  Cerebellum and Basal Nuclei .................................... 204
  Optic, Auditory, and Vestibular Systems ....................... 220
  Limbic System .................................................. 232
Preface to the Sixth Edition

Previous editions of Neuroanatomy have endeavored 1) to provide a structural basis for understanding the function of the central nervous system; 2) to emphasize points of clinical relevance through use of appropriate terminology and examples; and 3) to integrate neuroanatomical and clinical information in a format that will meet the educational needs of the user. The goal of the sixth edition is to continue this philosophy and to present structural information and concepts in an even more clinically useful and relevant format. Information learned in the basic science setting should flow as seamlessly as possible into the clinical setting.

I have received many constructive suggestions and comments from my colleagues and students. This is especially the case for the modifications made in Chapters 2, 5, 7, 8, and 9 in this new edition. The names of the individuals who have provided suggestions or comments are given in the Acknowledgments. This thoughtful and helpful input is greatly appreciated and has influenced the preparation of this new edition.

The major changes made in the sixth edition of Neuroanatomy are as follows:

First, recognizing that brain anatomy is seen in clear and elegant detail in MRI and CT, and that this is the primary way the brain is viewed in the health care setting, additional new images have been incorporated into this new edition. Every effort has been made to correlate the MRI or CT with brain or spinal cord anatomy by relating these images on the same page or on facing pages. New MRI or CT have been introduced into chapter 2 (spinal cord, meningeal hemorrhages correlated with the meninges, cisterns, hemorrhage into the brain, hemorrhage into the ventricles correlated with the structure of the ventricles), chapter 5 (spinal cord and brainstem), and chapter 8 (vascular). Second, the structure of the central nervous system should be available to the student (or the medical professional for that matter) in a format that makes this information immediately accessible, and applicable, to the requirements of the clinical experience. It is commonplace to present brain structure in an anatomical orientation (e.g., the colliculi are “up” in the image and the interpeduncular fossa is “down”). However, when the midbrain is viewed in an axial MRI or CT, the reverse is true: the colliculi are “down” in the image and the interpeduncular fossa is “up”. There are many good reasons for making brainstem images available in an anatomical orientation and for teaching this view in the academic setting. These reasons are recognized in this book. On the other hand, the extensive use of MRI or CT in all areas of medicine, not just the clinical neurosciences, requires that students be clearly aware of how brain and spinal cord structure is viewed, and used, in the clinical environment. To address this important question, a series of illustrations, including MRI or CT, are introduced in the spinal cord and brainstem sections of chapter 5. These images are arranged to show 1) the small colorized version of the spinal cord or brainstem in an anatomical orientation; 2) the same image flipped bottom-to-top into a clinical orientation; and 3) the clinical orientation of the colorized line drawing followed by T1 and T2 MRI and/or CT at levels comparable to the line drawing and corresponding stained section. This approach retains the inherent strengths of the full-page, colorized line drawing and its companion stained section in the anatomical orientation. At the same time, it introduces, on the same set of pages, the important concept that CNS anatomy, both external and internal, is oriented differently in MRI or CT. It is the clinical orientation issue that will confront the student/clinician in the clinical setting. It is certainly appropriate to introduce, and even stress, this view of the brain and spinal cord in the basic science years.

Third, new images have been included in chapter 8. These include, but are not limited to, new examples of general vessel arrangement in MRA, examples of specific vessels in MRI, and some additional examples of hemorrhage.

Fourth, additional examples of cranial nerves traversing the subarachnoid space are included. In fact, the number of MRI showing cranial nerves has doubled. In addition, each new plate starts with a gross anatomical view of the nerve (or nerves) shown in the succeeding MRI in that figure.

Fifth, additional clinical information and correlations have been included. These are in the form of new images, new and/or modified figure descriptions, and changes in other portions of the textual elements.

Sixth, in some instances, existing figures have been relocated to improve their correlation with other images. In other instances, existing figures have been repeated and correlated with newly added MRI or CT so as to more clearly illustrate an anatomical-clinical correlation.

Seventh, a new chapter (chapter 9), consisting of approximately 240 study and review questions and answers in the USMLE style, has been added. All of these questions have explained answers keyed to specific pages in the Atlas. Although not designed to be an exhaustive set, this new chapter should give the user of this atlas a unique opportunity for self-assessment.

Two further issues figured prominently in the development of this new edition. First, the question of whether to use eponyms in their possessive form. To paraphrase one of my clinical colleagues “Parkinson did not die of his disease (Parkinson disease), he died of a stroke; it was never his own personal disease.” There are rare exceptions, such as Lou Gehrig’s disease, but the point is well taken. McKusick (1998a,b) has also made compelling arguments in support of using the non-possessive form of eponyms. It is, however, acknowledged that views differ on this question—much like debating how many angels can dance on the head of a pin. Consultation with my neurology and neurosurgery colleagues, a review of some of the more comprehensive neurology texts (e.g., Rowland, 2000; Victor and Ropper, 2001), and the standards established in The Council of Biology Editors Manual for Authors, Editors, and Publishers (1994) and the American Medical Association’s Manual of Style (1998) clearly indicate an overwhelming preference for the non-possessive form of eponyms. It is, however, acknowledged that views differ on this question—much like debating how many angels can dance on the head of a pin. Consultation with my neurology and neurosurgery colleagues, a review of some of the more comprehensive neurology texts (e.g., Rowland, 2000; Victor and Ropper, 2001), and the standards established in The Council of Biology Editors Manual for Authors, Editors, and Publishers (1994) and the American Medical Association’s Manual of Style (1998) clearly indicate an overwhelming preference for the non-possessive form of eponyms. It is, however, acknowledged that views differ on this question—much like debating how many angels can dance on the head of a pin. Consultation with my neurology and neurosurgery colleagues, a review of some of the more comprehensive neurology texts (e.g., Rowland, 2000; Victor and Ropper, 2001), and the standards established in The Council of Biology Editors Manual for Authors, Editors, and Publishers (1994) and the American Medical Association’s Manual of Style (1998) clearly indicate an overwhelming preference for the non-possessive form of eponyms. It is, however, acknowledged that views differ on this question—much like debating how many angels can dance on the head of a pin. Consultation with my neurology and neurosurgery colleagues, a review of some of the more comprehensive neurology texts (e.g., Rowland, 2000; Victor and Ropper, 2001), and the standards established in The Council of Biology Editors Manual for Authors, Editors, and Publishers (1994) and the American Medical Association’s Manual of Style (1998) clearly indicate an overwhelming preference for the non-possessive form of eponyms.
adopted by the International Federation of Associations of Anatomists, supersedes all previous terminology lists. Every effort has been made to incorporate any applicable new or modified terms into this book. The number of changes is modest and related primarily to directional terms: posterior for dorsal, anterior for ventral, etc. In most cases, the previous term appears in parentheses following the official term, i.e., posterior (dorsal) cochlear nucleus. It is almost certain that some changes have eluded detection; these will be caught in subsequent printings.

Last, but certainly not least, the sixth edition is a few pages longer than was the fifth edition. This results exclusively from the inclusion of more MRI and CT, a better integration of anatomical-clinical information, including more clinical examples (text and illustrations), and the inclusion of Study/Review and USMLE style questions with explained answers.

Preface to the First Edition

This atlas is a reflection of, and a response to, suggestions from professional and graduate students over the years I have taught human neurobiology. Admittedly, some personal philosophy, as regards teaching, has crept into all parts of the work.

The goal of this atlas is to provide a maximal amount of useful information, in the form of photographs and drawings, so that the initial learning experience will be pleasant, logical, and fruitful, and the review process effective and beneficial to longterm professional goals. To this end several guiding principles have been followed. First, the entire anatomy of the central nervous system (CNS), external and internal, has been covered in appropriate detail. Second, a conscientious effort has been made to generate photographs and drawings of the highest quality: illustrations that clearly relay information to the reader. Third, complementary information always appears on facing page. This may take the form of two views of related structures such as brainstem or successive brain slices or a list of abbreviations and description for a full-page figure. Fourth, illustrations of blood supply have been included and integrated into their appropriate chapters. When gross anatomy of the brain is shown, the patterns of blood vessels and relationships of sinuses appear on facing pages. The distribution pattern of blood vessels to internal CNS structures is correlated with internal morphology as seen in stained sections. Including information on external vascular patterns, both external and internal, and the summary pathway drawings may be useful to the individual requiring a succinct, yet comprehensive review before taking board exams in the neurological, neurosurgical, and psychiatric specialties.

The details in some portions of this atlas may exceed that found in comparable parts of other atlases. If one is to err, it seems more judicious to err on the side of greater detail than on the side of inadequate detail. If the student is confronted with more information on a particular point than is needed during the initial learning process, he or she can simply bypass the extra information. However, once the initial learning is completed, the additional information will be there to enhance the review process. If students have inadequate information in front of them it may be difficult, or even impossible, to fill in missing points that may not be part of their repertoire of knowledge. In addition, information may be inserted out of context, and, thereby, hinder the learning experience.

A work such as this is bound to be subject to oversights, and for such foibles, I am solely responsible. I welcome comments, suggestions, and corrections from my colleagues and from students.

Duane E. Haines
As was the case in previous editions of this book, my colleagues and students in both medical and graduate programs have been most gracious in offering their suggestions and comments. I greatly appreciate their time and interest in the continuing usefulness of this book.

As changes were being contemplated for this new edition, input on potential modifications was solicited from faculty as well as students in an effort to ascertain how these changes might impact on the usefulness of this Atlas. These individuals went out of their way to review the documents that were provided and to give insightful, and sometimes lengthy, comments on the pros and cons of the ideas being considered. This input was taken into consideration as the initial plans were modified and finalized by the author and then incorporated into this new edition. The faculty who gave generously of their time and energy were Drs. A. Agmon, C. Anderson, R. Baisden, S. Baldwin, J. L. Culberson, B. Hallas, J. B. Hutchins, T. Imig, G. R. Leichnetz, E. Levine, R. C. S. Lin, J. C. Lynch, T. McGraw-Ferguson, G. F. Martin, G. A. Mikhailoff, R. L. Norman, R. E. Papka, H. J. Ralston, J. Rho, L. T. Robertson, J. D. Schlag, K. L. Simpson, and C. Stefan. The students who offered helpful and insightful comments were A. Alqueza (medical student, University of Florida at Gainesville), A. S. Bristol (graduate student, University of California at Irvine), L. Simmons (medical student, Vanderbilt University), J. A. Tucker (medical student, The University of Mississippi Medical Center), S. Thomas (graduate student, University of Maryland at College Park), and M. Tomblyn (medical student, Rush Medical College). I greatly appreciate their comments and suggestions.

I would also like to thank my colleagues in the Department of Anatomy at The University of Mississippi Medical Center (UMMC) for their many helpful suggestions and comments. My colleagues in the Department of Neurosurgery at UMMC (Drs. A. Parent [Chairman], L. Harkey, J. Lancon, J. Ross, D. Esposito, and G. Mandybur) and in the Department of Neurology at UMMC (especially Drs. J. Corbett [Chairman], S. Subramony, H. Uschmann, and M. Santiago) have offered valuable input on a range of clinical issues. I am especially indebted to Dr. J. A. Lancon (Neurosurgery) for his significant contributions to this new edition. These include his willingness to participate as co-author of Chapter 9 and his careful review of all new clinical information added to the book. I would also like to thank Ms. Amanda Ellis, B.S.N., for keeping my friend John on track.

Dr. R. Brent Harrison (former Chairman of Radiology, UMMC), Dr. Robert D. Halpert (current Chairman of Radiology, UMMC) and Dr. Gurmett Dhilon (Neuroradiology) generously continue to give me full access to all their facilities. I would like to express a special thanks to Mr. W. (Eddie) Herrington (Chief CT/MRI Technologist) and Mr. Joe Barnes (Senior MRI Technologist) for their outstanding efforts to supply new images and their special efforts to generate images at specific planes for this new edition. In the same vein, Drs. G. Dhilon and S. Crawford also made special attempts to get specific MRI at special planes. I am also deeply appreciative to several technologists and nurses in the CT/MRI suite, and particularly to Master Johnathan Barnes, for being such cooperative “patients” as we worked to generate scans that matched stained sections in the Atlas as closely as possible.

Modifications, both great and small, to the artwork and labeling scheme, as well as some new renderings, were the work of Mr. Michael Schenk (Director of Biomedical Illustration Services). Mr. Bill Armstrong (Director of Biomedical Photography) produced outstanding photographs of gross specimens and slices, CTs, MRIs, and MRAs. I am very appreciative of the time, effort, and dedication of these individuals to create the very best artwork and photographs possible for this new edition. Ms. Katherine Squires did all the typing for the sixth edition. Her excellent cooperation, patience, and good-natured rapport with the author were key elements in completing the final draft in a timely manner.

This sixth edition would not have been possible without the interest and support of the publisher, Lippincott Williams & Wilkins. I want to express thanks to my editor, Ms. Betty Sun (Acquisitions Editor), to Mr. Dan Pepper (Associate Managing Editor), to Ms. Erica Lukanich (Editorial Assistant), Ms. Jennifer Weir (Associate Production Manager), and to Mr. Joe Scott (Marketing Manager) for their encouragement, continuing interest, and confidence in this project. Their cooperation has given me the opportunity to make the improvements seen herein.

Last, but certainly not least, I would like to express a special thanks to my wife, Gretchen. She put up with me while these revisions were in progress, carefully reviewed all changes in the text and all questions/answers, and was a tangible factor in getting everything done. I dedicate this edition to Gretchen.
Introduction
and
Reader’s Guide
At a time when increasing numbers of atlases and textbooks are becoming available to students and instructors, it is appropriate to briefly outline the approach used in this volume. Most books are the result of 1) the philosophic approach of the author/instructor to the subject matter and 2) students’ needs as expressed through their suggestions and opinions. The present atlas is no exception, and as a result, several factors have guided its further development. These include an appreciation of what enhances learning in the laboratory and classroom, the inherent value of correlating structure with function, the clinical value of understanding the blood supply to the central nervous system (CNS), and the essential importance of integrating anatomy with clinical information and examples. The goal is to make it obvious to the user that structure and function in the CNS side the skull, producing neurological deficits, is vascular-related. To emphasize the value of this information, the distribution pattern of blood vessels is correlated with external spinal cord and brain anatomy (Chapter 2) and with internal structures such as tracts and nuclei (Chapter 5), reviewed in each pathway drawing (Chapter 7), and shown in angiograms, MRAs, and MRVs (Chapter 8). This approach has several advantages: 1) the vascular pattern is immediately related to the structures just learned, 2) vascular patterns are shown in the sections of the atlas in which they belong, 3) the reader cannot proceed from one part of the atlas to the next without being reminded of blood supply, and 4) the conceptual importance of the distribution pattern of blood vessels in the CNS is repeatedly reinforced.

The ability to diagnose a neurologically compromised patient is specifically related to a thorough understanding of pathway structure, function, blood supply, and the relationships of this pathway to adjacent structures. To this end Chapter 7 provides a series of semidiagrammatic illustrations of various clinically relevant pathways. Each figure shows 1) the trajectory of fibers that comprise the entire pathway; 2) the laterality of fibers comprising the pathway, this being an extremely important concept in diagnosis; 3) the positions and somatotopy of fibers comprising each pathway at representative levels; 4) a review of the blood supply to the entire pathway; 5) important neurotransmitters associated with fibers of the pathway; and 6) examples of deficits seen following lesions of the pathway at various levels throughout the neuraxis. This chapter is designed to be used by itself or integrated with other sections of the atlas; it is designed to provide the reader with the structural and clinical essentials of a given pathway in a single illustration.

The present atlas addresses these points. The goal is not only to show external and internal structure per se but also to demonstrate that the relationship between brain anatomy and MRI/CT, the blood supply to specific areas of the CNS and the arrangement of pathways located therein, the neuroactive substances associated with pathways, and examples of clinical deficits are inseparable components of the learning experience. An effort has been made to provide a format that is dynamic and flexible—one that makes the learning experience an interesting and rewarding exercise.

The relationship between blood vessels and specific brain regions (external and/or internal) is extremely important considering that approximately 50% of what goes wrong inside the skull, producing neurological deficits, is vascular-related. To emphasize the value of this information, the distribution pattern of blood vessels is correlated with external spinal cord and brain anatomy (Chapter 2) and with internal structures such as tracts and nuclei (Chapter 5), reviewed in each pathway drawing (Chapter 7), and shown in angiograms, MRAs, and MRVs (Chapter 8). This approach has several advantages: 1) the vascular pattern is immediately related to the structures just learned, 2) vascular patterns are shown in the sections of the atlas in which they belong, 3) the reader cannot proceed from one part of the atlas to the next without being reminded of blood supply, and 4) the conceptual importance of the distribution pattern of blood vessels in the CNS is repeatedly reinforced.

The ability to diagnose a neurologically compromised patient is specifically related to a thorough understanding of pathway structure, function, blood supply, and the relationships of this pathway to adjacent structures. To this end Chapter 7 provides a series of semidiagrammatic illustrations of various clinically relevant pathways. Each figure shows 1) the trajectory of fibers that comprise the entire pathway; 2) the laterality of fibers comprising the pathway, this being an extremely important concept in diagnosis; 3) the positions and somatotopy of fibers comprising each pathway at representative levels; 4) a review of the blood supply to the entire pathway; 5) important neurotransmitters associated with fibers of the pathway; and 6) examples of deficits seen following lesions of the pathway at various levels throughout the neuraxis. This chapter is designed to be used by itself or integrated with other sections of the atlas; it is designed to provide the reader with the structural and clinical essentials of a given pathway in a single illustration.
The advent and common use of imaging methods (MRI, MRA, and MRV) mandates that such images become an integral part of the educational process when teaching and/or learning clinically applicable neuroscience. To this end, this book contains about 175 MRI and CT images and 12 MRA and MRV. All of these images are directly correlated with external brain anatomy such as gyri and sulci, internal structures including pathways and nuclei, cranial nerves and adjacent structures, or they demonstrate examples of hemorrhages related to the meninges and ventricles or the parenchyma of the brain.

**Imaging the Brain (CT and MRI):** Imaging the brain *in vivo* is now commonplace for the patient with neurological deficits that may indicate a compromise of the central nervous system. Even most rural hospitals have, or have easy access to, CT or MRI. With these facts in mind, it is appropriate to make a few general comments on these imaging techniques and what is routinely seen, or best seen, in each. For details of the methods and techniques of CT and MRI consult sources such as Grossman (1996), Lee et al. (1999), or Buxton (2002).

**Computed Tomography (CT):** In CT, the patient is passed between a source of x-rays and a series of detectors. Tissue density is measured by the effects of x-rays on atoms within the tissue as these x-rays pass through the tissue. Atoms of higher number have a greater ability to attenuate (stop) x-rays while those with lower numbers are less able to attenuate x-rays. The various attenuation intensities are computerized into numbers (Hounsfield units or CT numbers). Bone is given the value of +1,000 and is white, while air is given a value of −1,000 and is black. Extravascular blood, an enhanced tumor, fat, the brain (grey and white matter), and cerebrospinal fluid form an intervening continuum from white to black. A CT image of a patient with subarachnoid hemorrhage illustrates the various shades seen in a CT (Fig. 1-1). In general, the following table summarizes the white to black intensities seen for selected tissues in CT.

<table>
<thead>
<tr>
<th>STRUCTURE/FLUID/SPACE</th>
<th>GREY SCALE</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bone, acute blood</td>
<td>Very white</td>
</tr>

<td>Medium grey to black</td>
</tr>
<tr>
<td>Air, Fat</td>
<td>Very black</td>
</tr>
</tbody>
</table>

The advantages of CT are 1) it is rapidly done, which is especially important in trauma; 2) it clearly shows acute and subacute hemorrhages into the meningeal spaces and brain; 3) it shows bone (and skull fractures) to advantage; and 4) it is less expensive than MRI. The disadvantages of CT are 1) it does not clearly show acute or subacute infarcts or ischemia, or brain edema; 2) it does not clearly differentiate white from grey matter within the brain nearly as well as MRI; and 3) it exposes the patient to ionizing radiation.

**Magnetic Resonance Imaging (MRI):** The tissues of the body contain proportionately large amounts of protons (hydrogen). Protons have a positive nucleus, a shell of negative electrons, and a north and south pole; they function like tiny spinning bar magnets. Normally, these atoms are arranged randomly in relation to each other due to the constantly changing magnetic field produced by the electrons. MRI uses this characteristic of protons to generate images of the brain and body.

When radio waves are sent in short bursts into the magnet containing the patient, they are called a radiofrequency pulse (RP). This pulse may vary in strength. When the frequency of the RP matches the frequency of the spinning proton, the proton will absorb energy from the radio wave (resonance). The effect is two-fold. First, the magnetic effects of some protons are cancelled out and second, the magnetic effects and energy levels in others are increased. When the RP is turned off, the relaxed protons release energy (an “echo”) that is received by a coil and computed into an image of that part of the body.

The two major types of MRI images (MRI/T1 and MRI/T2) are related to the effect of RP on protons and the reactions of these protons (relaxation) when the RP is turned off. In general, those cancelled out protons return slowly to their original magnetic strength. The image constructed from this time constant is called T1 (Fig. 1-2). On the other hand, those protons that achieved a higher energy level (were not cancelled-out) lose their energy more rapidly as they return to their original state; the image constructed from this time constant is T2 (Fig. 1-3). The creation of a T1-weighted image versus a T2-weighted image is based on a variation in the times used to receive the “echo” from the relaxed protons.
The following table summarizes the white to black intensities seen in MRI images that are T1-weighted versus T2-weighted. It should be emphasized that a number of variations on these two general MRI themes are routinely seen in the clinical environment.

The advantages of MRI are 1) it can be manipulated to visualize a wide variety of abnormalities or abnormal states within the brain; and 2) it can show great detail of the brain in normal and abnormal states. The disadvantages of MRI are 1) it does not show acute or subacute subarachnoid hemorrhage or hemorrhage into the substance of the brain in any detail; 2) it takes a much longer time to do and, therefore, is not useful in acute situations or in some types of trauma; 3) it is, comparatively, much more expensive than CT, and 4) the scan is extremely loud and may require sedation in children.

The ensuing discussion briefly outlines the salient features of individual chapters. In some sections, considerable flexibility has been designed into the format; at these points, some suggestions are made as to how the atlas can be used. In addition, new clinical correlations and examples have been included and a new chapter of USMLE-style review questions has been added.

