidepressant drugs may suppress symptoms of the psychiatric illness, but it is the relapse in the presence of some type of stress that makes the diagnosis. Repeated observation may bear out the existence of an anxiety state or gloomy mood, as the patient resists rehabilitation.

Tuberculosis, brucellosis, Lyme disease, hepatitis, subacute bacterial endocarditis, mycoplasmal pneumonia, EBV, CMV, cosackie B and other viral infections, and malaria, hookworm, giardiasis, and other parasitic infections need to be included in the differential diagnosis and a search made for their characteristic symptoms, signs, and, when appropriate, laboratory findings. There should also be a search for anemia, azotemia, chronic inflammatory disease such as temporal arteritis–polyarteritis rheumatica (sedimentation rate), and occult tumor; an endocrine survey (thyroid, calcium, and cortisol levels) and an evaluation for sleep apnea are also in order in obscure cases. It must be remembered that chronic intoxication with alcohol, barbiturates, or other sedative drugs, some of which are given to suppress nervousness or insomnia, may contribute to fatigability. The rapid and recent onset of fatigue should always suggest the presence of an infection, a disturbance in fluid balance, gastrointestinal bleeding, or rapidly developing circulatory failure of either peripheral or cardiac origin. The features that suggest sleep apnea have been mentioned above and are discussed further on page 419.

Finally, it bears repeating that lassitude and fatigue must always be distinguished from genuine weakness of muscle. The demonstration of reduced muscular power, reflex changes, fasciculations, and atrophy sets the case analysis along different lines; bringing up for further consideration diseases of the peripheral nervous system and muscle. This must also be done in the face of fatigue that yields to rest less easily than expected (true asthenia). Rare, difficult-to-diagnose diseases that cause inexcusable muscle weakness and exercise intolerance are masked hypertrophicism, hyperparathyroidism, ossifying hemangiomata with hypophosphatemia, some of the kaleidoscopic periarterial syndromes, hyperinsulinism, disorders of carbohydrate and lipid metabolism, the mitochondrial myopathies, and possibly adenylate deaminase deficiency.

**NEUROUSNESS, ANXIETY, STRESS, AND IRRITABILITY**

The world is full of nervous, tense, apprehensive, and worried people. The stresses of contemporary society are often blamed for their plight. The poet W. H. Auden referred to our time as “the age of anxiety.” But history informs us that our own age is not unique in this respect. Medical historians have identified comparable periods of pervasive anxiety dating back to the time of Marcus Aurelius and Constantine, when societies were undergoing rapid and profound changes and individuals were assailed by an overwhelming sense of insecurity, personal insignificance, and fear of the future (Rosen).

Like lassitude and fatigue, nervousness, irritability, and anxiety are among the most frequent symptoms encountered in office and hospital practice. We use the term anxiety to denote an intermittent or sustained emotional state characterized by subjective feelings of nervousness, irritability, uneasy anticipation, and

In the panic attack, or panics, as they are called, the patient is suddenly overwhelmed by feelings of apprehension, or a fear that he may lose control, die, or have a heart attack, become insane, or commit some terrible crime. These experiences are accompanied by a series of physiologic reactions, mainly sympathoadrenal hyperactivity, resembling the “fight-or-flight” reaction. Breathlessness, a feeling of

Suffocation, dizziness, sweating, trembling, palpitation, and precordial or gastric distress are common but not invariable physical accompaniments. As a persistent and

severe state, the patient experiences fluctuating degrees of nervousness, apprehension, palpitation or excessive cardiac impulse, shortness of breath,

light-headedness, faintness, easy fatigue, and intolerance of physical exertion. Attacks tend to occur during periods of relative calm and in nonthreatening circumstances. Usually, the apprehension and physical symptoms escalate over a period of time to an hour and then abate over 20 to 30 min, leaving the patient tired and asthenic. The dramatic effects of the panic attack have usually abated by the time the patient reaches a doctor’s office or an emergency department, but the blood pressure may still be elevated and there may be tachycardia. Otherwise the patient looks remarkably collected. Often, discrete anxiety attacks and persistent states of anxiety merge with one another. The fear of further attacks leads many patients, particularly women, to become agoraphobic and homebound, fearing public places, especially if alone.