### Chapter 2

This chapter presents 1) the gross anatomy of the spinal cord and its principal arteries; 2) the external morphology of the brain, accompanied by MRIs and drawings of the vasculature patterns from the same perspective; 3) cranial nerves as seen in specimens and in MRI; and 4) the meninges and ventricular spaces. Emphasis is placed on correlating external brain and spinal cord anatomy with the respective vasculature patterns and on correlating external brain structures and cranial nerves as seen in specimens with how the same structures appear in MRI. Information concerning the organization of the meninges includes clinical correlations, examples of extradural, so-called "subdural", and subarachnoid hemorrhages in CT and examples of cisterns in MRI. The section showing the structure and relations of the ventricular system now includes samples of hemorrhage into lateral, third, and fourth ventricles.

### Chapter 3

The dissections in Chapter 3 offer views of some of those brain structures introduced in Chapter 2. Certain structures and/or structural relationships—for example, the orientation of the larger association bundles—are particularly suited to such a presentation. This chapter uses a representative series of dissected views to provide a broader basis for learning human neuroanatomy. Because it is not feasible to illustrate every anatomic feature, the views and structures selected are those that are usually emphasized in medical neurobiology courses. These views provide basic information necessary to make more detailed dissections, if appropriate, in a particular learning situation.
Chapter 4

The study of general morphology of the hemisphere and brainstem is continued in the two sections of Chapter 4. The first section contains a representative series of unstained coronal slices of brain, each of which is accompanied, on the same page, by MRIs. The brain slice is labeled (by complete names), and the MRIs are labeled with a corresponding abbreviation. The second section contains a series of unstained brain slices cut in the axial plane, each of which is accompanied, again on the same page, by MRIs. Labeling of the axial slices is as done for the coronal slices.

The similarities between the brain slices and the MRIs are remarkable, and this style of presentation closely integrates anatomy in the slice with that as seen in the corresponding MRI. Because the brain, as sectioned at autopsy or in clinical pathologic conferences, is viewed as an unstained specimen, the preference here is to present the material in a format that will most closely parallel what is seen in these clinical situations.

Chapter 5

This chapter has been revised with special emphasis on increasing the correlation between anatomical and clinical information. This new edition retains the quality and inherent strengths of the line drawings and the stained sections being located on facing pages in this chapter. However, an innovative approach (described below) is introduced that allows the use of these images in their classic Anatomical Orientation and, at the same time, their conversion to the Clinical Orientation so universally recognized and used in clinical imaging techniques.

Chapter 5 consists of six sections covering, in sequence, the spinal cord, medulla oblongata, cerebellar nuclei, pons, midbrain, and diencephalon and basal nuclei, all with MRI. In this format, the right-hand page contains a complete image of the stained section. The left-hand page contains a labeled line drawing of the stained section, accompanied by a figure description, and a small orientation drawing. The section part of the line drawing is printed in a 60% screen of black, and the leader lines and labels are printed at 100% black. This gives the illustration a sense of depth and texture, reduces competition between lines, and makes the illustration easy to read at a glance.

Beginning with the first spinal cord level (coccygeal, Figure 5-1), the long tracts that are most essential to understanding how to diagnose the neurologically impaired patient are colored. These tracts are the posterior column—medial lemniscus system, the lateral corticospinal tract, and the anterolateral system. In the brainstem, these tracts are joined by the colorized spinal trigeminal tract, the ventral trigeminothalamic tract, and all of the motor and sensory nuclei of cranial nerves. This scheme continues rostrally into the caudal nuclei of the dorsal thalamus and the posterior limb of the internal capsule. In addition to the coloring of the artwork, each page has a key that specifies the structure and function of each colored structure. This approach emphasizes anatomical—clinical integration.

Semidiagrammatic representations of the internal blood supply to the spinal cord, medulla, pons, midbrain, and forebrain follow each set of line drawings and stained sections. This allows the immediate, and convenient, correlation of structure with its blood supply as one is studying the internal anatomy of the neuraxis. In addition, tables that summarize the vascular syndromes of the spinal cord, medulla, pons, midbrain, and forebrain are located on the pages facing each of these vascular drawings. While learning or reviewing the internal blood supply to these parts of the neuraxis, one can also correlate the deficits seen when the same vessels are occluded. It is essential to successful diagnosis to develop a good understanding of what structure is served by what vessel.

The diencephalon and basal nuclei section of this chapter uses ten cross-sections to illustrate internal anatomy. It should be emphasized that 8 of these 10 sections (those parallel to each other) are all from the same brain.

The internal anatomy of the brainstem is commonly taught in an anatomical orientation. That is, posterior structures, such as the vestibular nuclei and colliculi, are “up” in the image, while anterior structures, such as the pyramid and crus cerebri, are “down” in the image. However, when the brainstem is viewed in the clinical setting, as in CT or MRI, this orientation is reversed. In the clinical orientation, posterior structures (4th ventricle, colliculi) are “down” in the image while anterior structures (pyramid, basilar pons, crus cerebri) are “up” in the image.

Recognizing that many users of this book are pursuing a health care career (as a practitioner or teacher of future clinicians), it is essential to introduce MRI and CT of the brainstem into chapter 5. This accomplishes two important points. First, it allows correlation of the size, shape, and configuration of brainstem sections (line drawings and stained slices) with MRI and CT at comparable levels. Second, it offers the user the opportunity to visualize how nuclei, tracts (and their somatotopy) and vascular territories are represented in MRI and CT. Understanding the brain in the Clinical Orientation (as seen in MRI or CT) is extremely important in diagnosis. To successfully introduce MRI and CT in the brainstem portion of chapter 5, a continuum from Anatomical Orientation to Clinical Orientation to MRI needs to be clearly illustrated. This is achieved by 1) placing a small version of the colorized line drawing on the facing page (page with the stained section) in Anatomical Orientation; 2) showing how this image is flipped top to bottom into a Clinical Orientation; and 3) following this flipped image with (usually) T1 and T2 MRIs at levels comparable to the accompanying line drawing and...
stained section (Fig. 1-4). This approach retains the anatomical strengths of the spinal cord and brainstem sections of chapter 5 but allows the introduction of important concepts regarding how anatomical information is arranged in images utilized in the clinical environment.

Every effort has been made to use MRI and CT that match, as closely as possible, the line drawings and stained sections in the spinal cord and brainstem portions of chapter 5. Recognizing that this match is subject to the vicissitudes of angle and individual variation, special sets of images were used in chapter 5. The first set consisted of T1- and T2-weighted MRI generated from the same individual; these are identified, respectively, as “MRI, T1-weighted” and “MRI, T2-weighted” in chapter 5. The second set consisted of CT images from a patient who had an injection of the radiopaque contrast media Isovue-MR® 200 (iopamidol injection 41 %) into the lumbar cistern. This contrast media diffused throughout the spinal and cranial subarachnoid spaces, outlining the spinal cord and brainstem (Fig. 1-5). Images at spinal levels show neural structures as grey surrounded by a light subarachnoid space; this is a “CT myelogram”. A comparable image at brainstem levels (grey brain, light CSF) is a “CT cisternogram”. These designations are used in chapter 5. While all matches are not perfect, not all things in life or medicine are, the vast majority of matches between MRI, CT, and drawings/sections are excellent and clearly demonstrate the intended points.

Chapter 6

The three-dimensional anatomy of internal structures in the CNS can also be studied in stained sections that correlate similar structures in different planes. The photographs of stained axial and sagittal sections and of MRIs in Chapter 6 are organized to provide four important levels of information. First, the general internal anatomy of brain structures can be easily identified in each photograph. Second, axial photographs are on left-hand pages and arranged from dorsal to ventral (Figures 6-1 to 6-9), whereas sagittal photographs are on right-hand pages and arranged from medial to lateral (Figures 6-2 to 6-10). This setup, in essence, provides complete representation of the brain in both planes for use as independent study sets (axial only, sagittal only) or as integrated/correlated sets (compare facing pages). Third, because axial and sagittal sections are on facing pages and the plane of section of each is indicated on its companion by a heavy line, the reader can easily visualize the positions of internal structures in more than one plane and develop a clear concept of three-dimensional topography. In other words, one can identify structures dorsal or ventral to the axial plane by comparing them with the sagittal, and structures medial or lateral to the sagittal plane by comparing them with the axial. Such comparisons facilitate a more full understanding of three-dimensional relationships in the brain. Fourth, the inclusion of MRIs with representative axial and sagittal stained sections provides excellent examples of the fact that structures seen in the teaching laboratory are easy to recognize in clinical images.
These MRIs are also not labeled so as to allow the user to develop his/her interpretive skills.

**Chapter 7**

This chapter provides summaries of a variety of clinically relevant CNS tracts and/or pathways and has four features that enhance student understanding. First, the inclusion of pathway information in atlas format broadens the basis one can use to teach functional neurobiology. This is especially the case when pathways are presented in a style that enhances the development of diagnostic skills. Second, each drawing illustrates, in line color, a given pathway completely, showing its 1) origins, longitudinal extent, course throughout the neuraxis and termination; 2) laterality—an all-important issue in diagnosis; 3) point of decussation, if applicable; 4) position in representative cross sections of the brainstem and spinal cord; and 5) the somatotopic organization of fibers within the pathway, if applicable. The blood supply to each pathway is reviewed on the facing page. Third, a brief summary mentions the main neuroactive substances associated with cells and fibers composing particular segments of the pathway under consideration. The action of the substance, if widely agreed on, is indicated as excitatory (+) or inhibitory (−). This allows the reader to closely correlate a particular neurotransmitter with a specific population of projection neurons and their terminals. The limitations of this approach, within the confines of an atlas, are self-evident. The transmitters associated with some pathways are not well known; consequently, such information is not provided for some connections. Also, no attempt is made to identify substances that may be colocalized, to discuss their synthesis or degradation, or to mention all neurotransmitters associated with a particular cell group. The goal here is to introduce the reader to selected neurotransmitters and to integrate and correlate this information with a particular pathway, circuit, or connection. Fourth, the clinical correlations that accompany each pathway drawing provide examples of deficits resulting from lesions, at various levels in the neuraxis, of the fibers composing that specific pathway. Also, examples are given of syndromes or diseases in which these deficits are seen. The ways in which these clinical correlations can be used to enrich the learning process are described in Figure 7-3 on page 176.

The drawings in this section were designed to provide the maximum amount of information, to keep the extraneous points to a minimum, and to do it all in a single, easy-to-follow illustration. A complete range of relevant information is contained in each drawing and in its description as explained in the second point above.

Because it is not possible to anticipate all pathways that may be taught in a wide range of neurobiology courses, flexibility has been designed into Chapter 7. The last figure in each section is a blank master drawing that follows the same general format as the preceding figures. Photocopies of these blank master drawings can be used by the student for learning and/or review of any pathway and by the instructor to teach additional pathways not included in the atlas or as a substrate for examination questions. The flexibility of information as presented in Chapter 7 extends equally to student and instructor.

**Chapter 8**

This chapter contains a series of angiograms (arterial and venous phases), magnetic resonance angiography (MRA) images, and magnetic resonance venography (MRV) images. The angiograms are shown in lateral and anterior–posterior projections—some as standard views with corresponding digital subtraction images. MRA and MRV technology are noninvasive methods that allow for the visualization of arteries (MRA) and veins and venous sinuses (MRV). There are, however, many situations when both arteries and veins are seen with either method. Use of MRA and MRV is commonplace, and this technology is an important diagnostic tool. A number of new vascular images have been included in this revised version of Chapter 8.

**Chapter 9**

A primary goal in the study of functional human neurobiology is to become a competent health care professional. Another, and equally significant, goal is to pass examinations. These may be course examinations, the National Board Subject Exam (some courses require these), or standardized tests, such as the USMLE Step 1 and Step 2, given at key intervals and taken by all students.

The questions comprising chapter 9 were generated in the recognition that examinations are an essential part of the educational process. Whenever possible, and practical, these questions are in the USMLE Step 1 style (single best answer). These questions emphasize 1) anatomical and clinical concepts and correlations; 2) the application of basic human neurobiology to medical practice; and 3) how neurological deficits and diseases relate to damage in specific parts of the nervous system. In general, the questions are grouped by chapter. However, in some instances, questions draw on information provided in more than one chapter. This is sometimes essential in an effort to make appropriate structural/functional/clinical correlations. At the end of each group of questions the correct answers are provided and explained. Included with the explanation is a reference to the page (or pages) containing the answer, be that answer in the text or in a figure. Although not exhaustive, this list of questions should provide the user of this atlas with an excellent opportunity for self-assessment covering a broad range of clinically relevant topics.
No universally accepted way to identify specific features or structures in drawings or photographs exists. The variety of methods seen in currently available atlases reflects the personal preferences of the authors. Such is the case in the present endeavor. The goal of this atlas is to present basic functional and clinical neuroanatomy in an understandable and useful format.

Among currently available atlases, most figures are labeled with either the complete names of structures or with numbers or letters that are keyed to a list of the complete names. The first method immediately imparts the greatest amount of information; the second method is the most succinct. When using the complete names of structures, one must exercise care to not compromise the quality or size of the illustration, the number of structures labeled, or the size of labels used. Although the use of single letters or numbers results in minimal clutter on the figure, a major drawback is the fact that the same number or letter may appear on several different figures and designate different structures in all cases. Consequently, no consistency occurs between numbers and letters and their corresponding meanings as the reader examines different figures. This atlas uses a combination of complete words and abbreviations that are clearly recognized versions of the complete word.

In response to suggestions made by those using this book over the years, the number of abbreviations in the sixth edition has been reduced, and the number of labels using the complete name has been increased. Simultaneously, complete names and abbreviations have been used together in some chapters to the full advantage of each method. For example, structures are labeled on a brain slice by the complete name, but the same structure in the accompanying MRI is labeled with a corresponding abbreviation (see Chapters 2 and 4). This uses the complete word(s) on the larger image of a brain structure while using the shorter abbreviation on the smaller image of the MRI.

The abbreviations used in this atlas do not clutter the illustration; they permit labeling of all relevant structures and are adequately informative while stimulating the thinking–learning process. The abbreviations are, in a very real sense, mnemonics. When learning gyri and sulci of the occipital lobe, for example, one realizes that the abbreviation “LinGy” in the atlas could only mean “lingual gyrus.” It could not be confused with other structures in other parts of the nervous system. Regarding the pathways, “RuSp” could mean only “rubrospinal tract” and “LenFas,” the “lenticular fasciculus.” As the reader learns more and more terminology from lectures and readings, he or she will be able to use these abbreviations with minimal reference to the accompanying list. In addition, a subtle advantage of this method of labeling is that, as the reader looks at the abbreviation and momentarily pauses to ponder its meaning, he or she may form a mental image of the structure and the complete word. Because neuroanatomy requires one to conceptualize and form mental images to more clearly understand CNS relationships, this method seems especially useful.

External Morphology of the Central Nervous System
Posterior (upper) and anterior (lower) views showing the general features of the spinal cord as seen at levels C₂–C₅. The dura and arachnoid are reflected, and the pia is intimately adherent to the spinal cord and rootlets. Posterior and anterior spinal medullary arteries (see Figure 2-3 on facing page) follow their respective roots. The posterior spinal artery is found medial to the entering posterior rootlets (and the dorsolateral sulcus), while the anterior spinal artery is in the anterior median fissure (see also Figure 2-2, facing page).
Posterior (upper) and anterior (lower) views showing details of the spinal cord as seen in the C7 segment. The posterior (dorsal) root ganglion is partially covered by dura and connective tissue.

**2-2** Posterior (upper) and anterior (lower) views showing details of the spinal cord as seen in the C7 segment. The posterior (dorsal) root ganglion is partially covered by dura and connective tissue.

**2-3** Semidiagrammatic representation showing the origin and general location of principal arteries supplying the spinal cord. The anterior and posterior radicular arteries arise at every spinal level and serve their respective roots and ganglion. The anterior and posterior spinal medullary arteries (also called medullary feeder arteries or segmental medullary arteries) arise at intermittent levels and serve to augment the blood supply to the spinal cord. The artery of Adamkiewicz is an unusually large spinal medullary artery arising usually on the left in low thoracic or upper lumbar levels (T₉–L₁). The arterial vasocorona is a diffuse anastomotic plexus covering the cord surface.
Overall posterior (A,B) and sagittal MRI (C, T2-weighted) views of the lower thoracic, lumbar, sacral, and coccygeal spinal cord segments and the cauda equina. The dura and arachnoid are retracted in A and B. The cauda equina is shown in situ in A, and in B the nerve roots of the cauda equina have been spread laterally to expose the conus medullaris and filum terminale internum. This latter structure is also called the pial part of the filum terminale. See Figures 5-1 and 5-2 on pages 84–87 for cross-sectional views of the cauda equina.

In the sagittal MRI (C), the lower portions of the cord, the filum terminale internum, and cauda equina are clearly seen. In addition, the intervertebral discs and the bodies of the vertebrae are clear. The lumbar cistern is an enlarged part of the subarachnoid space caudal to the end of the spinal cord. This space contains the anterior and posterior roots from the lower part of the spinal cord that collectively form the cauda equina. The filum terminale internum also descends from the conus medullaris through the lumbar cistern to attach to the inner surface of the dural sac. The dural sac ends at about the level of the S2 vertebra and is attached to the coccyx by the filum terminale externum (also see Fig. 2-47 on page 47). A lumbar puncture is made by inserting a large gauge needle (18-22 gauge) between the L3 and L4 vertebra or L4 and L5 vertebra and retrieving a sample of cerebrospinal fluid from the lumbar cistern. This sample may be used for a number of diagnostic procedures.
Lateral (A) and medial (B) views of the cerebral hemisphere showing the landmarks used to divide the cortex into its main lobes.

On the lateral aspect, the central sulcus (of Rolando) separates frontal and parietal lobes. The lateral sulcus (of Sylvius) forms the border between frontal and temporal lobes. The occipital lobe is located caudal to an arbitrary line drawn between the terminus of the parieto-occipital sulcus and the preoccipital notch. A horizontal line drawn from approximately the upper two-thirds of the lateral fissure to the rostral edge of the occipital lobe represents the border between parietal and temporal lobes. The insular cortex (see also Figs. 2-46 on page 45 and 3-1 on page 56) is located internal to the lateral sulcus. This part of the cortex is made up of long and short gyri that are separated from each other by the central sulcus of the insula. The insula, as a whole, is separated from the adjacent portions of the frontal, parietal, and temporal opercula by the circular sulcus.

On the medial aspect, the cingulate sulcus separates medial portions of frontal and parietal lobes from the limbic lobe. An imaginary continuation of the central sulcus intersects with the cingulate sulcus and forms the border between frontal and parietal lobes. The parieto-occipital sulcus and an arbitrary continuation of this line to the preoccipital notch separate the parietal, limbic, and temporal lobes from the occipital lobe.
Lateral (A) and medial (B) views of the cerebral hemisphere showing the more commonly described Brodmann areas. In general, area 4 comprises the primary somatomotor cortex, areas 3, 1, and 2 the primary somatosensory cortex, and area 17 the primary visual cortex. Area 41 is the primary auditory cortex, and the portion of area 6 in the caudal part of the middle frontal gyrus is generally recognized as the frontal eye field.

The inferior frontal gyrus has three portions: a pars opercularis, pars triangularis, and a pars orbitalis. A lesion that is located primarily in areas 44 and 45 (shaded) will give rise to what is called a Broca aphasia, also called expressive or nonfluent aphasia.

The inferior parietal lobe consists of supramarginal (area 40) and angular (area 39) gyri. Lesions in this general area of the cortex (shaded), and sometimes extending into area 22, will give rise to what is known as Wernicke aphasia, also sometimes called receptive or fluent aphasia.
Lateral (A) and medial (B) views of the cerebral hemisphere showing the somatotopic organization of the primary somatomotor and somatosensory cortices. The lower extremity and foot areas are located on medial aspects of the hemisphere in the anterior paracentral (motor) and the posterior paracentral (sensory) gyri. The remaining portions of the body extend from the margin of the hemisphere over the convexity to the lateral sulcus in the precentral and postcentral gyri.

In general, the precentral gyrus can be divided into three regions: the lateral third representing the face area, the middle third representing the hand and upper extremity areas, and the medial third representing the trunk and the hip. Lesions of the somatomotor cortex result in motor deficits on the contralateral side of the body while lesions in the somatosensory cortex result in a loss of sensory perception from the contralateral side of the body.

The medial surface of the right hemisphere (B) illustrates the position of the left portions of the visual field. The inferior visual quadrant is located in the primary visual cortex above the calcarine sulcus while the superior visual quadrant is found in the cortex below the calcarine sulcus.
2-8 Dorsal view of the cerebral hemispheres showing the main gyri and sulci and an MRI (inverted inversion recovery—lower left) and a CT (lower right) identifying structures from the same perspective. Note the area of infarction representing the territory of the anterior cerebral artery (ACA).
2-9 Dorsal view of the cerebral hemispheres showing the location and general branching patterns of the anterior (ACA), middle (MCA), and posterior (PCA) cerebral arteries. Gyri and sulci can be identified by a comparison with Figure 2-8 (facing page).

2-10 Dorsal view of the cerebral hemispheres showing the location of the superior sagittal sinus and the locations and general branching patterns of veins. Gyri and sulci can be identified by a comparison with Figure 2-8 (facing page). See Figures 8-4 and 8-5 (pp. 243–244) for comparable angiograms (venous phase) of the superior sagittal sinus.
Lateral view of the left cerebral hemisphere showing the principal gyri and sulci and an MRI (inversion recovery) identifying many of these structures from the same perspective.

2-11
2-12 Lateral view of the right cerebral hemisphere showing the branching pattern of the middle cerebral artery. Gyri and sulci can be identified by comparison with Figure 2-11 (facing page). The middle cerebral artery initially branches in the depths of the lateral sulcus (as M₂ and M₃ segments); these branches seen on the surface of the hemisphere represent the M₄ segment. Terminal branches of the posterior and anterior cerebral arteries course over the edges of the temporal and occipital lobes, and parietal and frontal lobes, respectively (see Figure 2-9 on page 17). See Figure 8-1 (p. 240) for a comparable angiogram of the middle and anterior cerebral arteries.

2-13 Lateral view of the right cerebral hemisphere showing the locations of sinuses and the locations and general branching patterns of veins. Gyri and sulci can be identified by comparison with Figure 2-11 (facing page). Communications between veins and sinuses or between sinuses are also indicated. See Figures 8-2 (p. 241) and 8-11 (p. 250) for comparable angiogram and MRV of the sinuses and superficial veins.
Ventral view of the cerebral hemispheres and diencephalon with the brainstem caudal to midbrain removed and two MRIs (inversion recovery—lower left; T2-weighted—lower right) showing many structures from the same perspective.
2-15 Ventral view of the cerebral hemisphere with the brainstem removed, which shows the branching pattern of the posterior cerebral artery (PCA) and some branches of the anterior and middle cerebral arteries. The P₁ and P₃ segments of the PCA are shown on Figure 2-21 on page 25. Shown here are P₁ (origin of temporal arteries) and P₄ (origin of calcarine and parietooccipital arteries) segments. Gyri and sulci can be identified by comparison with Figure 2-14 (facing page).

2-16 Ventral view of the cerebral hemisphere, with brainstem removed, showing the locations and relationships of the main sinuses. Gyri and sulci can be identified by comparison with Figure 2-14 (facing page). The listings preceded by an en-dash (−) under principal sinuses are the main tributaries of that sinus. See Figures 8–5 (p. 245), 8–9 (p. 248), and 8–11 (p. 250) for comparable MRV of the transverse sinus.
Ventral view of the cerebral hemispheres, diencephalon, brainstem, and cerebellum and two MRIs (both T1-weighted images) that shows structures from the same perspective. A detailed view of the ventral aspect of the brainstem is seen in Figure 2-20 on page 24.
2-18 Ventral view of the cerebral hemispheres, diencephalon, brainstem, and cerebellum, which shows the arterial patterns created by the internal carotid and vertebrobasilar systems. Note the cerebral arterial circle (of Willis). Gyri and sulci can be identified by comparison with Figure 2-17 (facing page). Details of the cerebral arterial circle and the vertebrobasilar arterial pattern are shown in Figure 2-21 on page 25. See Figure 8-9 and 8-10 (pp. 248–249) for comparable MRA of the cerebral arterial circle and its major branches.

2-19 Ventral view of the cerebral hemispheres, diencephalon, brainstem, and cerebellum showing the locations and relationships of principal sinuses and veins. The listings preceded by a dash (–) under principal sinuses are the main tributaries of that sinus.
Detailed ventral view of the diencephalon and brainstem with particular emphasis on cranial nerves and related structures. The dots on the left side represent the approximate position of the roots of the hypoglossal nerve on that side; the general position of the (spinal) accessory nerve is shown on the right by the dark line.
Ventral view of the brainstem showing the relationship of brain structures and cranial nerves to the arteries forming the vertebrobasilar system and the cerebral arterial circle (of Willis). The posterior spinal artery usually originates from the posterior inferior cerebellar artery (left), but it may arise from the vertebral (right). Although the labyrinthine artery may occasionally branch from the basilar (right), it most frequently originates from the anterior inferior cerebellar artery (left). Many vessels that arise ventrally course around the brainstem to serve dorsal structures. The anterior cerebral artery consists of A1 (between the internal carotid bifurcation and the anterior communicating artery) and segments A2–A5 which are distal to the anterior communicating artery (see Figure 8-3 on p. 242 for details). Lateral to the internal carotid bifurcation is the M1 segment of the middle cerebral artery (MCA), which divides and continues as the M2 segments (branches) on the insular cortex. The M1 branches of the MCA are those located on the inner surface of the opercula, and the M2 branches are located on the lateral aspect of the hemisphere. Between the basilar bifurcation and the posterior communicating artery is the P1 segment of the posterior cerebral artery; P2 is between the posterior communicator and the first temporal branches. See Figure 8-9, 8-10, and 8-12 (pp. 248, 249, 251) for comparable MRA of the cerebral arterial circle and vertebrobasilar system. See Figure 8-12 on p. 251 for blood supply of the choroid plexus.
2-22 Lateral view of the left side of the brainstem emphasizing structures and cranial nerves on the ventral aspect of the thalamus and brainstem. Compare with Figure 2-24 on the facing page. The cerebellum and portions of the temporal lobe have been removed.

2-23 View of the ventral aspect of the diencephalon and part of the brainstem with the medial portions of the temporal lobe removed. Note structures of the hypothalamus, cranial nerves, and optic structures, including the lateral geniculate body.
Lateral view of the brainstem and thalamus showing the relationship of structures and cranial nerves to arteries. Arteries that serve dorsal structures originate from ventrally located parent vessels. The approximate positions of the posterior spinal and labyrinthine arteries, when they originate from the vertebral and basilar arteries, respectively, are shown as dashed lines. Compare with Figure 2-22 on the facing page. See Figure 8-7 (p. 246) for comparable angiogram of the vertebrobasilar system. See Figure 8-12 on p. 251 for blood supply of the choroid plexus.

A proton density MRI through basal regions of the hemisphere and through the midbrain showing several major vessels that form part of the cerebral arterial circle (of Willis). Compare to Figure 2-21 on page 25. See Figure 8-9 and 8-10 (pp. 248–249) for comparable MRA of the cerebral arterial circle.
Midsagittal view of the right cerebral hemisphere and diencephalon, with brainstem removed, showing the main gyri and sulci and two MRI (both T1-weighted images) showing these structures from the same perspective. The lower MRI is from a patient with a small colloid cyst in the interventricular foramen. When compared to the upper MRI, note the enlarged lateral ventricle with resultant thinning of the corpus callosum.

A colloid cyst (colloid tumor) is a congenital growth usually discovered in adult life once the flow of CSF through the interventricular foramina is compromised (obstructive hydrocephalus). The patient may have headache, unsteady gait, weakness of the lower extremities, visual or somatosensory disorders, and/or personality changes or confusion. Treatment is usually by surgical removal.
2-27 Midsagittal view of the cerebral hemisphere and diencephalon showing the locations and branching patterns of anterior and posterior cerebral arteries. The positions of gyri and sulci can be extrapolated from Figure 2-26 (facing page). Terminal branches of the anterior cerebral artery arch laterally over the edge of the hemisphere to serve medial regions of the frontal and parietal lobes, and the same relationship is maintained for the occipital and temporal lobes by branches of the posterior cerebral artery. See Figures 8-1 (p. 240) and 8-7 (p. 246) for comparable angiogram of anterior and posterior cerebral arteries.

2-28 Midsagittal view of the cerebral hemisphere and diencephalon that shows the locations and relationships of sinuses and the locations and general branching patterns of veins. The position of gyri and sulci can be extrapolated from Figure 2-26 (facing page). TV = Terminal vein (superior thalamostriate vein). See Figures 8-2 (p. 241) and 8-11 (p. 250) for comparable angiogram (venous phase) and MRV showing veins and sinuses.
A midsagittal view of the right cerebral hemisphere and diencephalon with the brainstem and cerebellum in situ. The MRI (T1-weighted image) shows many brain structures from the same perspective.
A midsagittal view of the right cerebral hemisphere and diencephalon with the brainstem in situ focusing on the details primarily related to the diencephalon and third ventricle. The MRI (T1-weighted image) shows these brain structures from the same perspective. Hyth = hypothalamus.
Rostral (A, superior surface), caudal (B, inferior surface), and an inferior view (C, inferior aspect) of the cerebellum. The view in C shows the aspect of the cerebellum that is continuous into the brainstem via cerebellar peduncles. The view in C correlates with superior surface of the brainstem (and middle superior cerebellar peduncles) as shown in Figure 2-34 on page 34.

Note that the superior view of the cerebellum (A) correlates closely with cerebellar structures seen in axial MRIs at comparable levels (D, E). Structures seen on the inferior surface of the cerebellum, such as the tonsil (F), correlate closely with an axial MRI at a comparable level. In G, note the appearance of the margin of the cerebellum, the general appearance and position of the lobes, and the obvious nature of the middle cerebellar peduncle. All MRI images are T1-weighted.
2-32 A median sagittal view of the cerebellum (A) showing its relationships to the midbrain, pons, and medulla. This view of the cerebellum also illustrates the two main fissures and the vermis portions of lobules I-X. Designation of these lobules follows the method developed by Larsell.

Lobules I-V are the vermis parts of the anterior lobe; lobules VI-IX are the vermis parts of the posterior lobe; and lobule X (the nodulus) is the vermis part of the flocculonodular lobe. Note the striking similarities between the gross specimen (A) and a median sagittal view of the cerebellum in a T1-weighted MRI (B) and a T2-weighted MRI (C).

2-33 Lateral and slightly rostral view of the cerebellum and brainstem with the middle and superior cerebellar peduncles exposed. Note the relationship of the trochlear nerve to the inferior colliculus and the relative positions of, and distinction between, motor and sensory roots of the trigeminal nerve. See page 40, Figure 2-41D for an MRI showing the trochlear nerve.
Detailed dorsal view of the brainstem, with cerebellum removed, providing a clear view of the rhomboid fossa (and floor of the fourth ventricle) and contiguous parts of the caudal diencephalon. The dashed line on the left represents the position of the sulcus limitans and the area of the inferior cerebellar peduncle is shown on the right. The tuberculum cinereum is also called the trigeminal tubercle (tuberculum trigeminale) because it is the surface representation of the spinal trigeminal tract and its underlying nucleus. Figure 3-10 on page 61 also shows a comparable view of the brainstem and the posterior portions of the diencephalon.
2-35 Dorsal view of the brainstem and caudal diencephalon showing the relationship of structures and some of the cranial nerves to arteries. The vessels shown in this view have originated ventrally and wrapped around the brainstem to gain their dorsal positions. In addition to serving the medulla, branches of the posterior inferior cerebellar artery also supply the choroid plexus of the fourth ventricle. The tuberculum cinereum is also called the trigeminal tubercle. See Figure 8-12 on p. 251 for blood supply of the choroid plexus.
External Morphology of the Central Nervous System

2-36 Lateral view of the left side of the brainstem emphasizing structures that are located dorsally. The cerebellum and portions of the temporal lobe have been removed. Compare with Figure 2-38 on the facing page.

2-37 The floor of the fourth ventricle (rhomboid fossa) and immediately adjacent structures. Also compare with Figure 2-34 on page 34.
Lateral view of the brainstem and thalamus, which shows the relationship of structures and cranial nerves to arteries. The approximate positions of the labyrinthine and posterior spinal arteries, when they originate from the basilar and vertebral arteries, respectively, are shown as dashed lines. Arteries that distribute to dorsal structures originate from large ventral vessels. Compare with Figure 2-36 on the facing page.
The anterior communicating artery or its junction with the anterior cerebral artery (D) is the most common site of supratentorial (carotid system) aneurysms. Rupture of aneurysms at this location is one of the more common causes of spontaneous subarachnoid hemorrhage. The proximity of these vessels to optic structures and the hypothalamus (D) explain the variety of visual and hypothalamic disorders experienced by these patients. A lesion of the optic nerve results in blindness in that eye and loss of the afferent limb of the pupillary light reflex. Lesions in, or caudal to, the optic chiasm result in deficits in the visual fields of both eyes.
Inferior view of the hemisphere showing the exiting fibers of the oculomotor nerve (III), and their relationship to the posterior cerebral and superior cerebellar arteries (A). The MRIs of cranial nerve III are shown in sagittal (B, T2-weighted; D, T1-weighted) and in axial (C, T1-weighted) planes. Note the relationship of the exiting fibers of the oculomotor nerve to the posterior cerebral and superior cerebellar arteries (A, B) and the characteristic appearance of the III nerve as it passes through the subarachnoid space toward the superior orbital fissure (C). The sagittal section (D) is just off the midline and shows the position of the oculomotor nerve in the interpeduncular fossa rostral to the basilar pons and caudal to optic structures.

That portion of the posterior cerebral artery located between the basilar artery and the posterior communicating artery (A) is the P1 segment. The most common site of aneurysms in the infratentorial area (vertebrobasilar system) is at the bifurcation of the basilar artery, also called the basilar tip. Patients with aneurysms at this location may present with eye movement disorders and pupillary dilation due to damage to the root of the third nerve (A, B).
A median sagittal view of the brainstem and diencephalon (A) reveals the position of the oculomotor nerve (III) in relation to adjacent structures. The MRI in B and C show the position of the oculomotor nerve in sagittal (B, T1-weighted) and in axial (C, T2-weighted) planes. Note the relationship of the oculomotor nerve to the adjacent posterior cerebral and superior cerebellar arteries (B, C). Also compare these images with that of figure 2-40B on page 39. In D (T2-weighted), the trochlear nerve is seen passing through the ambient cistern around the lateral aspect of the midbrain (compare with Fig. 2-32 on page 32).

The oculomotor (III) and trochlear (IV) nerves are the cranial nerves of the midbrain. The third nerve exits via the interpeduncular fossa to innervate four major extraocular muscles (see Fig. 7-15 on page 201) and, through the ciliary ganglion, the sphincter pupillae muscles. Damage to the oculomotor nerve may result in paralysis of most eye movement, a dilated pupil, and loss of the efferent limb of the pupillary light reflex, all in the ipsilateral eye. The fourth nerve is unique in that it is the only cranial nerve to exit the posterior (dorsal) aspect of the brainstem and is the only cranial nerve motor nucleus to innervate, exclusively, a muscle on the contralateral side of the midbrain.
The trigeminal nerve (V) is the largest of the cranial nerve roots exiting the brainstem (A). It exits at an intermediate position on the lateral aspect of the pons roughly in line with cranial nerves VII, IX, and X. The fifth nerve, and these latter three, are mixed nerves in that they have motor and sensory components. The trigeminal nerve is shown in axial MRI (B, T1-weighted; C, T2-weighted) and in coronal planes (D, E, both T1-weighted images). Note the characteristic appearance of the root of the trigeminal nerve as it traverses the subarachnoid space (B and C), the origin of the trigeminal nerve, and the position of the sensory root of the nerve at the lateral aspect of the pons in the coronal plane (D, E). In addition, the MRI in C clearly illustrates the position of the trigeminal ganglion in the middle cranial fossa.

Trigeminal neuralgia (tic douloureux) is a lancinating paroxysmal pain within the V<sub>2</sub>–V<sub>3</sub> territories frequently triggered by stimuli around the corner of the mouth. The causes are probably multiple and may include neurovascular compression by the superior cerebellar artery (see the apposition of this vessel to the nerve root in C), multiple sclerosis, tumors, and ephaptic transmission within the nerve or ganglion.
The cranial nerves at the pons medulla junction are the abducens (VI), the facial (VII), and the vestibulocochlear (VIII) (A). The facial and vestibulocochlear nerves both enter the internal acoustic meatus, the facial nerve distributing eventually to the face through the stylomastoid foramen, and the vestibulocochlear nerve to structures of the inner ear. MRI in the axial plane, B, C, D, (all T2-weighted images) show the relationships of the vestibulocochlear root and the facial nerve to the internal acoustic meatus. Also notice the characteristic appearance of the cochlea (B, C) and the semicircular canals (C). In addition to these two cranial nerves, the labyrinthine branch of the anterior inferior cerebellar artery also enters the internal acoustic meatus.

The so-called acoustic neuroma, a tumor associated with the eighth nerve, is actually a vestibular schwannoma since it arises from the neurilemma sheath of the vestibular root. Most patients with this tumor have hearing loss, tinnitus and equilibrium problems, or vertigo. As the tumor enlarges (to more than about 2 cm) it may cause facial weakness (seventh root), numbness (fifth root), or abnormal corneal reflex (fifth or seventh). Treatment is usually by surgery, radiation therapy, or a combination thereof.
The glossopharyngeal (IX) and vagus (X) nerves (A) exit the lateral aspect of the medulla via the postolivary sulcus; the ninth nerve exits rostral to the row of rootlets comprising the tenth nerve (A). These nerves are generally in line with the exits of the facial and trigeminal nerves; all of these are mixed nerves. The exit of the glossopharyngeal nerve (A, B) is close to the pons–medulla junction and correlates with the corresponding shape (more rectangular) of the medulla. The vagus nerve exits at a slightly more caudal position (A, C, D); the shape of the medulla is more square and the fourth ventricle is smaller. The ninth and tenth cranial nerves and the spinal portion of the accessory nerve (XI) exit the skull via the jugular foramen.

Glossopharyngeal neuralgia is a lancinating pain originating from the territories served by the ninth and tenth nerves at the base of the tongue and throat. Trigger events may include chewing and swallowing. Lesions of nerves passing through the jugular foramen (IX, X, XI) may result in loss of the gag reflex (motor limb via ninth nerve), and drooping of the ipsilateral shoulder accompanied by an inability to turn the head to the opposite side against resistance (eleventh nerve).
The hypoglossal nerve (XII) (A) exits the inferolateral aspect of the medulla via the preolivary sulcus. This cranial nerve exits in line with the abducens nerve found at the pons–medulla junction and in line with the exits of the third and fourth nerves of the midbrain. The twelfth nerve exit is characteristically located laterally adjacent to the pyramid, which contains corticospinal fibers.

In axial MRI (B, T2-weighted; C, T1-weighted), note the characteristic position of the hypoglossal nerve in the subarachnoid space and its relation to the overall shape of the medulla. This shape is indicative of a cranial nerve exiting at more mid-to-caudal medullary levels. In B, note its relationship to the preolivary sulcus and olivary eminence. The hypoglossal exits the base of the skull by traversing the hypoglossal canal. A lesion of the hypoglossal nerve results in a deviation of the tongue to the ipsilateral side on attempted protrusion.
2-46  Lateral view of the left cerebral hemisphere with the cortex overlying the insula removed. Structures characteristic of the insular cortex, and immediately adjacent areas, are clearly seen in the two MRIs in the sagittal plane through lateral portions of the hemisphere (inversion recovery—upper; T1-weighted image—lower).
A wide variety of disease processes and lesions may involve the meninges; only a few examples are mentioned here.

Bacterial infections of the meninges (bacterial meningitis) are commonly called leptomeningitis because the causative organisms are usually found in the subarachnoid space and involve the pia and arachnoid. The organism seen in about one-half of adult cases is Streptococcus pneumoniae; while in neonates and children up to about 1 year it is Escherichia coli. The patient becomes acutely ill (i.e., confusion, fever, stiff neck, stupor), may have generalized or focal signs/symptoms, and, if not treated rapidly, will likely die. Treatment is with appropriate antibiotics. Patients with viral meningitis may become ill over a period of several days, experience headache, confusion, and fever, but, with supportive care, will recover after an acute phase of approximately 1–2 weeks. These patients usually recover with no permanent deficits.

The most common cause of an epidural (extradural) hematoma is a skull fracture that results in a laceration of a major dural vessel, such as the middle meningeal artery. In approximately 15% of cases, bleeding may come from a venous sinus. The extravasated blood dissects the dura mater off the inner table of the skull; there is no preexisting (extradural) space for the blood to enter. These lesions are frequently large, lens (lenticular) shaped, may appear loculated, and are “short and thick” compared to subdural hematomas (see Fig. 2-48 on page 48). The patient may lapse into a coma and, if the lesion is left untreated, death may result. In some cases, the patient may initially be unconscious followed by a lucid interval (the patient is wide awake), then subsequently deteriorate rapidly and die; this is called “talk and die.” Treatment of choice for large lesions is surgical removal of the clot and coagulation of the damaged vessel.

Tearing of bridging veins (veins passing from the brain outward through the arachnoid and dura), usually the result of trauma, is a common cause of subdural hematoma. This designation is somewhat a misnomer because the extravasated blood actually dissects through a specialized, yet structurally weak, cell layer at the dura-arachnoid interface; this is the dural border cell layer. There is no preexisting “subdural space” in the normal brain. Acute subdural hematomas, more commonly seen in younger patients, are usually detected immediately or within a few hours after the precipitating incident. Chronic subdural hematomas, usually seen in the elderly, are frequently of unknown origin; may take days or weeks to become symptomatic; and cause a progressive change in mental status of the patient. This lesion appears “long and thin,” compared to an epidural hematoma, follows the surface of the brain, and may extend for considerable distances (see Fig. 2-48 on p. 48 and Fig. 2-51 on p. 51). Treatment is surgical evacuation (for larger or acute lesions) or close monitoring for small, asymptomatic, or chronic lesions.

The most common cause of subarachnoid hemorrhage is trauma. In approximately 80% of patients with spontaneous (nontraumatic) subarachnoid hemorrhage, the precipitating event is rupture of an intracranial aneurysm. Symptomatic bleeding from an arteriovenous malformation occurs in approximately 5% of cases. Blood collects in, and percolates through, the subarachnoid space and cisterns (see Fig. 2-51 on page 51). Sometimes, the deficits seen (assuming the patient is not in coma) may be a clue as to location, especially if cranial nerves are nearby. Onset is sudden; the patient complains of an excruciating headache and may remain conscious, become lethargic and disoriented, or may be comatose. Treatment of an aneurysm is to surgically occlude it (by clip or coil), if possible, and to protect against the development of vasospasm. During surgery, some blood in the subarachnoid space and cisterns may be removed.

Tumors of the meninges (meningiomas) are classified in different ways but they usually arise from arachnoid cap/stem cells (a small number are dural in origin) around the villi or at places where vessels or cranial nerves penetrate the dura-arachnoid. These tumors grow slowly (symptoms may develop almost imperceptibly over years), are histologically benign, may result in hyperostosis of the overlying skull, and frequently contain calcifications. In decreasing order, meningiomas are found in the following locations: parasagittal area + falx (together 29%), convexity 15%, sella 13%, sphenoid ridge 12%, and olfactory groove 10%. Treatment is primarily by surgical removal, although some meningiomas are treated by radiotherapy.
Semidigrammatic representation of the central nervous system and its associated meninges. The details show the relationships of the meninges in the area of the superior sagittal sinus, on the lateral aspect of the cerebral hemisphere, and around the spinal cord. Cerebrospinal fluid is produced by the choroid plexi of lateral, third, and fourth ventricles. It circulates through the ventricular system (small arrows) and enters the subarachnoid space via the medial foramen of Magendie and the two lateral foramen of Luschka. In the living situation the arachnoid is attached to the inner surface of the dura. There is no actual or potential subdural space.
Examples of epidural (extradural) hemorrhages (A, B) and of acute (C) and subacute (D) subdural hematoma. Note the lenticular shape of the epidural lesions (A, B), their loculated appearance, and their location external to the substance of the brain. In contrast, the acute subdural lesion (C) is quite thin and extends over a longer distance on the cortex.

In D, the subdural hematoma has both chronic and subacute phases. The chronic phase is indicated by the upper two and lower two arrows where the blood is replaced by fluid, and the subacute phase by the middle arrow where fresher blood has entered the lesion. Note the extent of this lesion on the surface of the cortex and its narrowness compared to epidural lesions. The patient in D also has small hemorrhages into the substance of the brain, the larger of these in the region of the genu of the internal capsule. Images A–D are CT. For additional comments on epidural and subdural hemorrhages see page 46.
Examples of hemorrhages into the substance of the brain that, in some cases, have also resulted in blood in the ventricular system. The large hemorrhages into the hemisphere (A, B) have resulted in enlargement of the ventricles, a midline shift, and, in the case of A, a small amount of blood in the posterior horn of the lateral ventricle. In these examples, the lesion is most likely a result of hemorrhage from lenticulostrate branches of the M1 segment.