Because panic is a common disorder, affecting 1 to 2 percent of the population at some time in their lives, and the symptoms mimic neurologic disease, the

anxiety neurosis. The term neurocirculatory asthenia (among many others) has been applied to the chronic form with prominent exercise intolerance (see Chap. 56). The symptoms of anxiety may vary, however, be part of several other psychiatric disorders. Anxiety may be combined with other somatic symptoms in hysteria and is the most prominent feature of photic neurosis. Symptoms of persistent anxiety with insomnia, lassitude, and fatigue should always raise the suspicion of a depressive illness, especially when they begin in middle adult life or beyond. Also, panic attacks may sometimes herald the onset of a schizophrenic illness. As with fatigue, the symptoms of both anxiety and depression are prominent features of the syndrome of posttraumatic nervous instability, also called posttraumatic stress syndrome (see page 945). Also, when visceral symptoms predominate or the psychic counterparts of fear and apprehension are absent, the presence of thyrotoxicosis, Cushing disease, pheochromocytoma, hypoglycemia, and menopausal symptoms should be suspected.

Cause, Mechanism, and Biologic Significance of Nervousness and Anxiety

These have been the subjects of much speculation, and completely satisfactory explanations are not available. As noted above, some individuals go through life in a chronic state of low-grade anxiety, the impetus for which may or may not be apparent. They are by nature, or constitutionally, nervous and subject to this character trait. Spontaneous episodes of anxiety demand another explanation. Some psychologists regard anxiety as anticipatory behavior, i.e., a state of uneasiness about something that may happen in the future. William McDougall spoke of it as “an emotional state arising when a continuing strong desire seems likely to miss its goal.” The primary emotion, somewhat muted perhaps, may be one of fear, and its arousal under conditions that are not overtly threatening may be explained as a conditioned response to some recondite component of a formerly threatening stimulus.

In psychoanalytic theory, anxiety is regarded as the individual’s response to some undefined threat from within, i.e., it lies in the “subconscious.” A primitive drive has been aroused that is not compatible with current social practices and can be satisfied only at the risk of harming the person.

Physicians have searched for evidence of visceral impairment, without success. The patient with anxiety neurosis is often in poor physical condition and has an increased blood lactate concentration in both the resting state and after exercise; infusions of lactacid are said to make the symptoms of anxiety worse and, in susceptible individuals, to elicit a panic attack. The patient seems not to tolerate the work or exercise needed to build up his stamina. The urinary excretion of epinephrine has been found elevated in some patients; in others, there is an increased urinary excretion of norepinephrine and its metabolites. During periods of intense anxiety, aldosterone excretion is increased to two or three times normal.

There is also suggestive evidence that corticosteroids and corticotropic releasing hormone (CRH) have a role in the genesis of anxiety. A systemic release of corticosteroid accompanies all states of stress, and the administration of corticosteroids may give rise to anxiety and panic in some patients and to depression in others—suggesting a linkage between steroid stimulation of the brain and the limbic system activities that generate these states. In animal models, stress elicited by pain, cold, or by withdrawal of alcohol and other drugs precipitates activity in CRH pathways (amygdala to hypothalamus, raphe nuclei, nucleus ceruleus, and other regions of the brainstem); blocking such activity by drugs or by destruction of the amygdala eliminates anxiety and fear-like behavior. Admittedly the concepts of fear, stress, and anxiety are used interchangeably in these models, but repeated stimuli that produce fear and stress eventually induce a state akin to anxiety, and the amygdala appears to be involved in the perpetuation of this anxiety state. The meaning of these effects, i.e., whether they are primary or secondary, is not certain, but it is evident that prolonged and diffuse anxiety is associated with certain biochemical abnormalities of the brain and probably of the brain.

In the role of the amygdala, animal studies have related acute anxiety to a disturbance of function of the locus ceruleus and the septal and hippocampal areas—the principal norepinephrine-containing nuclei. It is noteworthy that the locus ceruleus is involved in rapid-eye-movement (REM) sleep and that drugs such as the biclyclic antidepressants and monoamine oxidase inhibitors, which suppress REM sleep, also decrease anxiety. Certain of the serotonin receptors in the brain, different from those implicated in depression, have been related to anxiety. Other parts of the brain must also be involved: bifrontal orbital leukotomy also diminishes anxiety, possibly by interrupting the medial forebrain connections with the limbic parts of the brain. Positron emission tomography (PET) studies in subjects who anticipate an electric shock show enhanced activity in the temporal lobes and insula, implicating these regions in the experience of acute anxiety (see also page 547).