Blood in the substance of the brain and in the ventricular system may also result from trauma (C). In this example (C), blood is seen in the frontal lobe and in the third ventricle and cerebral aqueduct. The enlarged temporal horns (C) of the lateral ventricles are consistent with the interruption of CSF flow through the cerebral aqueduct (noncommunicating hydrocephalus). Images A–C are CT.
A median sagittal MRI (A, T2-weighted) of the brain showing the positions of the major cisterns associated with midline structures. Axial views of the midbrain (B, T1-weighted), pons (C, T2-weighted), and medulla (D, T2-weighted) represent the corresponding planes indicated in the sagittal view (A).

Cisterns are the enlarged portions of the subarachnoid space that contain arteries and veins, roots of cranial nerves, and, of course, cerebrospinal fluid. Consequently, the subarachnoid space and cisterns are continuous one with the other. In addition, the subarachnoid space around the brain is continuous with that around the spinal cord. Compare these cisterns with blood-filled parts of the subarachnoid space and cisterns in Figure 2-51 on the facing page.
Blood in the subarachnoid space and cisterns. In these CT examples, blood occupies the subarachnoid space and cisterns, outlining these areas in white. Consequently, the shape of the cisterns is indicated by the configuration of the white area, the white area representing blood.

Around the base of the brain (A), it is easy to identify the cisterns related to the midbrain, the supraoptic recess which is devoid of blood, and blood extending laterally into the Sylvian cistern. In some cases (B), subdural hemorrhage may penetrate the arachnoid membrane and result in blood infiltrating between gyri, such as this example with blood on the cortex of the insula. In C, the blood is located around the midbrain (crural and ambient cisterns), extends into the Sylvian cistern, and into the cistern of the lamina terminalis. The sharp interface between the lamina terminalis cistern (containing blood) and the third ventricle (devoid of blood) represents the position of the lamina terminalis. In D, blood is located in cisterns around the pons but avoids the rostral part of the fourth ventricle. Compare these images with the locations of some of the comparable cisterns as seen in Figure 2-50 on the facing page. Images A–D are CT.
Lateral (above) and dorsal (below) views of the ventricles and the choroid plexus. The dashed lines show the approximate positions of some of the important structures that border on the ventricular space. The choroid plexus is shown in red and structures bordering on the various portions of the ventricular spaces are color-coded; these colors are continued in Figure 2-53 on the facing page. Note the relationships between the choroid plexus and various parts of the ventricular system. The large expanded portion of the choroid plexus found in the area of the atrium is the glomus (glomus choroideum). See Figure 8-12 on p. 251 for details of blood supply to the choroid plexus.
Lateral view of the ventricular system and corresponding semidiagrammatic cross-sectional representations from rostral (A) to caudal (G) identifying specific structures that border on the ventricular space. In the cross-sections, the ventricle is outlined by a heavy line, and the majority of structures labeled have some direct relevance to the ventricular space at that particular level. The color-coding corresponds to that shown in Figure 2-52 on the facing page.
Examples of hemorrhage occupying portions of the ventricular system (ventricular hemorrhage). In these CT images, blood appears white within the ventricles. Consequently, the shape of the ventricular system is outlined by the white area, and the specific portion of the ventricular system is correspondingly labeled.

Note blood in the anterior horn, atrium, and posterior horn of the lateral ventricles (A, B), and blood clearly outlining the shape of the third ventricle (B). Blood also clearly outlines central portions of the fourth ventricle (C) and caudal portions of the fourth ventricle (D), including an extension of blood into the left lateral recess of the fourth ventricle. In addition to these images, Figure 2-49 on page 49 shows blood in the cerebral aqueduct and in the most inferior portions of the third ventricle. Images A–D are CT.
Dissections of the Central Nervous System
3-1 Lateral view of the right cerebral hemisphere with the inferior and parts of the middle frontal gyri and precentral and postcentral gyri removed to show the insular cortex, transverse temporal gyri, and related structures.

3-2 Dissection of the lateral aspect of the right cerebral hemisphere showing the locations and relationships of some of the main bundles of subcortical white matter. This dissection is deep to that shown in Figure 3-1 (above) and superficial to that shown in Figure 3-3 on page 57.
3-3 Dissection of the lateral aspect of the right cerebral hemisphere showing the relationship between fibers radiating from the internal capsule (corona radiata) and those of the superior longitudinal fasciculus. The lenticular nucleus is shown in situ, lateral to the internal capsule. This is a deeper dissection of the specimen shown in Figure 3-2 on page 56.

3-4 Dissection of the lateral aspect of the right cerebral hemisphere showing the internal capsule and the concavity left by removal of the lenticular nucleus. Note the other bundles of subcortical white matter. This is a deeper dissection of the specimen shown in Figure 3-3 (above).
3-5 Dissection of the medial aspect of the left cerebral hemisphere showing the cingulum and spiral fibers of the hippocampus.

3-6 Overview of a dissection showing the ventral aspect of the cerebral hemispheres. Note the structures related to ventricular spaces and the structures located at the mesencephalon–diencephalon interface. A number of structures in addition to those labeled can be identified.
Detailed view of a dissection showing the ventral aspects of the cerebral hemispheres; this is of the same specimen shown in Figure 3-6 on page 58. Note the continuum of optic nerve, chiasm, and tract to the lateral geniculate body; the relationship of the optic tract to the crus cerebri; and the relationship of hypothalamic structures on the ventral aspect of the brain. In addition to those labeled, other structures can be identified.
3-8 Dissected view of the brain from the dorsal aspect showing structures associated with the lateral ventricles. Note the appearance of insular and transverse temporal gyri, the fornix, and other structures in addition to those labeled.

3-9 Dissected view of the brain from the dorsal aspect showing lateral and third ventricles, the dorsal surface of the diencephalon, the insula and transverse temporal gyri, and the colliculi. The majority of the fornix and the roof of the third ventricle have been removed. The small tufts of choroid plexus identify the locations of the interventricular foramina. Note the massa intermedia traversing the third ventricle and other structures in addition to those labeled.
A dissection showing caudal diencephalic structures, several telencephalic structures, and the interface of the mesencephalon with caudal parts of the thalamus. On the right side, note the continuation between the fornix and hippocampus; on the left, these structures have been removed to expose the underlying pulvinar. The superior colliculi (SC), the inferior colliculi (IC), and the crus cerebri (CC), as seen from the dorsal aspect, are identified. The asterisks represent the exit points of the trochlear nerves. For further details of the dorsal brainstem, see Figure 2-34 on page 34. Note structures in addition to those labeled.
Internal Morphology of the Brain in Slices and MRI

Brain Slices in the Coronal Plane with MRI

**Orientation to Coronal MRIs:** When looking at a coronal MRI image, you are viewing the image as if you are looking at the face of the patient. Consequently, the observer’s right is the left side of the brain in the MRI and the left side of the patient’s brain. Obviously, the concept of what is the left side versus what is the right side of the patient’s brain is enormously important when using MRI (or CT) to diagnose a neurologically impaired individual.

To reinforce this concept, the rostral surface of each coronal brain slice was photographed. So, when looking at the slice, the observer’s right field of view is the left side of the brain slice. This view of the slice correlates exactly with the orientation of the brain as seen in the accompanying coronal MRIs.
The rostral surface of a coronal section of brain through the anterior limb of the internal capsule and the head of the caudate nucleus. The two MRI images (both are inversion recovery) are at the same plane and show many of the structures identified in the brain slice.
The rostral surface of a coronal section of brain through the level of the anterior commissure and the column of the fornix. The two MRI images (both are inversion recovery) are at the same plane and show many of the structures identified in the brain slice.
The rostral surface of a coronal section of brain through the level of the anterior tubercle of the thalamus and the column of the fornix just caudal to the anterior commissure. Portions of the columns of the fornix and the septum (drawn in as black lines) were removed to more adequately expose the anterior tubercles of the thalamus. The terminal vein is also called the superior thalamostriate vein. The two MRI images (both are inversion recovery) are at the same plane and show many of the structures identified in the brain slice.
The rostral surface of a section of brain through the anterior nucleus of the thalamus, mammillothalamic tract, and mammillary bodies. The two MRI images (both are inversion recovery) are at the same plane and show many of the structures identified in the brain slice. The globus pallidus is clearly divided into its lateral and medial segments in the brain slice. Additionally, the terminal vein is also called the superior thalamostriate vein.
The rostral surface of a coronal section of brain through caudal parts of the ventral lateral nucleus, the massa intermedia, the subthalamic nucleus, and basilar pons. The two MRI images (both are inversion recovery) are at the same plane and show many of the structures identified in the brain slice. The terminal vein is also called the superior thalamostriate vein.
The rostral surface of a coronal section of brain through the lateral dorsal and centromedian nuclei, rostral midbrain (red nucleus), and corticospinal fibers in the basilar pons. The MRI image (inversion recovery) is at the same plane and shows many of the structures identified in the brain slice. The terminal vein is also called the superior thalamostriate vein.
The rostral surface of a coronal section of brain through the pulvinar, medial, and lateral geniculate nuclei, the basilar pons, and middle cerebellar peduncle. The two MRI images (both inversion recovery) are at the same plane and show many of the structures in the brain slices. The terminal vein is also called the superior thalamostriate vein. For details of the cerebellum see Figures 2-31 to 2-33 on pp. 32 and 33.
The rostral surface of a coronal section of brain through the pulvinar nucleus, the superior colliculus, the middle cerebellar peduncle, and the rostral portion of the medulla oblongata. The two MRI images (both are inversion recovery) are at the same plane and show many of the structures identified in the brain slice. The terminal vein is also called the superior thalamostriate vein. For details of the cerebellum see Figures 2-31 to 2-33 on pp. 32 and 33.
The rostral surface of a coronal section of brain through the splenium of corpus callosum, the inferior colliculus, the middle cerebellar peduncle in the base of the cerebellum, and the rostral portion of the medulla oblongata. The plane of the section is also through the atrium of the lateral ventricles. The two MRI images (both are inversion recovery) are at the same plane and show many of the structures identified in the brain slice. For details of the cerebellum see Figures 2-31 to 2-33 on pp. 32 and 33.
Internal Morphology of the Brain in Slices and MRI

Brain Slices in the Axial Plane with MRI

**Orientation to Axial MRIs:** When looking at an axial MRI image, you are viewing the image as if standing at the patient’s feet and looking toward his or her head while the patient is lying on his or her back. Consequently, and as is the case in coronal images, the observer’s right is the left side of the brain in the MRI and the left side of the patient’s brain. It is absolutely essential to have a clear understanding of this right-versus-left concept when using MRI (or CT) in the diagnosis of the neurologically impaired patient.

To reinforce this concept, the ventral surface of each axial slice was photographed. So, when looking at the slice, the observer’s right is the left side of the brain slice. This view of the slice correlates exactly with the orientation of the brain as seen in the accompanying axial MRIs.
Ventral surface of an axial section of brain through dorsal portions of corpus callosum. The plane of the section just touches the upper portion of the body of caudate nucleus. The two MRI images (both inversion recovery) are at a similar plane and show some of the structures identified in the brain slice. The terminal vein is also called the superior thalamostriate vein.
Ventral surface of an axial section of brain through the splenium of corpus callosum and the head of the caudate nucleus. This plane includes only a small portion of the dorsal thalamus. The two MRI images (inversion recovery—left; T2-weighted—right) are at a comparable plane and show some of the structures identified in the brain slice. The terminal vein is also called the superior thalamostriate vein.
Ventral surface of an axial section of brain through the genu of the corpus callosum, head of caudate nucleus, centromedian nucleus, and dorsal portions of the pulvinar. The two MRI images (inversion recovery—left; T2-weighted—right) are at the same plane and show many of the structures identified in the brain slice. The arrowheads in the brain slice and in the MRIs are pointing to the mammillothalamic tract. The terminal vein is also called the superior thalamostriate vein.
Ventral surface of an axial section of brain through the anterior commissure, column of fornix, medial and lateral geniculate nuclei, and superior colliculus. The medial and lateral segments of the globus pallidus are visible on the slice. The lateral and medial segments of the globus pallidus can be discerned on the right side of the brain. The MRI images (both T2-weighted) are at approximately the same plane and show many of the structures identified in the brain slice.
Ventral surface of an axial section of brain through the hypothalamus, mammillary body, crus cerebri, and inferior colliculus. The two MRI images (inversion recovery—left; T2-weighted—right) are at similar planes and show many of the structures identified in the brain slice. For details of the cerebellum see Figures 2-31 to 2-33 on pp. 32 and 33.
Ventral surface of an axial section of brain through rostral parts of the basilar pons and the anterior lobe of the cerebellum. The two MRI images (T2-weighted—left; inversion recovery—right) are at the same plane and show many of the structures identified in the brain slice. For details of the cerebellum see Figures 2-31 to 2-33 on pp. 32 and 33.
Ventral surface of an axial section of brain through the middle regions of the basilar pons, the exit of the trigeminal nerve, the fourth ventricle, and the cerebellar nuclei. The three MRI images (inverted inversion recovery—upper left; T2-weighted—upper right; T1-weighted—lower) are at the same planes and show many of the structures identified in the brain slice. Note the lesion in the basilar pons (upper right). For details of the cerebellum see Figures 2-31 to 2-33 on pp. 32 and 33.
Ventral surface of an axial section of brain through portions of the medulla oblongata, just caudal to the pons–medulla junction and the posterior lobe of the cerebellum. The three MRI images (T1-weighted—upper left and right; T2-weighted—lower) are at the same plane and show many of the structures identified in the brain slice. Note the lateral medullary lesion (lower), also known as the posterior inferior artery syndrome or the lateral medullary syndrome (of Wallenberg). For details of the cerebellum see Figures 2-31 to 2-33 on pp. 32 and 33.
Internal Morphology of the Spinal Cord and Brain in Stained Sections

Basic concepts that are essential when one is initially learning how to diagnose the neurologically impaired patient include 1) an understanding of cranial nerve nuclei and 2) how these structures relate to long tracts. The importance of these relationships is clearly seen in the combinations of deficits that generally characterize lesions at different levels of the neuraxis. First, deficits of only the body that may present as motor or sensory losses (long tracts) on the same, or opposite, sides are indicative of spinal cord lesions (e.g., Brown-Sequard syndrome). Spinal cord injuries characteristically have motor and sensory levels; these are the lowest functional levels remaining in the compromised patient. Second, cranial nerve deficits (on one side of the head) in combination with long tract signs (on the opposite side of the body) characterize lesions in the brainstem (e.g., lateral medullary or Weber syndromes). These patterns of loss are frequently called alternating or crossed deficits. In these examples cranial nerve signs are better localizing signs than are long tract signs. A localizing sign can be defined as an objective neurologic abnormality that correlates with a lesion (or lesions) at a specific neuroanatomical location (or locations). Third, motor and sensory deficits on the same side of the head and body are usually indicative of a lesion in the forebrain.

Color Coded Cranial Nerve Nuclei and Long Tracts: Cranial nerve nuclei are coded by their function: pink, sensory; red, motor. These structures are colored bilaterally to make it easy to correlate cranial nerve and long tract function on both sides of the midline. For example, one can easily correlate damage to the hypoglossal nerve root and the adjacent corticospinal fibers on one side while comparing this pattern with the clinical picture of a lateral medullary syndrome on the other side.

Long tracts are color-coded beginning at the most caudal spinal cord levels (e.g., see Figures 5-31 and 5-32), with these colors extending into the dorsal thalamus (see Figure 5-30) and the posterior limb of the internal capsule (see Figures 5-31 and 5-32). The colorized spinal tracts are the fasciculus gracilis (dark blue), the fasciculus cuneatus (light blue)*, the anterolateral system (dark green), and the lateral corticospinal tract (grey). In the brainstem, these spinal tracts are joined by the spinal trigeminal tract and ventral trigeminothalamic fibers (both are light green). The long tracts are color-coded on one side only, to emphasize 1) laterality of function and dysfunction, 2) points at which fibers in these tracts may decussate, and 3) the relationship of these tracts to cranial nerves.

A color key appears on each page. This key identifies the various tracts and nuclei by their color and specifies the function of each structure on each page. This approach not only emphasizes anatomical and clinical concepts, but also lends itself to a variety of instructional settings.

Correlation of MRI and CT with Spinal Cord and Brainstem: As one is learning basic anatomical concepts it is essential to consider how this information may be used in the clinical environment. To this end, MRI (T1- and T2-weighted) and CT (myelogram/cisternogram) images are introduced into the spinal cord and brainstem sections of this chapter (see also Chapter 1). To show the relationship between basic anatomy and how MRI and CT are viewed, a series of self-explanatory illustrations are provided on each set of facing pages in these sections. This continuum of visual information consists of (1) a small version of the colorized line drawing in an Anatomical Orientation, (2) a top-to-bottom flip of this illustration that brings it into a Clinical Orientation, and (3) a CT (spinal cord) or MRI and CT (brainstem) that follows this clinically oriented image. Every effort is made to identify and use MRI and CT that correlate, as closely as possible, with their corresponding line drawing and stained section. This approach recognizes and retains the strength of the anatomical approach, introduces essential clinical concepts while at the same time allowing the user to customize the material to suit a range of educational applications.

*The dark and light blue colors represent information originating from lower and upper portions of the body, respectively.
5-1 Transverse section of the spinal cord showing the characteristics of a sacral level. The gray matter occupies most of the cross-section; its H-shaped appearance is not especially obvious at sacral–coccygeal levels. The white matter is a comparatively thin mantle. The sacral cord, although small, appears round in the CT myelogram. Note the appearance of the sacral spinal cord surrounded by the upper portion of the cauda equina (left) and the cauda equina as it appears caudal to the conus medullaris in the lumbar cistern (right). Compare with Figure 2-4 on page 12.
Anatomical orientation

Clinical orientation

CT myelogram

CT myelogram

The Spinal Cord With CT
5-2 Transverse section of the spinal cord showing its characteristic appearance at lumbar levels (L4). Posterior and anterior horns are large in relation to a modest amount of white matter, and the general shape of the cord is round. Fibers of the medial division of the posterior root directly enter the gracile fasciculus. The lumbar spinal cord appears round in the CT myelogram. The roots of upper portions of the cauda equina surround the lower levels of the lumbar spinal cord (right).
The Spinal Cord With CT

CT myelogram

Anterior root

Posterior root

Lumbar spinal cord

Cauda equina

CT myelogram
Transverse section of the spinal cord showing its characteristic appearance at thoracic levels (T4). The white matter appears large in relation to the rather diminutive amount of gray matter. Posterior and anterior horns are small, especially when compared to low cervical levels and to lumbar levels. The overall shape of the cord is round. The thoracic spinal cord appears round in CT myelogram.
The Spinal Cord With CT

Anatomical orientation
Clinical orientation
CT myelogram

Anterior root
Posterior root
Transverse section of the spinal cord showing its characteristic appearance at lower cervical levels (C7). The anterior horn is large, and there is—proportionally and absolutely—a large amount of white matter. The overall shape of the cord is oval. The lower portions of the cervical spinal cord appears oval in MRI (left) and in CT myelogram (center and right).
The Spinal Cord With CT

Anatomical orientation
Clinical orientation
CT myelogram
MRI, T2 weighted image
CT myelogram
5-5 Transverse section of the spinal cord at the C1 level. Lateral corticospinal fibers are now located medially toward the decussation of the corticospinal fibers, also called the motor decussation or pyramidal decussation (see also Figure 5-8, page 98). At this level, fibers of the spinal trigeminal tract are interdigitated with those of the dorsolateral tract. The spinal cord at C₁ and C₂ levels appear round in CT myelogram when compared to low cervical levels (see Figure 5-4).

Vascular Syndromes or Lesions of the Spinal Cord

Acute Central Cervical Spinal Cord Syndrome: Results from occlusion of the anterior spinal artery.

**Deficit**
- Bilateral paresis or flaccid paralysis of upper extremities
- Irregular loss of pain and temperature sensations bilaterally over body below lesion

**Structure Damage**
- Medial portions of both lateral corticospinal tracts; ventral grey horns at cervical levels
- Anterolateral system fibers (partial involvement bilaterally)

**Comment:** Hyperextension of the neck may cause damage to the vertebral arteries (which give rise to the anterior spinal artery), or it may directly damage the anterior spinal artery, causing a spasm. This vascular damage leads to a temporary or permanent interruption of blood supply. Deficits may resolve within a few hours or may be permanent, depending on the extent of vascular complication. Sparing of the dorsal columns (proprioception, vibratory sense) is a hallmark; approximately the anterior two-thirds of the spinal cord is ischemic.

Thrombosis of Anterior Spinal Artery: This may occur in a hypertensive crisis, as a result of trauma resulting from a dissecting aortic aneurysm, or in patients with atherosclerosis. It may occur at all spinal levels but is more frequently seen in thoracic and lumbosacral levels unless trauma is the primary cause. Results are bilateral flaccid paraplegia (if lesion is below cervical levels) or quadriplegia (if lesion is in cervical levels), urinary retention, and loss of pain and temperature sensation. Flaccid muscles may become spastic over a period of a day to weeks, with hyperactive deep tendon reflexes and extensor plantar (Babinski) reflexes. In addition, lesions at high cervical levels may also result in paralysis of respiratory muscles. The artery of Adamkiewicz (an especially large spinal medullary artery) is usually located at spinal levels T5–L1 and more frequently arises on the left side. Occlusion of this vessel may infarct lumbosacral levels of the spinal cord.

**Hemorrhage in the spinal cord:** This is rarely seen but may result from trauma or bleeding from congenital vascular lesions. Symptoms may develop rapidly or gradually in stepwise fashion, and blood is usually present in the cerebrospinal fluid.

**Arteriovenous malformation in spinal cord:** More frequently found in lower cord levels. Symptoms (micturition problems are seen early, motor deficits, lower back pain) may appear over time and may seem to resolve then recur (get better then worse). These lesions are usually found external to the cord (extramedullary) and can be surgically treated, especially when the major feeding vessels are few in number and easily identified. Foix-Alajouanine syndrome is an inflammation of spinal veins with subsequent occlusion that results in infarct of the spinal cord and a necrotic myelitis. The symptoms are ascending pain and a flaccid paralysis.

Brown-Sequard syndrome: This syndrome is a hemisection of the spinal cord that may result from trauma, compression of the spinal cord by tumors or hematomas, or significant protrusion of an intervertebral disc. The deficits depend on the level of the causative lesion. The classic signs are (1) a loss of pain and thermal sensation on the contralateral side of the body beginning about 1–2 segments below the level of the lesion (damage to anterolateral system fibers), (2) a loss of discriminative touch and proprioception on the ipsilateral side of the body below the lesion (interruption of posterior column fibers), and (3) a paralysis on the ipsilateral side of the body below the lesion (damage to lateral corticospinal fibers). This syndrome is classified as an incomplete spinal cord injury (see below) and the majority of patients with this lesion will regain some type of motor and sensory function. Compression of the spinal cord may result in some, but not all, of the signs and symptoms of the syndrome.

Syringomyelia: This condition is cavitation of central portion of the spinal cord. A cavitation of the central canal with an ependymal cell lining is hydromyelia. A syrinx may originate in central portions of the spinal cord, may communicate with the central canal, and is most commonly seen in cervical levels of the spinal cord. The most common deficits are a bilateral loss of pain and thermal sensation due to damage to the anterior white commissure: the loss reflects the levels of the spinal cord damaged (e.g., a cape distribution over the shoulder and upper extremities). The other commonly seen deficit results from extension of the cavity into the anterior horn(s). The result is an unilateral or bilateral paralysis of the upper extremities (cervical levels) or lower extremities (lumbosacral levels) due to damage to the anterior motor neuron cells. A syrinx in the spinal cord, particularly in cervical levels, may be associated with a variety of other developmental defects in the nervous system.

Spinal Cord Lesions: A complete spinal cord lesion is characterized by a bilateral and complete loss of motor and sensory function below the level of lesion persisting for more than 24 hours. The vast majority of the patients with complete lesions (95%+) will suffer some permanent deficits. Incomplete spinal cord lesions are those with preservation of sacral cord function at presentation. The above described cases are examples of incomplete spinal cord lesions.

5-6  Semidigrammatic representation of the internal blood supply to the spinal cord. This is a tracing of a C4 level, with the positions of principal tracts superimposed on the left and the general pattern of blood vessels superimposed on the right.

All of the brainstem sections used in Figures 5-9 through 5-13 (medulla), 5-17 through 5-20 (pons), and 5-22 through 5-25 (mid-brain) are from an individual who had an infarct (green in drawing) in the posterior limb of the internal capsule. This lesion damaged corticospinal fibers (grey in drawing), resulting in a contralateral hemiplegia of the arm and leg, and damaged sensory radiations that travel from thalamic nuclei to the somatosensory cortex through the posterior limb of the internal capsule. Although the patient survived the initial episode, corticospinal fibers (grey) distal to the lesion (green) underwent degenerative changes and largely disappeared. This Wallerian (anterograde) degeneration takes place because the capsular infarct effectively separates the descending corticospinal fibers from their cell bodies in the cerebral cortex. Consequently, the location of corticospinal fibers in the middle one-third of the crus cerebri of the mid-brain, in the basilar pons, and in the pyramid of the medulla is characterized by the obvious lack of myelinated axons in these structures when compared to the opposite side. In the brainstem, these degenerated fibers are ipsilateral to their cells of origin but are contralateral to their destination in the spinal cord—hence, the contralateral motor deficit. These photographs give the user the unique opportunity of seeing where corticospinal fibers are located at all levels of the human brainstem. Also, one is constantly reminded of 1) the relationship of corticospinal fibers to other structures, 2) the deficits one can expect to see at representative levels due to this lesion, and 3) the general appearance of degenerated fibers in the human central nervous system. These images can be adapted to a wide range of instructional formats.

Clinical orientation

MRI, T2-weighted image

MRI, T1-weighted image

CT cisternogram
Vascular Syndromes or Lesions of the Medulla Oblongata

**Medial Medullary Syndrome:** Results from occlusion of branches of anterior spinal artery.

**Deficits**
- Contralateral hemiplegia of arm and leg
- Contralateral loss of position sense, vibratory sense and discriminative touch
- Deviation of tongue to ipsilateral side when protruded; muscle atrophy and fasciculations

**Structure Damaged**
- Pyramidal (corticospinal) fibers
- Medial lemniscus
- Hypoglossal nerve in medulla or hypoglossal nucleus

**Comment:** The medial medullary syndrome is rare compared to the more common occurrence of the lateral medullary syndrome. Nystagmus may result if the lesion involves the medial longitudinal fasciculus or the nucleus prepositus hypoglossi. The lesion may involve ventral trigeminothalamic fibers, but diminished pain and thermal sense from the contralateral side of the face is rarely seen. The combination of a contralateral hemiplegia and ipsilateral deviation of the tongue is called an inferior alternating hemiplegia when the lesion is at this level.

**Lateral Medullary Syndrome:** Results from occlusion of posterior inferior cerebellar artery or branches of PICA to dorsolateral medulla (PICA syndrome, Wallenberg syndrome). In many cases the lateral medullary syndrome frequently results from occlusion of the vertebral artery with consequent loss of flow into PICA.

**Deficits**
- Ipsilateral Horner syndrome (miosis, ptosis, anhidrosis, flushing of face)
- Nausea, diplopia, tendency to fall to ipsilateral side, nystagmus, vertigo
- Ataxia to the ipsilateral side
- Ipsilateral Horner syndrome (miosis, ptosis, anhidrosis, flushing of face)
- Descending hypothalamospinal fibers
- Vestibular nuclei (mainly inferior and medial)
- Restiform body and spinocerebellar fibers

**Structure Damaged**
- Anterolateral system fibers
- Spinal trigeminal tract and nucleus
- Nucleus ambiguus, roots of 9th and 10th nerves
- Nucleus motorius, roots of 10th nerve
- Ipsilateral Horner syndrome (miosis, ptosis, anhidrosis, flushing of face)
- Descending hypothalamospinal fibers
- Vestibular nuclei (mainly inferior and medial)
- Restiform body and spinocerebellar fibers

**Comment:** In addition to the above, involvement of the solitary tract and nucleus may (rarely) cause dysguesia. Dypnea and tachycardia may be seen in patients with damage to the dorsal motor nucleus of the vagus. It is also possible that damage to respiratory centers in the reticular formation or to the vagal motor nucleus may result in hiccup (singultus). Bilateral medullary damage may cause the syndrome of “Ondine’s curse,” an inability to breathe without willing it or “thinking about it.”

**Tonsillar Herniation:** Although the cerebellar tonsil is not part of the medulla, the herniation of this structure (tonsillar herniation) down through the foramen magnum has serious consequences for function of the medulla. The coning of the cerebellar tonsils into, and through, the foramen magnum may compress the medulla resulting in cardiac and respiratory arrest. This is due to a combination of pressure on the medulla and the occlusion of small vessels serving cardiac and respiratory centers in the lateral area of the medulla. Patients experiencing a sudden herniation of the cerebellar tonsils may lose consciousness rapidly and die.

**Syringobulbia:** A cavitation within the brainstem (syringobulbia) may exist with syringomyelia, be independent of syringomyelia, or in some cases both may exist and communicate with each other. The cavity in syringobulbia is usually on one side of the midline of the medulla. Signs and symptoms of syringobulbia may include weakness of tongue muscles (hypoglossal nucleus or nerve), weakness of pharyngeal, palatal, and vocal musculature (ambiguus nucleus), nystagmus (vestibular nuclei), and loss of pain and thermal sensation on the ipsilateral side of the face (spinal trigeminal tract and nucleus or crossing of trigeminothalamic fibers).
5-15 Transverse section through the dorsal aspects of medulla at the level of the cochlear nuclei and the cerebellar nuclei. The plane corresponds to about the middle of the dentate nucleus and caudal portions of the globus and emboliform nuclei. For additional details of the medulla at this level see figure 5-12 on page 106.
Transverse section through dorsal portions of pons at the level of the abducens nucleus (and facial colliculus) and through rostral portions of the cerebellar nuclei. For additional details of the pons at this level see Figure 5-17 on page 116.
5-17 Transverse section of the caudal pons through the facial motor nucleus, abducens nucleus (and facial colliculus), and the intramedullary course of fibers of facial and abducens nerves.

The Pons With MRI and CT
Transverse section of the rostral pons through the exit of the trochlear nerve and rostral portions of the exit of the trigeminal nerve.
Vascular Syndromes or Lesions of the Pons

**Medial Pontine Syndrome:** Results from occlusion of paramedian branches of basilar artery.

**Deficits**
- Contralateral hemiplegia of arm and leg
- Contralateral loss or decrease of position and vibratory sense and discriminative touch (arm and leg)
- Ipsilateral lateral rectus muscle paralysis
- Paralysis of conjugate gaze toward side of lesion

**Structure Damaged**
- Corticospinal fibers in basilar pons
- Medial lemniscus
- Abducens nerve fibers or nucleus
- Paramedian pontine reticular formation (pontine gaze center)

**Comment:** The combination of corticospinal deficits on one side of the body coupled with a cranial nerve motor deficit on the opposite is called a *middle alternating hemiplegia* when the lesion is at this level. Diplopia will result (abducens nerve lesion) on gaze toward the side of the lesion. Involvement of the abducens nucleus may also result in an inability to adduct the contralateral medial rectus muscle (damage to abducens internuclear neurons).

At caudal levels the lesion may extend lateral to involve the lateral lemniscus (*hypacusis*), parts of the middle cerebellar peduncle (some *ataxia*), the facial motor nucleus (*ipsilateral facial paralysis*), the spinal trigeminal tract and nucleus (*ipsilateral loss of pain and thermal sensation from the face*), and the anterolateral system (*contralateral loss of pain and thermal sensation from the body*). At rostral pontine levels the lesion may extend into the medial lemniscus or may involve only the arm fibers within this structure (*contralateral loss of vibratory sense, proprioception, and discriminative touch*), the motor nucleus of the trigeminal nerve (*ipsilateral paralysis of masticatory muscles*), or may damage the anterolateral system and rostral portions of the spinal trigeminal tract and nucleus (*loss of pain and thermal sensation from the body* [contralateral] and from the face [ipsilateral]).

**Lateral Pontine Syndrome:** Results from occlusion of long circumferential branches of basilar artery.

**Deficit**
- Ataxia, unsteady gait, fall toward side of lesion
- Vertigo, nausea, nystagmus, deafness, tinnitus, vomiting (at caudal levels)
- Ipsilateral paralysis of facial muscles
- Ipsilateral paralysis of masticatory muscles
- Ipsilateral Horner syndrome
- Ipsilateral loss of pain and thermal sense from face
- Contralateral loss of pain and thermal sense from body
- Paralysis of conjugate horizontal gaze

**Structure Damaged**
- Middle and superior cerebellar peduncles (caudal and rostral levels)
- Vestibular and cochlear nerves and nuclei
- Facial motor nucleus (caudal levels)
- Trigeminal motor nucleus (midpontine levels)
- Descending hypothalamospinal fibers
- Spinal trigeminal tract and nucleus
- Anterolateral system
- Paramedian pontine reticular formation (at mid to caudal levels)

**Comment:** The various combinations of these deficits may vary depending on whether the lesion is located in lateral pontine areas at caudal levels versus lateral pontine areas at rostral levels. As noted above lesions located in lateral portions of the pontine tegmentine may also extend medial at either caudal or rostral levels and give rise to some of the deficits discussed above in the section on medial pontine syndrome.

Vascular Syndromes or Lesions of the Midbrain

**Medial Midbrain (Weber) Syndrome:** May result from occlusion of paramedian branches of P_1 segment of posterior cerebral artery.

<table>
<thead>
<tr>
<th>Deficit</th>
<th>Structure Damaged</th>
</tr>
</thead>
<tbody>
<tr>
<td>Contralateral hemiplegia of arm and leg</td>
<td>Corticospinal fibers in crus cerebri</td>
</tr>
<tr>
<td>Ipsilateral paralysis of eye movement; eye oriented down and out and pupil dilated and fixed</td>
<td>Oculomotor nerve</td>
</tr>
</tbody>
</table>

**Comment:** This combination of motor deficits at this level of the brainstem is called a superior alternating hemiplegia. This pattern consists of ipsilateral paralysis of eye movement and contralateral hemiplegia of the upper and lower extremities. Damage to the corticonuclear (corticobulbar) fibers in the crus cerebri may result in a partial deficit in tongue and facial movement on the contralateral side. These cranial nerve deficits are seen as a deviation of the tongue to the side opposite the lesion on attempted protrusion and a paralysis of the lower half of the facial muscles on the contralateral side. Although parts of the substantia nigra are frequently involved, akinetic or dyskinesia are not frequently seen.

**Central Midbrain Lesion (Claude syndrome)**

<table>
<thead>
<tr>
<th>Deficit</th>
<th>Structure Damaged</th>
</tr>
</thead>
<tbody>
<tr>
<td>Ipsilateral paralysis of eye movement; eye oriented down and out and pupil dilated and fixed</td>
<td>Oculomotor nerve</td>
</tr>
<tr>
<td>Contralateral ataxia and tremor of cerebellar origin</td>
<td>Red nucleus and cerebellothalamic fibers</td>
</tr>
</tbody>
</table>

**Comment:** The lesion in this syndrome may extend laterally into the medial lemniscus and the dorsally adjacent ventral trigeminothalamic fibers. If this was the case, there could conceivably be a loss or diminution of position and vibratory sense and of discriminative touch from the contralateral arm and partial loss of pain and thermal sensation from the contralateral face.

**Benedikt syndrome:** This results from a larger lesion of the midbrain that essentially involves both of the separate areas of Weber and Claude. The main deficits are contralateral hemiplegia of arm and leg (corticospinal fibers), ipsilateral paralysis of eye movement with dilated pupil (oculomotor nerve), and cerebellar tremor and ataxia (red nucleus and cerebellothalamic fibers). Slight variations may be present based on the extent of the lesion.

**Parinaud syndrome:** This syndrome is usually caused by a tumor in the pineal region, such as germinoma, astrocytoma, pineocytoma/pineoblastoma, or any of a variety of other tumors that impinge on the superior colliculi. The potential for occlusion at the cerebral aqueduct in these cases also indicates that hydrocephalus may be a component of this syndrome. The deficits in these patients consist of a paralysis of upward gaze (superior colliculi), hydrocephalus (occlusion of the cerebral aqueduct), and eventually a failure of eye movement due to pressure on the oculomotor and trochlear nuclei. These patients may also exhibit nystagmus due to involvement of the medial longitudinal fasciculus.

**Uncal Herniation:** Herniation of the uncus occurs in response to large and rapidly expanding lesions in the cerebral hemisphere, this being a supratentorial location. Uncal herniation is an extrusion of the uncus through the tentorial notch (tentorial incisura) with resultant pressure on the oculomotor nerve and the crus cerebri of the midbrain. Initially the pupils, unilaterally or bilaterally, may dilate or respond slowly to light, followed by weakness of oculomotor movement. As herniation progresses the pupils will be fully dilated, eye movements regulated by the oculomotor nerve may be slow or absent, and the eyes will deviate slightly laterally due to the unopposed actions of the abducens nerves. There is usually weakness on the contralateral side of the body due to compression of corticospinal fibers in the crus cerebri. However, if pressure is sufficient the entire midbrain may shift so that there can be contralateral as well as ipsilateral weakness due to pressure on the same side and pressure on the opposite side of the crus cerebri. This hemiplegia ipsilateral to the herniation and ipsilateral to the oculomotor deficits is called the Kernohan phenomenon. As damage from the pressure on the midbrain extends down and into the upper pons the pupils are dilated and fixed, eye movement is largely absent, respiration is decreased, and the patient will become decerebrate (upper and lower extremities extended, toes pointed inward, fingers flexed, forearm pronated, head and neck extended).

5-27 Semidiagrammatic representation of the internal distribution of arteries in the midbrain. Selected main structures are labeled on the left side of each section; the typical pattern of arterial distribution overlaps these structures on the right side. The general distribution patterns of the vessels to the midbrain as shown here may vary somewhat from patient to patient. For example, the adjacent territories served by neighboring vessels may overlap differing degrees at their margins or the territory of a particular vessel may be larger or smaller than seen in the general pattern.

Arterial Patterns Within The Midbrain With Vascular Syndromes

137

Rostral Caudal

Anteromedial (paramedian) branches of basilar bifurcation and P1 segment

Lateral branches of quadrigeminal (level of inferior colliculus), quadrigeminal and posterior medial choroidal arteries (level of superior colliculus)

Anterolateral (short circumferential) branches of the quadrigeminal and medial posterior choroidal arteries

Quadrigeminal and superior cerebellar arteries (level of inferior colliculus), quadrigeminal and posterior medial choroidal arteries (level of superior colliculus)

Thalamogeniculate artery
Coronal section of forebrain through the sphenium of the corpus callosum and crus of fornix, and extending into the inferior colliculus and exit of the trochlear nerve. Many of the structures labeled in this figure can be easily identified in the T1-weighted MRI adjacent to the photograph.
Coronal section of the forebrain through the pulvinar and the medial and lateral geniculate nuclei. The section extends into upper portions of the midbrain tegmentum. Many of the structures labeled in this figure can be easily identified in the T1-weighted MRI adjacent to the photograph.
5-30 Slightly oblique section of the forebrain through the pulvinar, ventral posteromedial, and ventral posterolateral nuclei. The section extends rostrally through the subthalamic nucleus and ends in the caudal hypothalamus just dorsal to the mamillary bodies as seen by the position of the (postcommissural) fornix.
Coronal section of the forebrain through the lateral ventricle, massa intermedia, and subthalamic nucleus. Many of the structures labeled in this figure can be easily identified in the T1-weighted MRI adjacent to the photograph.
Coronal section of the forebrain through the anterior nucleus of the thalamus and mammillary body. Many of the structures labeled in this figure can be easily identified in the T1-weighted MRI.
Slightly oblique section of the forebrain through the anterior nucleus of the thalamus and the subthalamic nucleus. The section also includes the rostral portion of the midbrain tegmentum. Many of the structures labeled in this figure can be easily identified in the T1-weighted MRI adjacent to the photograph.
The Diencephalon and Basal Nuclei With MRI
Coronal section of the forebrain through the interventricular foramen, genu of the internal capsule, rostral tip of the dorsal thalamus, and about the middle one-third of the hypothalamus. Many of the structures labeled in this figure can be easily identified in the T1-weighted MRI adjacent to the photograph.
5-35 Coronal section of the forebrain through the anterior commissure and rostral aspects of the hypothalamus. Many of the structures labeled in this figure can be easily identified in the T1-weighted MRI.
Coronal section of the forebrain through the **head of the caudate nucleus**, rostral portions of the **optic chiasm**, and the **nucleus accumbens**. Many of the structures labeled in this figure can be easily identified in the T1-weighted MRI adjacent to the photograph.
Coronal section of forebrain through the head of the caudate nucleus and the anterior horn of the lateral ventricle. Many of the structures labeled in this figure can be easily identified in the T1-weighted MRI adjacent to the photograph.
The Diencephalon and Basal Nuclei With MRI
Vascular Syndromes or Lesions of the Forebrain

Forebrain vascular lesions result in a wide range of deficits that include motor and sensory losses and a variety of cognitive disorders. Forebrain vessels may be occluded by a thrombus. This is a structure (usually a clot) formed by blood products and frequently attached to the vessel wall. Deficits may appear slowly, or wax and wane, as the blood flow is progressively restricted.

Vessels may also be occluded by embolization. A foreign body, or emboli (fat, air, piece of thrombus, piece of sclerotic plaque, clump of bacteria, etc.), is delivered from some distant site into the cerebral circulation where it lodges in a vessel. Since this is a sudden event deficits usually appear quickly and progress rapidly. Interruption of blood supply to a part of the forebrain will result in an "infarct" of the area served by the occluded vessel.

**Lesion in the Subthalamic Nucleus:** Small vascular lesions occur in the subthalamic nucleus, resulting in rapid and unpredictable flailing movements of the contralateral extremities (hemiballismus). Movements are more obvious in the arm than in the leg. The clinical expression of this lesion is through corticospinal fibers, therefore it is on the contralateral side of the body.

**Occlusion of Lenticulostriate Branches to Internal Capsule:** Damage to the internal capsule may result in contralateral hemiplegia (corticospinal fibers) and a loss, or diminution, of sensory perception (pain, thermal sense, proprioception) caused by damage to thalamocortical fibers traversing the posterior limb of the overlying sensory cortex. If the lesion extends into the genu of the capsule, a partial paralysis of facial muscles and tongue movement may also occur contralaterally.

**Infarction of Posterior Thalamic Nuclei:** Occlusion of vessels to posterior thalamic regions results in either a complete sensory loss (pain/thermal sense, touch, vibratory and position sense) on the contralateral side of the body, or a dissociated sensory loss. In the latter case the patient may experience pain/thermal sensory losses but not position/vibratory losses, or vice versa. As the lesion resolves the patient may experience intense persistent pain, thalamic pain, or anesthesia dolorosa.

**Occlusion of Distal Branches of the Anterior (ACA) or Middle (MCA) Cerebral Arteries:** Occlusion of distal branches of the ACA results in motor and sensory losses in the contralateral foot, leg, and thigh owing to damage to the anterior and posterior paracentral gyri (primary motor and sensory cortices for lower extremity). Occlusion of distal branches of MCA results in contralateral motor and sensory losses of the upper extremity, trunk, and face with sparing of the leg and foot, and a consensual deviation of the eyes to the ipsilateral side. This represents damage to the precentral and postcentral gyri and to the frontal eye fields.

**Watershed Infarct:** Sudden systemic hypotension, hypoperfusion, or embolic showers may result in infarcts at border zones between the territories served by the ACA, MCA, and posterior cerebral artery (PCA). Anterior watershed infarcts (at the ACA–MCA junction) result in a contralateral hemiparesis (mainly leg) and expressive language or behavioral changes. Posterior watershed infarcts (MCA–PCA interface) result in visual deficits and language problems.

**Anterior Choroidal Artery Syndrome:** Occlusion of this vessel may result from small emboli or small vessel disease. This syndrome may also occur as a complication of temporal lobectomy (removal of the temporal lobe to treat intractable epilepsy). The infarcted area usually includes the optic tract, lower portions of the basal nuclei, and lower aspects of the internal capsule. The patient experiences a contralateral hemiplegia, hemihypathesia, and homonymous hemianopsia. These deficits are due to, respectively, involvement of corticospinal fibers in the posterior limb of the internal capsule or possibly in the crus cerebri, involvement of thalamocortical fibers in the posterior limb of the internal capsule, and involvement of the fibers of the optic tract.

**Parkinson Disease:** Parkinson disease (paralysis agitans) results from a loss of the dopamine-containing cells in the substantia nigra. Although this part of the brain is located in the midbrain, the terminals of these nigrostriatal fibers are in the putamen and the caudate nucleus. The classic signs and symptoms of this disease are a stooped posture, resting tremor, rigidity, shuffling or festinating gait, and difficulty initiating or maintaining movement (akinesia, hypokinesia, or bradykinesia). Initially, the tremor and walking difficulty may appear on one side of the body, but these signs usually spread to both sides with time. This is a neurodegenerative disease that has, in its later stages, a dementia component.