Several alterations in neurotransmitter function have been implicated in the anxious state. The finding that a small proportion of the inherited personality trait of anxiety can be accounted for by one polymorphism of the serotonin transporter gene is provocative (Lesch et al) but requires further study.

Anxiety, being so ubiquitous, is probably not without biologic significance. It strengthens social bonds at certain moments in life, among men in combat, for example, or less commonly, in the life-long period of separation (separation anxiety). Anxiety may lead to a decrease in associative marriage and to increased suicide rates. Also, intense intellectual activity can be facilitated by controlled amounts of anxiety. Barratt and White found that mildly anxious medical students performed better on examinations than those lacking anxiety. As anxiety increases, so does the standard of performance, but only to a point, after which increasing anxiety causes a
**Stress and Stress Syndromes**

The psychologic phenomenon of stress is closely allied to nervousness and anxiety, and all of them are pervasive features of modern life. In general terms, stress has been defined as a feeling of self-doubt about being able to cope with some situation over a period of time. The term stress syndrome refers to perturbations of behavior and accompanying physiologic changes that are ascribable to environmental challenges of such intensity and duration as to overwhelm the individual's adaptive capacity. The biologic effects of this phenomenon can be recognized in many species—chickens laying fewer eggs when moved to new coops and cows giving less milk when put in a new barn, or monkeys going berserk when repeatedly threatened by threats that they cannot control. Human beings forced to work under confined conditions and constant danger and cultural groups removed from their home and traditional way of life lose their coping skills and suffer anxiety. Presumably they have increased an output of "stress hormones" (cortisol and adrenalin). Such psychologic disorders, bearing a direct relationship to environmental stressors, are among the most common occupational health problems. One such stress syndrome, in which an individual develops delayed or recurrent symptoms of anxiety after exposure to extreme psychologic or traumatic stressors, has been given its own name—post-traumatic stress disorder. Stress syndromes are distinguished from anxiety neurosis, in which the psychologic disturbance arises from within the individual and has no definite relationship to environmental stimuli. Whether certain individuals are by nature hyperresponsive to such stimuli is not known. The only therapeutic approach is to attempt to alter the patient's perception of stress—for example, with psychotherapy and meditation exercises—and to remove him, if possible, from recognizable environmental stressors. (See *Editorial* in References.)

**Irritability, Irritable Mood, and Aggressive Behavior**

The phenomenon of irritability, or an irritable mood, must be familiar to almost everyone, exposed as we are to all of the noise, niggling inconveniences, and annoyances of daily life. It is, nevertheless, a difficult symptom to interpret in the context of psychopathology. Freud used the term Reaktionskrankheit in a restricted sense—to denote an undue sensitivity to noise—and considered it a manifestation of anxiety, but obviously this symptom has a much broader connotation and significance. For one thing, some people are by nature irritable throughout life. Also, irritability is an almost expected reaction in overworked, overworried individuals, who become irritable by force of circumstances. An irritable mood or feeling may be present without observed manifestations (inward irritability), or there may be an overt loss of control of temper, with irascible verbal and behavioral outbursts, provoked by trivial but frustrating events.

Irritability in the foregoing circumstances can hardly be considered a departure from normal. However, when it becomes a recurrent event in a person of normally placid temperament, it assumes significance, for it may then signify an ongoing anxiety state or depression. Irritability is also a common symptom of obsessional neurosis. Here the irritability tends to be directed inward, indicating perhaps a sense of frustration with personal disability (*Snait and Taylor*). Depressed patients are frequently irritable; as a corollary, this symptom should always be sought in patients suspected of being depressed, since it is so readily recognized by both patients and their families. The days preceding menses and the mother's common postmenstrual mood disorder are characterized by high levels of outwardly directed irritability. Short-temperedness and irritability are also common features of the manic state. The most extreme degrees of irritability, exemplified by repeated quarrelsome and aggressive behavior (irritable aggression), are rarely observed in anxiety neurosis and endogenous depression but are usually the mark of sociopathy and brain damage. Such irritable aggressive behavior is also observed in some patients with Alzheimer disease and other types of dementia and following traumatic contusions of the temporal and frontal lobes.