**Transient Ischemic Attack:** A transient ischemic attack, commonly called TIA, is a temporary (and frequently focal) neurologic deficit that usually resolves within 10 to 30 minutes from the onset of symptoms. The cause is temporary occlusion of a vessel or inadequate perfusion of a restricted vascular territory. TIA that last 60+ minutes may result in some permanent deficits. This vascular event may take place anywhere in the central nervous system but is more common in the cerebral hemisphere.

Internal Morphology of the Brain in Stained Sections: Axial–Sagittal Correlations with MRI

Although the general organization of Chapter 6 has been described in Chapter 1 (the reader may wish to refer back to this section), it is appropriate to reiterate its unique features at this point. Each set of facing pages has photographs of an axial stained section (left-hand page) and a sagittal stained section (right-hand page). In addition to individually labeled structures, a heavy line appears on each photograph. This prominent line on the axial section represents the approximate plane of the sagittal section located on the facing page. On the sagittal section this line signifies the approximate plane of the corresponding axial section. The reader can identify features in each photograph and then, using this line as a reference point, visualize structures that are located either above or below that plane (axial to sagittal comparison) or medial or lateral to that plane (sagittal to axial comparison). This method of presentation provides a format for reconstructing and understanding three-dimensional relationships within the central nervous system.

The magnetic resonance image (MRI) placed on every page in this chapter gives the reader an opportunity to compare internal brain anatomy, as seen in stained sections, with those structures as visualized in clinical images generated in the same plane. Even a general comparison reveals that many features, as seen in the stained section, can be readily identified in the adjacent MRI.

This chapter is also organized so that one can view structures in either the axial or the sagittal plane only. Axial photographs appear on left-hand pages and are sequenced from dorsal to ventral (odd-numbered Figures 6-1 through 6-9), while sagittal photographs are on the right-hand pages and progress from medial to lateral (even-numbered Figures 6-2 through 6-10). Consequently, the user can identify and follow structures through an axial series by simply flipping through the left-hand pages or through a sagittal series by flipping through the right-hand pages. The inherent flexibility in this chapter should prove useful in a wide variety of instructional/learning situations. The drawings shown in the following illustrate the axial and sagittal planes of the photographs in this chapter.
Axial section through the head of the caudate nucleus and several key thalamic nuclei (anterior, centromedian, pulvinar, habenular). The heavy line represents the approximate plane of the sagittal section shown in Figure 6-2 (facing page). Many of the structures labeled in this photograph can be clearly identified in the adjacent T1-weighted MRI.

Synopsis of Functional Components, Tracts, Pathways, and Systems

The study of *regional neurobiology* (brain structures in gross specimens, in brain slices, in stained sections, and in MRI and CT) is the basis for the study of *systems neurobiology* (tracts, pathways, cranial nerves and their functions), which, in turn, is the basis for understanding and diagnosing the neurologically impaired patient. Building on the concepts learned in earlier chapters on external and internal brain anatomy in specimens and in MRI and CT, on brain vascular patterns, and on the relationships of cranial nerves with long tracts, this chapter explores *systems neurobiology* with a particular emphasis on clinical correlations.

The format of each set of facing pages is designed to summarize accurately and concisely, the relationships of a given tract or pathway. This includes, but is not limited to, 1) the location of the cells of origin for a given tract/pathway, 2) its entire course throughout the neuraxis and cerebrum, 3) the location of the decussation of these fibers, if applicable, 4) the neurotransmitters associated with the neurons comprising the tract/pathway, 5) a brief review of its blood supply, and 6) a summary of a number of deficits seen as a result of lesions at various points in the tract/pathway. The structure of an atlas does not allow a detailed definition of each clinical term on the printed page. However, the full definition of each clinical term or phrase is available on the CD that comes with this atlas; these are taken from the current edition of *Stedman’s Medical Dictionary*. In this respect, the full definitions are actually available in this book. Researching the full definition of a clinical term or phrase is a powerful and effective learning tool. Also, each clinical term or phrase is available in any standard medical dictionary or comprehensive neurology text.

The layout of the drawings in this chapter clearly shows the laterality of the tract/pathway. That is, the relationship between the location of the cell of origin and the termination of the fibers making up a tract/pathway or the projections of cranial nerve nuclei. *This information is absolutely essential to understanding the position of a lesion and correlating this fact with the deficits seen in the neurologically compromised patient*. For example, is the deficit on the same side as the lesion (ipsilateral), on the opposite side (contralateral), or on both sides (bilateral)? The concept of laterality is usually expressed as “right,” “left,” or “bilateral” in reference to the side of the deficit(s) when written on the patient’s chart.

This chapter is designed to maximize the correlation between structure and function, to provide a range of clinical examples for each tract/pathway, and to help the user develop a knowledge base that can be easily integrated into the clinical setting.
A semidiagrammatic summary of the positions of functional components as seen in the developing neural tube (left) and in the spinal cord and brainstem of the adult (right). In the neural tube, the alar plate and its associated GSA and GVA components are posterior (dorsal) to the sulcus limitans (SL) while the basal plate and its related GVE and GSE components are anterior (ventral) to the SL. In the adult spinal cord, this general posterior/anterior relationship is maintained, although the neural canal (as central canal) is reduced and/or absent.

Two major changes occur in the transition from spinal cord to brainstem in the adult. First, as the central canal of the cervical cord enlarges into the fourth ventricle and the cerebellum develops, the posterior portion of the neural tube is rotated laterally. Consequently, in the adult, the sulcus limitans is present in the brainstem with motor components (adult derivatives of the basal plate) medial to it, and sensory components (adult derivatives of the alar plate) are located laterally. Second, in the brainstem, special functional components (SVE to muscles of pharyngeal arch origin; SVA taste and olfaction; SSA vestibular, auditory, and visual systems) are intermingled with the rostral continuation of the general functional components as found in the spinal cord.

In the brainstem, however, there is a slight transposition of the SVE and GSA functional components. Embryologically, SVE cell groups appear between those associated with GSE and GVE components. As development progresses, however, SVE cell groups migrate (open arrow) to anterolateral areas of the tegmentum. Cell groups associated with the GSA functional component are displaced from their postero-lateral position in the developing brainstem by the newly acquired cell groups having SSA components (as well as other structures). Consequently, structures associated with the GSA component are located (open arrow) in more anterolateral and lateral areas of the brainstem. The approximate border between motor and sensory regions of the brainstem is represented by an oblique line drawn through the brainstem beginning at the SL. The medial (from midline) to lateral positions of the various functional components, as shown on the far right of this figure, are taken from their representative diagrams of brainstem and cord and are directly translatable to Figure 7–2 (facing page). The color-coding of the components on this figure correlate with that in Figure 7–2 on the facing page.

**Abbreviations**

| GSA | General somatic afferent |
| GSE | General somatic efferent |
| GVA | General visceral afferent |
| GVE | General visceral efferent |
| SSA | Special somatic afferent |
| SVA | Special visceral afferent |
| SVE | Special visceral efferent |
| SL | Sulcus limitans |
The medial to lateral positions of brainstem cranial nerve and spinal cord nuclei as shown here are the same as in Figure 7–1. This diagrammatic posterior (dorsal) view shows 1) the relative positions and names of specific cell groups and their associated functional components, 2) the approximate location of particular nuclei in their specific division of brainstem and/or spinal cord, and 3) the rostrocaudal continuity of cell columns (either as continuous or discrete cell groups) from one division of the brainstem to the next or from brainstem to spinal cord. The nucleus ambiguus is a column of cells composed of distinct cell clusters interspersed with more diffusely arranged cells, much like a string of beads. Nuclei associated with cranial nerves I (olfaction, SVA) and II (optic, SSA) are not shown. The color-coding used on this figure correlates with that on Figure 7–1 (facing page).
Orientation drawing for pathways. The trajectory of most pathways illustrated in Chapter 7 appears on individualized versions of this representation of the central nervous system (CNS). Although slight changes are made in each drawing, so as to more clearly diagram a specific pathway, the basic configuration of the CNS is as represented here. This allows the user to move from pathway to pathway without being required to learn a different representation or drawing for each pathway; also, laterality of the pathway, a feature essential to diagnosis (see introduction), is inherently evident in each illustration.

The forebrain (telencephalon and diencephalon) is shown in the coronal plane, and the midbrain, pons, medulla, and spinal cord are represented through their longitudinal axes. The internal capsule is represented in the axial plane in an effort to show the rostrocaudal distribution of fibers located therein.

The reader should become familiar with the structures and regions as shown here because their locations and relationships are easily transferable to subsequent illustrations. It may also be helpful to refer back to this illustration when using subsequent sections of this chapter.

Neurotransmitters: Three important facts are self-evident in the descriptions of neurotransmitters that accompany each pathway drawing. These are illustrated by noting, as an example, that glutamate is found in corticospinal fibers (see Figure 7–10). First, the location of neuronal cell bodies containing a specific transmitter is indicated (glutamate-containing cell bodies are found in cortical areas that project to the spinal cord). Second, the trajectory of fibers containing a particular neurotransmitter is obvious from the route taken by the tract (glutaminergic corticospinal fibers are found in the internal capsule, crus cerebri, basilar pons, pyramid, and lateral corticospinal tract). Third, the location of terminals containing specific neurotransmitters is indicated by the site(s) of termination of each tract (glutaminergic terminals of corticospinal fibers are located in the spinal cord gray matter). In addition, the action of most neuroactive substances is indicated as excitatory (+) or inhibitory (−). This level of neurotransmitter information, as explained here for glutaminergic corticospinal fibers, is repeated for each pathway drawing.

Clinical Correlations: The clinical correlations are designed to give the user an overview of specific deficits (i.e., hemiplegia, athetosis) seen in lesions of each pathway and to provide examples of some syndromes or diseases (i.e., Brown-Sequard syndrome, Wilson disease) in which these deficits are seen. Although purposefully brief, these correlations highlight examples of deficits for each pathway and provide a built-in mechanism for expanded study. For example, the words in italics in each correlation are clinical terms and phrases that are defined on the CD (from Stedman’s) included with this atlas or can be found in standard medical dictionaries and clinical neuroscience textbooks.

Consulting these sources, especially the CD available in this atlas, will significantly enhance understanding of the deficits seen in the neurologically compromised patient. Expanded information, based on the deficits mentioned in this chapter, is integrated into some of the questions for chapter 7. Referring to such sources will allow the user to glean important clinical points that correlate with the pathway under consideration, and enlarge his or her knowledge and understanding by researching the italicized words and phrases.

Posterior (Dorsal) Column-Medial Lemniscus System

7–4  The origin, course, and distribution of fibers composing the posterior (dorsal) column (PC)-medial lemniscus (ML) system. This illustration shows the longitudinal extent, the positions in representative cross-sections of brainstem and spinal cord, and the somatotopy of fibers in the PC and ML. The ML undergoes positional changes as it courses from the myelencephalon (medulla) rostrally toward the mesencephalic-diencephalic junction. In the medulla, ML and ALS fibers are widely separated and receive different blood supplies, whereas in the midbrain, they are served by a common arterial source. As the ML makes positional changes, the somatotopy therein follows accordingly. Fibers of the postsynaptic posterior column system (shown in green) are considered in detail in Figure 7–6 on page 182.

Neurotransmitters: Acetylcholine and the excitatory amino acids glutamate and aspartate are associated with some of the large-diameter, heavily myelinated fibers of the posterior horn and posterior columns.

Clinical Correlations: Damage to posterior column fibers on one side of the spinal cord (as in the Brown-Sequard syndrome) results in an ipsilateral loss of vibratory sensation, position sense, and discriminative touch (astereognosis, stereognosis) below the level of the lesion. The term stereoanesthesia is frequently used to specify a lesion of peripheral nerves that results in an inability to perceive proprioceptive and tactile sensations. The term tactile agnosia is sometimes considered to be synonymous with these preceding three terms. However, tactile agnosia is also used to describe deficits seen in lesions of the parietal cortex. Bilateral damage (as in tabes dorsalis or subacute combined degeneration of the spinal cord) produces bilateral losses. Although ataxia is the most common feature in patients with tabes dorsalis, they also have a loss of deep tendon reflexes, severe lancinating pain over the body below the head (more common in the lower extremity), and bladder dysfunction. The ataxia that may be seen in patients with posterior column lesions (sensory ataxia) is due to a lack of proprioceptive input and position sense. These individuals tend to forcibly place their feet to the floor in an attempt to stimulate such sensory input. A patient with mild ataxia due to posterior column disease may compensate for the motor deficit by using visual cues. Patients with subacute combined degeneration (SCD) of the spinal cord first have signs and symptoms of posterior column involvement, followed later by signs of corticospinal tract damage (spastic weakness of legs, increased deep tendon reflexes, Babinski sign).

Rostral to the sensory decussation, medial lemniscus lesions result in contralateral losses that include the entire body excluding the head. Brainstem lesions involving medial lemniscus fibers usually include adjacent structures, result in motor and additional sensory losses, and may reflect the distribution patterns of vessels (as in medial medullary or medial pontine syndromes). Large lesions in the forebrain may result in a complete contralateral loss of modalities carried in the posterior columns and anterolateral systems, or may produce pain (as in the thalamic syndrome).

Anterolateral System

The longitudinal extent and somatotopy of fibers composing the anterolateral system (ALS). The ALS is a composite bundle containing ascending fibers that terminate in the reticular formation (spino-reticular fibers), the mesencephalon (spinotectal fibers to deep layers of the superior colliculus, spinoperoideaqueductal fibers to the periaqueductal grey), the hypothalamus (spinohypothalamic fibers), and the sensory relay nuclei of the dorsal thalamus (spinothalamic fibers). Other fibers in the ALS include spinopinocial projections to the accessory olivary nuclei. Spinothalamic fibers terminate primarily in the VPL and reticulothalamic fibers terminate in some intralaminar nuclei, and in medial areas of the posterior thalamic complex.

Fibers from the PAG and nucleus raphe dorsals enter the nucleus raphe magnus and adjacent reticular area. These latter sites, in turn, project to laminae I, II, and V of the spinal cord via raphespinal and raphe magnus and adjacent reticular area. These latter sites, in turn, project to laminae I, II, and V of the spinal cord via raphespinal and reticulothalamic fibers terminate in some intralaminar nuclei, and in medial areas of the posterior thalamic complex.

Neurotransmitters: Glutamate (+), calcitonin gene-related peptide, and substance P (+)-containing posterior (dorsal) root ganglion cells project into laminae I, II (heavy), V (moderate), and III, IV (sparse). Some spinoreticular and spinothalamic fibers contain enkephalin (−), somatostatin (−), and cholecystokinin (+). In addition to enkephalin and somatostatin, some spinomesencephalic fibers contain vasoactive intestinal polypeptide (+). Neurons in the PAG and nucleus raphe dorsals containing serotonin and neurotransin project into the nuclei raphe magnus and adjacent reticular formation. Cells in these latter centers that contain serotonin and enkephalin send processes to spinal cord laminae I, II, and V. Serotonergic raphespinal or enkephalergic reticulospinal fibers may inhibit primary sensory fibers or projection neurons, conveying nociceptive (pain) information.

Clinical Correlations: Spinal lesions involving the anterolateral system (as in the Brown-Sequard syndrome) result in a loss of pain and temperature sensations on the contralateral side of the body beginning one to two levels caudal to the lesion. Syringomyelia produces bilateral sensory losses restricted to adjacent dermatomes because of damage to the anterior (ventral) white commissure. Vascular lesions in the spinal cord (such as acute central cervical cord syndrome) may result in a bilateral and spotty loss of pain and thermal sense below the lesion because the ALS has a dual vascular supply.

Vascular lesions in the lateral medulla (posterior inferior cerebellar artery syndrome) or lateral pons (anterior inferior cerebellar artery occlusion) result in a loss of pain and thermal sensations over the entire contralateral side of the body (ALS) as well as on the ipsilateral face (spinal trigeminal tract and nucleus), coupled with other motor and/or sensory deficits based on damage to structures these vessels serve. Note that the ALS and PC-ML systems are separated in the medulla (in different vascular territories) but are adjacent to each other in the midbrain (basically in the same vascular territory). Consequently, medullary lesions will not result in deficits related to both pathways, while a lesion in the midbrain may result in a contralateral loss of pain, thermal, vibratory, and discriminative touch sensations on the body, excluding the head.

Profound loss of posterior column and anterolateral system modalities, or intractable pain and/or paresthesias (as in the thalamic syndrome), may result from vascular lesions in the posterolateral thalamus. So-called thalamic pain may also be experienced by patients who have brainstem lesions.

### Abbreviations

- **A**: Input from upper extremity regions

Sensory Pathways

181
The origin, course, and distribution of fibers composing the postsynaptic-posterior column system (upper) and the spinocervicothalamic pathway (lower). Postsynaptic-posterior column fibers originate primarily from cells in lamina IV (some cells in laminae III and V-II also contribute), ascend in the ipsilateral dorsal fasciculi, and end in their respective nuclei in the caudal medulla. Moderate-to-sparse collaterals project to a few other medullary targets.

Fibers of the spinocervical part of the spinocervicothalamic pathway also originate from cells in lamina IV (less so from III and V). The axons of these cells ascend in the posterior part of the lateral funiculus (this is sometimes called the dorsolateral funiculus) and end in a topographic fashion in the lateral cervical nucleus: lumbosacral projections terminate posterolaterally and cervical projections anteromedially. Cells of the posterior column nuclei and the lateral cervical nucleus convey information to the contralateral thalamus via the medial lemniscus.

**Neurotransmitters:** Glutamate (+) and possibly substance P (+) are present in some spinocervical projections. Because some cells in laminae III-V have axons that collateralize to both the lateral cervical nucleus and the dorsal column nuclei, glutamate (and substance P) may also be present in some postsynaptic dorsal column fibers.

**Clinical Correlations:** The postsynaptic-posterior column and spinocervicothalamic pathways are not known to be major circuits in the human nervous system. However, the occurrence of these fibers may explain a well known clinical observation. Patients that have received an anterolateral cordotomy (this lesion is placed just ventral to the denticulate ligament) for intractable pain may experience complete or partial relief, or there may be a recurrence of pain perception within days or weeks. Although the cordotomy transects fibers of the anterolateral system (the main pain pathway), this lesion spares the posterior horn, posterior columns, and spinocervical fibers. Consequently, the recurrence of pain perception (or even the partial relief of pain) in these patients may be explained by these postsynaptic-dorsal column and spinocervicothalamic projections. Through these connections, some nociceptive (pain) information may be transmitted to the ventral posterolateral nucleus and on to the sensory cortex, via circuits that bypass the anterolateral system and are spared in a cordotomy.

Postsynaptic-Posterior (Dorsal) Column System and the Spinocervicothalamic Pathway
**Trigeminal Pathways**

7–7 The distribution of general sensory (GSA) information originating on cranial nerves V (trigeminal), VII (facial), IX (glossopharyngeal), and X (vagus). Some of these primary sensory fibers end in the chief sensory nucleus, but most form the spinal trigeminal tract and end in the spinal trigeminal nucleus.

Neurons in the spinal trigeminal nucleus and in ventral parts of the chief sensory nucleus give rise to crossed anterior (ventral) trigeminothalamic fibers. Collaterals of these ascending fibers influence the hypoglossal, facial (corneal reflex, supraorbital, or trigeminal facial reflex), and trigeminal motor nuclei; mesencephalic collaterals are involved in the jaw reflex, also called the jaw-jeer reflex. Collaterals also enter the dorsal motor vagal nucleus (vomiting reflex), the superior salivatory nucleus (tearing/lacrimal reflex), and the nucleus ambiguus and adjacent reticular formation (sneezing reflex). Uncrossed posterior (dorsal) trigeminothalamic fibers arise from posterior regions of the chief sensory nucleus.

**Neurotransmitters:** Substance P (+)-containing and cholecystokinin (+)-containing trigeminal ganglion cells project to the spinal trigeminal nucleus, especially its caudal part (pars caudalis). Glutamate (+) is found in many trigeminothalamic fibers arising from the chief sensory nucleus and the pars interpolaris of the spinal nucleus. It is present in fewer trigeminothalamic fibers from the pars caudalis and in almost none from the pars oralis. The locus ceruleus (noradrenergic fibers) and the raphe nuclei (serotonergic fibers) also project to the spinal nucleus. Enkephalin (−)–containing cells are present in caudal regions of the spinal nucleus, and enkephalinergic fibers are found in the nucleus ambiguus and in the hypoglossal, facial, and trigeminal motor nuclei.

**Clinical Correlations:** Lesions of the trigeminal ganglion or nerve proximal to the ganglion result in 1) a loss of pain, temperature, and tactile sensation from the ipsilateral face, oral cavity, and teeth; 2) ipsilateral paralysis of masticatory muscles; and 3) ipsilateral loss of the corneal reflex. Damage to peripheral portions of the trigeminal nerve may be traumatic (skull fracture, especially of supraorbital and infraorbital branch), inflammatory (as in herpes zoster), or result from tumor growth. The deficit would reflect the peripheral portion of the trigeminal nerve damaged.

**Trigeminal neuralgia (tic douloureux)** is a severe burning pain restricted to the peripheral distribution of the trigeminal nerve, usually its V2 (maxillary) division. This pain may be initiated by any contact to areas of the face such as the corner of the mouth, nose, lips, or cheek (e.g., shaving, putting make-up on, chewing, or even smiling). The attacks frequently occur without warning, may happen only a few times a month to many times in a single day, and are usually seen in patients 40 years of age or older. One probable cause of trigeminal neuralgia is compression of the trigeminal root by aberrant vessels, most commonly a loop of the superior cerebellar artery (see page 41). Other causes may include tumor, multiple sclerosis, and ephaptic transmission (ephaJ) in the trigeminal ganglion. This is the most common type of neuralgia.

In the medulla, fibers of the spinal trigeminal tract and ALS are served by the posterior inferior cerebellar artery (PICA). Consequently, an alternating hemianesthesia is one characteristic feature of the PICA syndrome. This is a loss of pain and thermal sensations on one side of the body and the opposite side of the face. Pontine gliomas may produce a paralysis of masticatory muscles (motor trigeminal damage) and some loss of tactile input (chief sensory nucleus damage), as well as other deficits based on what adjacent structures may be involved.

Solitary Pathways

Visceral afferent input (SVA-taste; GVA general visceral sensation) on cranial nerves VII (facial), IX (glossopharyngeal), and X (vagus) enters the solitary nuclei via the solitary tract. What we commonly call the solitary “nucleus” is actually a series of small nuclei that collectively form this rostrocaudal-oriented cell column.

Solitary cells project to the salivatory, hypoglossal, and dorsal motor vagal nuclei and the nucleus ambiguus. Solitary projections to the nucleus ambiguus are largely bilateral and are the intermediate neurons in the pathway for the gag reflex. The afferent limb of the gag-reflex is carried on the glossopharyngeal nerve, and the efferent limb originates from the nucleus ambiguous. In this respect, the efferent limb travels on both the glossopharyngeal and vagus nerves. Although not routinely tested, the gag-reflex should be evaluated in patients with dysarthria, dysphagia, or hoarseness. Solitariospinal fibers are bilateral with a contralateral preponderance and project to the phrenic nucleus, the intermediolateral cell column, and the ventral horn. The VPM is the thalamic center through which visceral afferent information is relayed onto the cerebral cortex.

Neurotransmitters: Substance P (+)-containing and cholecystokinin (+)-containing cells in the geniculate ganglion (facial nerve) and in the inferior ganglia of the glossopharyngeal and vagus nerves project to the solitary nucleus. Enkephalin (−), neuropeptide, and GABA (−) are present in some solitary neurons that project into the adjacent dorsal motor vagal nucleus. Cholecystokinin (+), somatostatin (−), and enkephalin (−) are present in solitary neurons, in cells of the parabrachial nuclei, and in some thalamic neurons that project to taste, and other visceral areas, of the cortex.

Clinical Correlations: Lesions of the geniculate ganglion, or facial nerve proximal to the ganglion, result in 1) ipsilateral loss of taste (ageusia) from the anterior two-thirds of the tongue and 2) an ipsilateral facial (Bell) palsy. Although a glossopharyngeal nerve lesion will result in ageusia from the posterior third of the tongue on the ipsilateral side, this loss is difficult to test. On the other hand, glossopharyngeal neuralgia is an idiopathic pain localized to the peripheral sensory branches of the IXth nerve in the posterior pharynx, posterior tongue, and tonsillar area. Although comparatively rare, glossopharyngeal neuralgia may be aggravated by talking or even swallowing. Occlusion of the posterior inferior cerebellar artery (as in the posterior inferior cerebellar artery or lateral medullary syndrome), in addition to producing an alternate hemianesthesia, will also result in ageusia from the ipsilateral side of the tongue because the posterior inferior cerebellar artery serves the solitary tract and nuclei in the medulla.

Interestingly, lesions of the olfactory nerves or tract (anosmia, loss of olfactory sensation; dysosmia, distorted olfactory sense) may affect how the patient perceives taste. Witness the fact that the nasal congestion accompanying a severe cold will markedly affect the sense of taste.

Corticospinal Tracts

7–10 The longitudinal extent of corticospinal fibers and their position and somatotopy at representative levels within the neuraxis. The somatotopy of corticospinal fibers in the basilar pons is less obvious than in the internal capsule, crus cerebri, pyramid, or spinal cord. In the decussation of the pyramids, fibers originating from upper extremity areas of the cerebral cortex cross rostral to those that arise from lower extremity areas. In addition to fibers arising from the somatomotor area of the postcentral gyrus (areas 3, 1, 2); the former terminate primarily in laminae VI–IX, while the latter end mainly in laminae IV and V. Prefrontal regions, especially area 6, and parietal areas 5 and 7 also contribute to the corticospinal tract.

Neurotransmitters: Acetylcholine, gamma-aminobutyric acid (–), and substance P (+, plus other peptides) are found in small cortical neurons presumed to function as local circuit cells or in cortico-cortical connections. Glutamate (+) is present in cortical efferent fibers that project to the spinal cord. Glutaminergic corticospinal fibers and terminals are found in all spinal levels but are especially concentrated in cervical and lumbosacral enlargements. This correlates with the fact that approximately 55% of all corticospinal fibers terminate in cervical levels of the spinal cord, approximately 20% in thoracic levels, and approximately 25% in lumbosacral levels. Some corticospinal fibers may branch and terminate at multiple spinal levels. Lower motor neurons are influenced by corticospinal fibers either directly or indirectly via interneurons. Acetylcholine and calcitonin gene-related peptides are present in these large motor cells and in their endings in skeletal muscle.

Clinical Correlations: Myasthenia gravis, a disease characterized by moderate to profound weakness of skeletal muscles, is caused by circulating antibodies that react with postsynaptic nicotinic acetylcholine receptors. Progressive muscle fatigability throughout the day is a hallmark of this disease. Ocular muscles are usually affected first (diplopia, ptosis), and in approximately 50% of patients, facial and oropharyngeal muscles are commonly affected (facial weakness, dysphagia, dysarthria). Weakness may also be seen in limb muscles but almost always in combination with facial/oral weaknesses.

Injury to corticospinal fibers on one side of the cervical spinal cord (as in the Brown-Sequard syndrome) results in weakness (hemiparesis) or paralysis (hemiplegia) of the ipsilateral upper and lower extremities. In addition, and with time, these patients may exhibit features of an upper motor neuron lesion (hyperreflexia, spasticity, loss of superficial abdominal reflexes, and the Babinski sign). Bilateral cervical spinal cord damage above C4–C5 may result in paralysis of all four extremities (quadriplegia). Unilateral spinal cord lesions in thoracic levels may result in paralysis of the ipsilateral lower extremity (monoplegia). If the thoracic spinal cord damage is bilateral both lower extremities may be paralyzed (paraplegia). Small lesions within the decussation of the pyramids may result in a bilateral paresis of the upper extremities (lesion in rostral portions) or a bilateral paresis of the lower extremities (lesion in caudal portions) based on the crossing patterns of fibers within the decussation.

Rostral to the pyramidal decussation, vascular lesions in the medulla (the medial medullary syndrome), pons (the Millard-Gubler or Forel syndrome), or midbrain (the Weber syndrome) all produce alternating (crossed) hemiplegias. These present as a contralateral hemiplegia of the upper and lower extremities, coupled with an ipsilateral paralysis of the tongue (medulla), facial muscles or lateral rectus muscle (pons), and most eye movements (midbrain). Sensory deficits are frequently seen as part of these syndromes. Lesions in the internal capsule (lancinating strokes) produce contralateral hemiparesis sometimes coupled with various cranial nerve signs due to corticonuclear (corticobulbar) fiber involvement. Bilateral weakness, indicative of corticospinal involvement, is also present in amyotrophic lateral sclerosis.

Corticuclear (Corticobulbar) Fibers

7–11 The origin, course, and distribution of corticuclear (corticobulbar) fibers to brainstem motor nuclei. These fibers influence—either directly or through neurons in the immediately adjacent reticular formation—the motor nuclei of oculomotor, trochlear, trigeminal, abducens, facial, glossopharyngeal and vagus (both via nucleus ambiguus), spinal accessory, and hypoglossal nerves.

Corticuclear (corticobulbar) fibers arise in the frontal eye fields (areas 6 and 8 in caudal portions of the middle frontal gyrus), the precentral gyrus (somatomotor cortex, area 4), and some originate from the postcentral gyrus (areas 3, 1, 2). Fibers from area 4 occupy the genu of the internal capsule, but those from the frontal eye fields (areas 8, 6) may traverse caudal portions of the anterior limb, and some (from areas 3, 1, 2), may occupy the most rostral portions of the posterior limb. Fibers that arise in areas 8 and 6 terminate in the rostral interstitial nucleus of the medial longitudinal fasciculus (vertical gaze center) and in the paramedian pontine reticular formation (horizontal gaze center); these areas, in turn, project respectively to the IIIrd and IVth, and to the VIth nuclei. Fibers from area 4 terminate in, or adjacent to, cranial nerve motor nuclei excluding those of III, IV, and VI.

Although not illustrated here, the superior colliculus receives cortical input from area 8 and from the parietal eye field (area 7) and also projects to the riMLF and PPRF. In addition, it is important to note that descending cortical fibers (many arising in areas 3, 1, 2) project to sensory relay nuclei of some cranial nerves and to other sensory relay nuclei in the brainstem, such as those of the posterior column system. Sensory relay nuclei of some cranial nerves and to other sensory relay nuclei that descending cortical fibers (many arising in areas 3, 1, 2) project respectively to the IIIrd and IVth, and to the VIth nuclei. Fibers from area 4 terminate in, or adjacent to, cranial nerve motor nuclei excluding those of III, IV, and VI.

Clinical Correlations: Lesions involving the motor cortex (as in cerebral artery occlusion) or the internal capsule (as in lacunar strokes) or occlusion of lenticulostriate branches of M1 give rise to a contralateral hemiplegia of the arm and leg (corticospinal fiber involvement) coupled with certain cranial nerve signs. Strictly cortical lesions may produce a transient gaze palsy in which the eyes deviate toward the lesioned side and away from the side of the hemiplegia. In addition to a contralateral hemiplegia, common cranial nerve findings in capsular lesions may include 1) deviation of the tongue toward the side of the weakness and away from the side of the lesion when protruded and 2) paralysis of facial muscles on the contralateral lower half of the face (central facial palsy). This reflects the fact that corticuclear (corticobulbar) fibers to genioglossus motor neurons and to facial motor neurons serving the lower face are primarily crossed. Interruption of corticuclear fibers to the nucleus ambiguus may result in weakness of palatal muscles contralateral to the lesion; the uvula will deviate towards the ipsilateral (lesioned) side on attempted phonation. In addition, a lesion involving corticobulbar fibers to the accessory nucleus may result in drooping of the ipsilateral shoulder (or an inability to elevate the shoulder against resistance) due to trapezius weakness, and difficulty in turning the head (against resistance) to the contralateral side due to weakness of the sternocleidomastoid muscle. In contrast to the alternating hemiplegia seen in some brainstem lesions, hemisphere lesions result in spinal and cranial nerve deficits that are generally, but not exclusively, contralateral to the cerebral injury.

Brainstem lesions, especially in the midbrain or pons, may result in the following: 1) vertical gaze palsies (midbrain), 2) the Parinaud syndrome—paralysis of upward gaze (tumors in area of pineal), 3) internuclear ophthalmoplegia (lesion in MLF between motor nuclei of III and VI), 4) horizontal gaze palsies (lesion in PPRF), or 5) the one-and-a-half syndrome. In the latter case, the lesion is adjacent to the midline and involves the abducens nucleus and adjacent PPRF, internuclear fibers from the ipsilateral abducens that are crossing to enter the contralateral MLF, and internuclear fibers from the contralateral abducens nucleus that cross to enter the MLF on the ipsilateral (lesioned) side. The result is a loss of ipsilateral abduction (lateral rectus) and adduction (medial rectus, the "one") and a contralateral loss of adduction (medial rectus, the "half"); the only remaining horizontal movement is contralateral abduction via the intact abducens motor neurons.

The origin, course, position in representative cross-sections of brainstem and spinal cord, and the general distribution of tectospinal and reticulospinal tracts. Tectospinal fibers originate from deeper layers of the superior colliculus, cross in the posterior (dorsal) tegmental decussation, and distribute to cervical cord levels. Several regions of cerebral cortex (e.g., frontal, parietal, temporal) project to the tectum, but the most highly organized corticotectal projections arise from the visual cortex. Pontoreticulospinal fibers (medial reticulospinal) tend to be uncrossed, while those from the medulla (bulboreticulospinal or lateral reticulospinal) are bilateral but with a pronounced ipsilateral preponderance. Corticoreticular fibers are bilateral with a slight contralateral preponderance and originate from several cortical areas.

**Neurotransmitters:** Corticotectal projections, especially those from the visual cortex, utilize glutamate (+). This substance is also present in most corticoreticular fibers. Some neurons of the gigantocellular reticular nucleus that send their axons to the spinal cord, as reticulospinal projections, contain enkephalin (−) and substance P (+). Enkephalinergic reticulospinal fibers may be part of the descending system that modulates pain transmission at the spinal level. Many reticulospinal fibers influence the activity of lower motor neurons.

**Clinical Correlations:** Isolated lesions of only tectospinal and reticulospinal fibers are essentially never seen. Tectospinal fibers project to upper cervical levels where they influence reflex movement of the head and neck. Such movements may be diminished or slowed in patients with damage to these fibers. Pontoreticulospinal (medial reticulospinal) fibers are excitatory to extensor motor neurons and to neurons innervating axial musculature; some of these fibers may also inhibit flexor motor neurons. In contrast, some bulboreticulospinal (lateral reticulospinal) fibers are primarily inhibitory to extensor motor neurons and to neurons innervating muscles of the neck and back; these fibers may also excite flexor motor neurons via interneurons. Reticulospinal (and vestibulospinal) fibers contribute to the spasticity that develops in patients having lesions of corticospinal fibers. These reticulospinal and vestibulospinal fibers (see Figure 7-13 on page 196) also contribute to the tonic extension of the arms and legs seen in decerebrate rigidity when spinal motor neurons are released from descending cortical control.

Rubrospinal and Vestibulospinal Tracts

The origin, course, and position in representative cross-sections of brainstem and spinal cord, and the general distribution of rubrospinal and vestibulospinal tracts. Rubrospinal fibers cross in the anterior (ventral) tegmental decussation and distribute to all spinal levels although projections to cervical levels clearly predominate. Cells in dorso-lateral regions of the red nucleus receive input from upper extremity areas of the motor cortex and project to cervical cord, but those in ventro-lateral areas of the nucleus receive some fibers from lower extremity areas of the motor cortex and may project in sparse numbers to lumbo-sacral levels. The red nucleus also projects, via the central tegmental tract, to the ipsilateral inferior olivary complex (rubroolivary fibers). Medial and lateral vestibular nuclei give rise to the medial and lateral vestibulospinal tracts, respectively. The former tract is primarily ipsilateral, projects to upper spinal levels, and is considered a component of the medial longitudinal fasciculus in the spinal cord. The latter tract is ipsilateral and somatotopically organized; fibers to lumbo-sacral levels originate from dorsal and caudal regions of the lateral nucleus, while those to cervical levels arise from its rostral and more ventral areas.

**Neurotransmitters:** Glutamate (+) is present in corticorubral fibers. Some lateral vestibulospinal fibers contain aspartate (+), whereas glycine (−) is present in a portion of the medial vestibulospinal projection. There are numerous gamma-aminobutyric acid (−)-containing fibers in the vestibular complex; these represent the endings of cerebellar corticovestibular fibers.

**Clinical Correlations:** Isolated injury to rubrospinal and vestibulospinal fibers is really not seen in humans. Deficits in fine distal limb movements seen in monkeys following experimental rubrospinal lesions may be present in humans. However, these deficits are overshadowed by the hemiplegia associated with injury to the adjacent corticospinal fibers. The contralateral tremor seen in patients with the Claude syndrome (a lesion of the medial midbrain) is partially related to damage to the red nucleus as well as to the adjacent cerebellothalamic fibers. These patients may also have a paucity of most eye movement on the ipsilateral side and a dilated pupil (mydriasis) due to concurrent damage to exiting rootlets of the oculomotor nerve. Medial vestibulospinal fibers primarily inhibit motor neurons innervating extensors and neurons serving muscles of the back and neck. Lateral vestibulospinal fibers may inhibit some flexor motor neurons, but they mainly facilitate spinal reflexes via their excitatory influence on spinal motor neurons innervating extensors. Vestibulospinal and reticulospinal fibers contribute to the spasticity seen in patients with damage to corticospinal fibers or to the tonic extension of the extremities in patients with decerebrate rigidity. In the case of decerebrate rigidity, the descending influences on spinal flexor motor neurons (corticospinal, rubrospinal) is removed; the descending brainstem influence on spinal extensor motor neurons predominates; this is augmented by excitatory spinoreticular input (via ALS) to some of the centers giving rise to reticulospinal fibers (see also Figure 7-12 on page 194).

Motor Pathways 197
Blank master drawing for motor pathways. This illustration is provided for self-evaluation of motor pathways understanding, for the instructor to expand on motor pathways not covered in this atlas, or both.
Cranial Nerve Efferents (III, IV, VI, XI-AccNu, XII)

7–15 The origin and peripheral distribution of GSE fibers from the oculomotor, trochlear, abducens, spinal accessory, and hypoglossal nuclei. Also shown are GVE fibers arising from the Edinger-Westphal nucleus and the distribution of postganglionic fibers from the ciliary ganglion. Internuclear abducens neurons project, via the MLF, to contralateral oculomotor neurons that innervate the medial rectus muscle (internuclear ophthalmoplegia pathway).

Some authors specify the functional component of neurons in the accessory nucleus as special visceral efferent, some specify it as somatic efferent, and some are noncommittal. Because, in humans, the trapezius and sternocleidomastoid muscles originate from cervical somites located caudal to the last pharyngeal arch, the functional component is designated here as GSE. In addition, experiments in animals reveal that motor neurons innervating the trapezius and sternocleidomastoid muscles are found in cervical cord levels C1 to approximately C6.

Neurotransmitters: Acetylcholine (and probably calcitonin gene-related peptide, CGRP) is found in the motor neurons of cranial nerve nuclei and in their peripheral endings. This substance is also found in cells of the Edinger-Westphal nucleus and the ciliary ganglion.

Clinical Correlations: Myasthenia gravis (MG) is a disease caused by autoantibodies that may directly block nicotinic acetylcholine receptors or damage the postsynaptic membrane (via complement mediated lysis) thereby reducing the number of viable receptor sites. Occlusion of receptors or damage the postsynaptic membrane (via complement mediated lysis) thereby reducing the number of viable receptor sites. Occlusion of receptors or damage the postsynaptic membrane (via complement mediated lysis) thereby reducing the number of viable receptor sites.

Cranial Nerve Efferents (V, VII, IX, and X)

7–16 The origin and peripheral distribution of fibers arising from the SVE motor nuclei of the trigeminal, facial, and glossopharyngeal and vagus (via the nucleus ambiguus) nerves. Also shown are the origin of GVE parasympathetic preganglionic fibers from the superior (to facial nerve) and inferior (to glossopharyngeal nerve) salivatory nuclei and from the dorsal motor vagal nucleus. Their respective ganglia are indicated as well as the structures innervated by postganglionic fibers arising from each. The SVE functional component specifies cranial nerve motor nuclei that innervate head muscles that arose, embryologically, from pharyngeal arches. Muscles innervated by the trigeminal nerve (V) come from the 1st arch, those served by the facial nerve (VII) from the 2nd arch; the stylohyoid muscle originates from the 3rd arch and is innervated by the glossopharyngeal nerve (IX), and the muscles derived from the 4th arch are served by the vagus nerve (X).

Neurotransmitters: The transmitter found in the cells of cranial nerve motor nuclei, and in their peripheral endings, is acetylcholine; CGRP is also colocalized in these motor neurons. This substance is also present in preganglionic and postganglionic parasympathetic neurons.

Clinical Correlations: Patients with myasthenia gravis frequently have oropharyngeal symptoms and complications that result in dysarthria, and dysphagia. These individuals have difficulty chewing and swallowing, their jaw may hang open, and the mobility of facial muscles is decreased. Impaired hearing (weakness of tensor tympani) and hyperacusis (weakness of stapedius) may also be present.

Lesions of the Vth nerve (as in meningiomas or trauma) result in 1) loss of pain, temperature, and touch on the ipsilateral face and in the oral and nasal cavities; 2) paralysis of ipsilateral masticatory muscles (jaw deviation to the lesioned side when closed); and 3) loss of the afferent limb of the corneal reflex. If especially large, a vestibular schwannoma may compress the trigeminal nerve root and result in a hemifacial sensory loss that may include the oral cavity. Trigeminal neuralgia (tic douloureux) is an intense, sudden, intermittent pain emanating from the area of the cheek, oral cavity, or adjacent parts of the nose (distribution of V2, or V3, see also Figure 7-7 on page 184).

Tumors (such as chordoma or vestibular schwannoma), trauma, or meningitis may damage the VIIth nerve, resulting in 1) an ipsilateral facial palsy (or Bell palsy); 2) loss of taste from the ipsilateral two-thirds of the tongue; and 3) decreased secretion from the ipsilateral lacrimal, nasal, and sublingual and submandibular glands. Injury distal to the chorda tympani produces only an ipsilateral facial palsy. A paralysis of the muscles on one side of the face with no paralysis of the extremities is a facial hemiplegia. On the other hand, intermittent and involuntary contraction of the facial muscles is called hemifacial spasm. One cause is compression of the facial root by an artery, most commonly a loop of the anterior inferior cerebellar artery or its branches. These patients may also have deficits (vertigo, tinnitus, hearing loss) suggesting involvement of the adjacent vestibulocochlear nerve.

Because of their common origin from NuAm, adjacent exit from the medulla, and passage through the jugular foramen, the IXth and Xth nerves may be damaged together (as in amyotrophic lateral sclerosis or in syringobulbia). The results are dysarthria, dysphagia, dysnea, loss of taste from the ipsilateral caudal tongue, and loss of the gag reflex, but no significant autonomic deficits. Bilateral lesions of the Xth nerve are life-threatening because of the resultant total paralysis (and closure) of the muscles in the vocal folds (vocalis muscle).

Spinocerebellar Tracts

7–17 The origin, course, and distribution pattern of fibers to the cerebellar cortex and nuclei from the spinal cord (posterior [dorsal] and anterior [ventral] spinocerebellar tracts, rostral spinocerebellar fibers) and from the external cuneate nucleus (cuneocerebellar fibers). Also illustrated is the somatotopy of those fibers originating from the spinal cord. These fibers enter the cerebellum via the restiform body, the larger portion of the inferior cerebellar peduncle, or in relationship to the superior cerebellar peduncle. After these fibers enter the cerebellum, collaterals are given off to the cerebellar nuclei while the parent axons of spinocerebellar and cuneocerebellar fibers pass on to the cortex, where they end as mossy fibers in the granular layer. Although not shown here, there are important ascending spinal projections to the medial and dorsal accessory nuclei of the inferior olivary complex (spino-olivary fibers). The accessory olivary nuclei (as well as the principal olivary nucleus) project to the cerebellar cortex and send collaterals into the nuclei (see Figure 7-18 on page 206).

Neurotransmitters: Glutamate (+) is found in some spinocerebellar fibers, in their mossy fiber terminals in the cerebellar cortex, and in their collateral branches that innervate the cerebellar nuclei.