**DEPRESSIVE REACTIONS**

There are few persons who do not experience periods of discouragement and despair. As with nervousness, irritability, and anxiety, depression of mood that is appropriate to a given situation in life (e.g., grief reaction) is seldom the basis of medical concern. Persons in these situations tend to seek help only when their grief or unhappiness is persistent and beyond control. However, there are numerous instances in which the symptoms of depression assert themselves for reasons that are not apparent. Often the symptoms are interpreted as a medical illness, bringing the patient first to the internist or neurologist. Sometimes another disease is found (such as chronic hepatitis or other infection or postinfectious asthenia) in which chronic fatigue is confused with depression: more often the opposite pertains, i.e., an endogenous depression is the essential problem even when there has been evidence earlier of a viral or bacterial infection. Since the risk of suicide is not inconsiderable in the depressed patient, an error in diagnosis may be life-threatening.

From the patient and the family it is learned that the patient has been "feeling unwell," "low in spirits," "blue," "glum," "unhappy," or "morbid." There has been a change in his emotional reactions of which the patient may not be fully aware. Activities that he formerly found pleasurable are no longer so. Often, however, change in mood is less conspicuous than reduction in psychic and physical energy, and it is this type of case that is so often misdiagnosed by internists and neurologists. A complaint of fatigue is almost invariable; not uncommonly, it is worse in the morning after a night of restless sleep. The patient complains of a "loss of pep," "weakness," "tiredness," "having no energy," and/or that his job has become more difficult. His outlook is pessimistic. The patient is irritable and preoccupied with uncontrollable worry over trivialities. With excessive worry, the ability to think with accustomed efficiency is reduced; the patient complains that his mind is not functioning properly and he is forgetful and unable to concentrate. If the patient is naturally of suspicious nature, paranoid tendencies may assert themselves.

Particularly troublesome is the patient's tendency to hypochondriasis. Indeed, most cases formerly diagnosed as hypochondriasis are now regarded as depression. Pain from whatever cause—a stiff joint, a toothache, feeling chest or abdominal pains, muscle cramps, or other disturbances such as constipation, frequency of urination, menstruation (premenstrual tension), or uterine irritability, has been given its own name—PMS (premenstrual syndrome). The pain may be due to many things, for instance, pressure on the temporal and frontal lobes.

When the patient is examined, his facial expression is often plaintive, troubled, pained, or anguished. The patient's attitude and manner betray a prevailing mood of depression, hopelessness, and despondency. Sighing is a frequent sign. In other words, the affect, which is the outward expression of feeling, is consistent with the depressed mood. During the interview the patient may sigh frequently or be tearful and may cry openly. In some, there is a kind of immobility of the face that mimics parkinsonism, though others are restless and agitated (pacing, wringing their hands, etc.). Occasionally the patient will smile, but the smile impresses one as more a social gesture than a genuine expression of feeling.

The stream of speech is slow. There may be long pauses between questions and answers. The latter are brief and may be monosyllabic. There is a paucity of ideas. The retardation extends to all topics of conversation and affects movement of the limbs as well (anergic depression). The most extreme forms of decreased motor activity, rarely seen in the office or clinic, border on muteness and stupor. Conversation is replete with pessimistic thoughts, fears, and expressions of unworthiness, inadequacy, inferiority, hopelessness, and sometimes guilt. In severe depressions, bizarre ideas and bodily delusions ("blood drying up," "bowels are blocked with cement," "I am half dead") may be expressed.

Three theories have emerged concerning the cause of the psychologic depressive state: (1) that the endogenous form is hereditary, (2) that a biochemical abnormality results in a periodic depletion in the brain of serotonin and norepinephrine, and (3) that a basic fault in character development exists. These theories are elaborated in Chap. 57. It is the authors' belief that depressive states are among the most commonly overlooked diagnoses in clinical medicine. Part of the trouble is with the word itself, which implies being unhappy about something. Endogenous depression should be suspected in all states of chronic ill health, hypochondriasis, disability that exceeds manifest signs of a medical disease, neurasthenia and ongoing fatigue, chronic pain syndromes—all of which may be termed "masked depressions." Inasmuch as recovery is the rule, suicide is a tragedy for which the medical profession must often share responsibility.

Depressive illnesses and theories of their causation and management are considered further in Chap. 57.
Chapter 25

THE LIMBIC LOBES AND THE NEUROLOGY OF EMOTION