Clinical Correlations: Lesions, or tumors, that selectively damage only spinocerebellar fibers are rarely, if ever, seen in humans. The ataxia one might expect to see in patients with a spinal cord hemisection (as in the Brown-Sequard syndrome) is masked by the hemiplegia resulting from the concomitant damage to lateral corticospinal (and other) fibers. Friedreich ataxia (hereditary spinal ataxia) is an autosomal recessive disorder the symptoms of which usually appear between 8 and 15 years of age. There is degeneration of anterior and posterior spinocerebellar tracts plus the posterior columns and corticospinal tracts. Degenerative changes are also seen in Purkinje cells in the cerebellum, in posterior root ganglion cells, in neurons of the Clarke column, and in some nuclei of the pons and medulla. The axial and appendicular ataxia seen in these patients correlates partially with the spinocerebellar degeneration and also partially with proprioceptive losses via the degeneration of posterior column fibers.

Spinocerebellar Tracts

Lobule V

Lobules II-IV

Intermediate zone (IZ) and "spinal border" cells (SBC)

Spinocerebellar Tracts

Cerebellum and Basal Nuclei (Ganglia) 205
Pontocerebellar, Reticulocerebellar, Olivocerebellar, Ceruleocerebellar, Hypothalamocerebellar, and Rapheocerebellar Fibers

7–18 Afferent fibers to the cerebellum from selected brainstem areas and the organization of corticopontine fibers in the internal capsule and crus cerebri as shown here. The cerebellar peduncles are also indicated. Pontocerebellar axons are mainly crossed, reticulocerebellar fibers may be bilateral (from RetTegNu) or mainly uncrossed (from LRNu and PRNu), and olivocerebellar fibers (OCblF) are exclusively crossed. Raphecerebellar, hypothalamocerebellar, and ceruleocerebellar fibers are, to varying degrees, bilateral projections. Although all afferent fibers to the cerebellum give rise to collaterals to the cerebellar nuclei, those from pontocerebellar axons are relatively small, having comparatively small diameters. Olivocerebellar axons end as climbing fibers, reticulocerebellar and pontocerebellar fibers as mossy fibers, and hypothalamocerebellar and ceruleocerebellar axons end in all cortical layers. These latter fibers have been called multilayered fibers in the literature because they branch in all layers of the cerebellar cortex.

**Neurotransmitters:** Glutamate (+) is found in corticopontine projections and in most pontocerebellar fibers. Aspartate (+) and corticotropin (+)-releasing factor are present in many olivocerebellar fibers. Ceruleocerebellar fibers contain noradrenalin, histamine is found in hypothalamocerebellar fibers, and some reticulocerebellar fibers contain enkephalin. Serotonergic fibers to the cerebellum arise from neurons found in medial areas of the reticular formation (open cell in Figure 7–18) and, most likely, from some cells in the adjacent raphe nuclei.

**Clinical Correlations:** Common symptoms seen in patients with lesions involving nuclei and tracts that project to the cerebellum are ataxia (of trunk or limbs), an ataxic gait, dysarthria, dysphagia, and disorders of eye movement such as nystagmus. These deficits are seen in some hereditary diseases (such as olivopontocerebellar degeneration, ataxia telangiectasia, or hereditary cerebellar ataxia), in tumors (brainstem gliomas), in vascular diseases (lateral pontine syndrome), or in other conditions such as alcoholic cerebellar degeneration or pontine hemorrhages (see Figure 7-19 on page 208 for more information on cerebellar lesions).

Pontocerebellar, Reticulocerebellar, Olivocerebellar, Ceruleocerebellar, Hypothalamocerebellar, and Raphecerebellar Fibers
Lesions involving midline structures (vermal cortex, fastigial nuclei) and/or the flocculonodular lobe result in truncal ataxia (titubation or tremor), nystagmus, and head tilting. These patients may also have a wide-based (cerebellar) gait, unable to walk in tandem (heel to toe), and may be unable to walk on their heels or on their toes. Generally, midline lesions result in bilateral motor deficits affecting axial and proximal limb musculature.

Damage to the intermediate and lateral cortices and the globose, emboliform, and dentate nuclei results in various combinations of the following deficits: dysarthria, dysmetria (hypometria, hypermetria), dysdiadochokinesia, tremor (static, kinetic, intention), rebound phenomenon, unsteady and wide-based (cerebellar) gait, and nystagmus. One of the more commonly observed deficits in patients with cerebellar lesions is an intention tremor, which is best seen in the finger-nose test. The finger-to-finger test is also used to demonstrate an intention tremor and to assess cerebellar function. The heel-to-shin test will show dysmetria in the lower extremity. If the heel-to-shin test is normal in a patient with his/her eyes open, the cerebellum is intact. If this test is repeated in the same patient with eyes closed and is abnormal, this would suggest a lesion in the posterior column-medial lemniscus system.

Cerebellar damage in intermittent and lateral areas (nuclei or cortex plus nuclei) causes movement disorders on the side of the lesion with ataxia and gait problems on that side; the patient may tend to fall toward the side of the lesion. This is because the cerebellar nuclei project to the contralateral thalamus, which projects to the motor cortex on the same side, which projects to the contralateral side of the spinal cord via the corticospinal tract. Other circuits (cerebellorubal-rubospinal) and feedback loops (cerebellolivary-olivocerebellar) follow similar routes. Consequently, the motor expression of unilateral cerebellar damage is toward the lesioned side because of these doubly crossed pathways.

Lesions of cerebellar efferent fibers, after they cross the midline in the decussation of the superior cerebellar peduncle, will give rise to motor deficits on the side of the body (excluding the head) contralateral to the lesion. This is seen in midbrain lesions such as the Claude syndrome.

Cerebellar Corticonuclear, Nucleocortical, and Corticovestibular Fibers

Cerebellar Nuclei:
1= Medial (Fastigial)
2= Posterior Interposed (Globose)
3= Anterior Interposed (Emboliform)
4= Lateral (Dentate)
Cerebellar Efferent Fibers

7–20 The origin, course, topography, and general distribution of fibers arising in the cerebellar nuclei. Cerebellofugal fibers project to several thalamic areas (VL and VA), to intralaminar relay nuclei in addition to the centromedian, and to a number of midbrain, pontine, and medullary targets. Most of the latter nuclei project back to the cerebellum (e.g., reticulo-cerebellar, pontocerebellar), some in a highly organized manner. For example, cerebello-olivary fibers from the dentate nucleus (DNu) project to the principal olivary nucleus (PO), and neurons of the PO send their axons back to the lateral cerebellar cortex, with collaterals going to the DNu.

The cerebellar nuclei can influence motor activity through, as examples, the following routes: 1) cerebellorubral-rubrospinal, 2) cerebelloreticular-reticulospinal, 3) cerebellothalamic-thalamocortical-corticospinal, and others. In addition, some direct cerebellospinal fibers arise in the fastigial nucleus as well as in the interposed nuclei.

Neurotransmitters: Many cells in the cerebellar nuclei contain glutamate (+), aspartate (+), or gamma-aminobutyric acid (−). Glutamate and aspartate are found in cerebellorubral and cerebellothalamic fibers, whereas some GABA-containing cells give rise to cerebellopontine and cerebellolo-olivary fibers. Some cerebelloreticular projections may also contain GABA.

Clinical Correlations: Lesions of the cerebellar nuclei result in a range of motor deficits depending on the location of the injury. Many of these are described in Figure 7–19 on page 208.

Blank master drawing for pathways projecting to the cerebellar cortex, and for efferent projections of cerebellar nuclei. This illustration is provided for self-evaluation of understanding of pathways to the cerebellar cortex and from the cerebellar nuclei, for the instructor to expand on cerebellar afferent/efferent pathways not covered in the atlas, or both.
Striatal Connections

The origin, course, and distribution of afferent fibers to, and efferent projections from, the neostriatum. These projections are extensive, complex, and in large part, topographically organized; only their general patterns are summarized here. Afferents to the caudate and putamen originate from the cerebral cortex (corticostriate fibers), from several of the intralaminar thalamic nuclei (thalamostriate), from the substantia nigra pars compacta (nigrostriate), and from some of the raphe nuclei. Neostriatal cells send axons into the globus pallidus (paleostriatum) as striopallidal fibers and into the substantia nigra pars reticulata as a strionigral projection.

**Neurotransmitters:** Glutamate (+) is found in corticostriate fibers, and serotonin is found in raphestriatal fibers from the nucleus raphe dorsalis. Four neuroactive substances are associated with striatal efferent fibers, these being gamma-aminobutyric acid (GABA)(−), dynorphin, enkephalin(−), and substance P(+) Enkephalinergic and GABA-ergic striopallidal projections are numerous to the lateral pallidum (origin of pallidoshubthalamic fibers), while dynorphin-containing terminals are more concentrated in its medial segment (source of pallidothalamic fibers). Enkephalin and GABA are also present in strionigral projections to the pars reticulata. Because substance P and GABA are found in striopallidal and strionigral fibers, some of the former may be collaterals of the latter. Dopamine is present in nigrostrial projection neurons and in their terminals in the neostriatum.

**Clinical Correlations:** Degenerative changes and neuron loss in the caudate nucleus and putamen result in movement disorders. Examples are seen in Sydenham chorea (rheumatic chorea), Huntington disease (a dominantly inherited disease), and Wilson disease (a genetic error in the patient’s ability to metabolize copper). In persons with Parkinson disease, a loss of the dopamine-containing cells in the pars compacta of the substantia nigra and of their nigrostrial terminals in the caudate nucleus and putamen occurs.

Sydenham chorea is a disease usually seen in children between 5 and 15 years of age, resulting from infection with hemolytic streptococcus. The choreiform movements are brisk and flowing, irregular, and may involve muscles of the limbs, face, oral cavity, and trunk. Dystonia may be seen; muscle weakness is common. In most patients, the disease resolves following successful treatment of the infection.

Huntington disease is a progressive genetic disorder the symptoms of which appear at 35 to 45 years of age. There is loss of GABA-ergic and enkephalinergic cells in the neostriatum (primarily the caudate) and cell loss in the cerebral cortex. Loss of neostriatal cell terminals in the lateral and medial segments of the globus pallidus correlate, respectively, with the development of choreiform movements and later with rigidity and dystonia. Loss of cortical neurons correlate, respectively, with personality changes and eventual dementia. Huntington chorea is rapid, unpredictable, and may affect muscles of the extremities, face, and trunk; abnormal movements seem to flow through the body. Patients commonly attempt to mask the abnormal movement by trying to make it appear to be part of an intended movement (parakinesia).

Symptoms in Wilson disease (hepatolenticular degeneration) appear in persons between 10 to 20 years of age. Copper accumulates in the basal nuclei (ganglia) and the frontal cortex, with resultant spongy degeneration in the putamen and cortex. These patients may show athetoid movements, rigidity and spasticity, dysarthria, dysphagia, contractures, and tremor. A unique movement of the hand and/or upper extremity in these patients is called a flapping tremor (asterixis) sometimes described as a wing-beating tremor. Copper can also be seen in the cornea (Kayser-Fleischer ring) in these patients.

In Parkinson disease (onset at 50 to 60 years of age), there is a progressive loss of dopaminergic cells in the substantia nigra-pars compacta, of their terminals in the caudate and putamen, and of their dendrites that extend into the substantia nigra-pars reticulata. Patients with Parkinson disease characteristically show a resting tremor (pill-rolling), rigidity (cog wheel or lead pipe), and bradykinesia or hypokinesia. The slowness of movement may also be expressed in speech (dysarthria, hypophonia, tachyphonia) and in writing (micrographia). These patients have a distinct stooped flexed posture and a festinating gait. Behavioral changes are also seen. Parkinson disease and Huntington disease are progressive neurodegenerative disorders.

Dystonia, a movement disorder seen in some patients with basal nuclei disease, is characterized by increased/sustained muscle contractions that cause twisting of the trunk or extremities resulting in abnormal posture. These patients may also have unusual and repetitive movements of the extremities or of the neck (cervical dystonia or spasmodic torticolis). Dystonia may be an inherited progressive disease or have other causes and may be seen in children or young adults. The symptoms may initially appear during movements or when talking but in later stages may be present at rest.

Pallidal Efferents and Nigral Connections

7–23 The origin, course, and distribution of efferent projections of the globus pallidus (upper illustration), and connections of the substantia nigra (lower drawing) that were not shown in relation to the pallidum or in Figure 7–22 on page 215. The ansa lenticularis (dashed line) arises around the internal capsule and passes caudally to join in the formation of the thalamic fasciculus. Pallidolenticular fibers originate primarily from the lateral pallidal segment, but pallidolenticular projections, via the ansa lenticularis and lenticular fasciculus, arise mainly from its medial segment. The substantia nigra has extensive connections, the clinically most important being the dopaminergic nigrostriatal fibers. The globus pallidus influences motor activity by way of pallidothalamic-thalamocortical-corticospinal (and corticonuclear [corticobulbar]) pathways.

Neurotransmitters: Gamma-aminobutyric acid (GABA)–containing cells in the globus pallidus give rise to pallidonigral projections, which end primarily in the substantia nigra-pars reticulata. Although GABA is also found in some subthalamopallidal axons, this latter projection contains many glutaminergic (Glu) fibers. Dopamine-containing, GABA (GABA)–containing, and glycine (Gly)–containing cells are present in the substantia nigra. Of these, dopamine is found in pars compacta neurons, which give rise to nigrostriatal, nigroamygdaloid, and several other projections; GABA in pars reticulata cells, which give rise to nigrocollicular and nigrothalamic fibers; and glycine in some local circuit nigral neurons. Glutamate (Glu) is found in corticofugal fibers, and serotonin (5-HT) is associated with raphe fibers; these latter fibers originate primarily from the nucleus raphe dorsalis.

The dopaminergic projections to the frontal cortex, shown here as arising only from SNpc, originates from this cell group as well as from the immediately adjacent ventral tegmental area. Excessive activity in neurons comprising this projection may play a partial role in schizophrenia.

Clinical Correlation: Movement disorders associated with lesions in the neostriatum and substantia nigra are reviewed in Figure 7–22 on page 214. Hemorrhage into, the occlusion of vessels serving or a tumor within, the subthalamic nucleus will result in violent flailing movements of the extremities, a condition called hemiballismus. Hemiballistic movements are seen contralateral to the lesion because the motor expression of this lesion is through the corticospinal tract. Lesions confined to the globus pallidus, as in hemorrhage of lenticulostriate arteries, may result in hypokinesia and rigidity without tremor.

Pupillary Pathways

7–25 The origin, course, and distribution of fibers involved in the pathway for the pupillary light reflex. In addition, the pathway for sympathetic innervation of the dilator muscle of the iris is also depicted. The pathway from the midbrain reticular formation to the intermediolateral cell column may also have a multisynaptic component, with relay stations in the pontine and medullary reticular formations. Postganglionic sympathetic fibers to the head originate from the superior cervical ganglion. Although not shown, descending projections to the intermediolateral cell column also originate from various hypothalamic areas and nuclei (hypothalamospinal fibers), some of which receive retinal input.

**Neurotransmitters:** Acetylcholine is the transmitter found in the preganglionic and postganglionic autonomic fibers shown in this illustration. In addition, N-acetylaspartylglutamate is present in some retinal ganglion cells (retinogeniculate projections).

**Clinical Correlations:** Total or partial blindness in one or both eyes may result from a variety of causes (such as glomas, meningiomas, strokes, aneurysms, infections, and demyelinating diseases); lesions may occur at any locus along the visual pathway. A complete lesion (for example, a transection) of the optic nerve will result in a loss of the opposite eye (of the amplex, a transection) of the optic nerve will result in insensitivity and lesions of the calcarine sulcus or follow an arching route (the Meyer, or Meyer-Archambault loop) through the temporal lobe to the lower bank (lingual gyrus) of the calcarine sulcus. Temporal lobe lesions involving the Meyer-Archambault loop, or involving fibers entering the lingual gyrus, can produce a homonymous superior quadrantanopia. A homonymous inferior quadrantanopia is seen in patients with damage to upper (parietal) parts of the geniculocalcine radiations or to these fibers as they enter the cuneus. Damage to the visual cortex adjacent to the calcarine sulcus (distal posterior cerebral artery occlusion) results in a right (or left) homonymous hemianopia. With the exception of macular sparing, this deficit is the same as that seen in optic tract lesions.

Vascular lesions (as in the lateral medullary syndrome), tumors (such as brainstem gliomas), or syringobulbia may interrupt the descending projections from hypothalamus (hypothalamospinal fibers) and midbrain to the intermediolateral cell column at upper thoracic levels. This may result in a Horner syndrome (ptosis, miosis, and anhidrosis) on the ipsilateral side. The enophthalmos (a slight sinking of the eyeball into the orbit) frequently mentioned in relation to Horner syndrome is not really very apparent in afflicted patients.

The origin, course, and distribution of the visual pathway are shown. Uncrossed retinogeniculate fibers terminate in laminae 2, 3, and 5, while crossed fibers end in laminae 1, 4, and 6. Geniculocalcarine fibers arise from laminae 3 through 6. Retinogeniculate and geniculocalcarine pathways are retinotopically organized (see facing page).

**Neurotransmitters:** Cholecystokinin (+) is present in some geniculocalcarine fibers. N-acetylaspartylglutamate is found in some retinogeniculate fibers, and in some lateral geniculate and visual cortex neurons.

**Clinical Correlations:** Deficits seen following lesions of various parts of visual pathways are described in Figure 7-25 on p. 220.

Visual Pathways

7–27 Semidiagrammatic representation of the retinographic arrangement of visual and retinal fields, and the subsequent topography of these projections throughout the visual system. Upper-case letters identify the binocular visual fields (A, B, C, D), the macula (M), and the monocular visual fields (A', B', C', D').

Clinical Correlations: Deficits seen following lesions of various parts of the visual pathway are described in Figure 7-25 on p. 220.
Blank master drawing of visual pathways. This illustration is provided for self-evaluation of visual pathway understanding, for the instructor to expand on aspects of the visual pathways not covered in the atlas, or both.
Hearing losses are most common, and/or part of the VIIIth nerve (as in streptomycin), or occlusion of the labyrinthine artery. Damage to the cochlear otosclerosis (of the canal, wax build-up) or disorders of the middle ear (conductive deafness). There are three categories of deafness. Clinical Correlations: Sensorineural hearing loss results from diseases involving the cochlea or the cochlear portion of the vestibulocochlear nerve. Central deafness results from damage to the cochlear nuclei or possibly their central connections. Hearing loss may result from trauma (such as fracture of the petrous bone), demineralizing diseases, tumors, certain medications (streptomycin), or occlusion of the labyrinthine artery. Damage to the cochlear part of the VIIIth nerve (as in vestibular schwannoma) results in tinnitus and/or deafness (partial or total) in the ipsilateral ear. High-frequency hearing losses are most common.

The Weber test and Rinne test are used to differentiate between neural hearing loss and conduction hearing loss, and to lateralize the deficit. In the Weber test, a tuning fork (512 Hz) is applied to the midline of the forehead or apex of the skull. In the normal patient, the sound (conducted through the bones of the skull) is heard the same in each ear. In the case of sensorineural hearing loss (lesions of the cochlea or cochlear nerve), the sound is best heard in the normal ear, while in conductive hearing loss, the sound is best heard in the abnormal ear. In the Rinne test, a tuning fork (512 Hz) is placed against the mastoid process. When the sound is no longer perceived, the prongs are moved close to the external acoustic meatus, where the sound is again heard; this is the situation in a normal individual (positive Rinne test). In middle ear disease, the sound is not heard at the external meatus after it has disappeared from touching the mastoid bone (abnormal or negative Rinne test). Therefore, a negative Rinne test signifies conductive hearing loss in the ear tested. In mild nerve deafness (cochlea or cochlear nerve lesions), the sound is heard by application of the tuning fork to the mastoid and movement to the ear (the Rinne test is positive). In severe nerve deafness, the sound may not be heard at either position. In addition to hearing loss and tinnitus, large vestibular schwannomas may result in other signs and symptoms. These include nausea, vomiting and ataxia/unsteady gait (vestibular root involvement), weakness of facial muscles (facial root involvement), and altered sensation from the face and a diminished corneal reflex (trigeminal root involvement). There may also be general signs associated with increased intracranial pressure (lethargy, headache, and vomiting).

Central lesions (as in gliomas or vascular occlusions) rarely produce unilateral or bilateral hearing losses that can be detected, the possible exception being pontine lesions that damage the trapezoid body and nuclei. Injury to central auditory pathways and/or primary auditory cortex may diminish auditory acuity, decrease the ability to hear certain tones, or make it difficult to precisely localize sounds in space. Patients with damage to secondary auditory cortex in the temporal lobe experience difficulty in understanding and/or interpreting sounds (auditory agnosia).

Vestibular Pathways

The origin, course, and distribution of the main afferent and efferent connections of the vestibular nuclei (see also Figures 7–13, 7–19, and 7–20). Primary vestibular afferent fibers may end in the vestibular nuclei or pass to cerebellar structures via the juxtarestiform body. Secondary vestibulocerebellar axons originate from the vestibular nuclei and follow a similar path to the cerebellum. Efferent projections from the vestibular nuclei also course to the spinal cord through vestibulospinal tracts (see Figure 7–13), as well as to the motor nuclei of the oculomotor, trochlear, and abducens nerves via the MLF. Cerebellar structures most extensively interconnected with the vestibular nuclei include the lateral regions of the vermal cortex of anterior and posterior lobes, the flocculonodular lobe, and the fastigial (medial) cerebellar nucleus.

Neurotransmitters: Gamma-aminobutyric (GABA) is the transmitter associated with many cerebellar corticovestibular fibers and their terminals in the vestibular complex; this substance is also seen in cerebellar corticonuclear axons. The medial vestibular nucleus also has fibers that are dynorphin-positive and histamine-positive; the latter arise from cells in the hypothalamus.

Clinical Correlations: The vestibular part of the VIIIth nerve can be damaged by many of the same insults that affect the cochlear nerve (see Figure 7–29). Damage to vestibular receptors of the vestibular nerve commonly results in vertigo. The patient may feel that his or her body is moving (subjective vertigo) or that objects in the environment are moving (objective vertigo). They have equilibrium problems, an unsteady (ataxic) gait, and a tendency to fall to the lesioned side. Deficits seen in nerve lesions—or in brainstem lesions involving the vestibular nuclei, include nystagmus, nausea, and vomiting, along with vertigo and gait problems. A facial palsy may also appear in concert with VIIIth nerve damage in patients who have a vestibular schwannoma. These vestibular deficits, along with partial or complete deafness, are seen in Ménière disease.

Lesions of those parts of the cerebellum with which the vestibular nerve and nuclei are most intimately connected (flocculonodular lobe and fastigial nucleus) result in nystagmus, truncal ataxia, ataxic gait, and a propensity to fall to the injured side. The nystagmus seen in patients with vestibular lesions and the internuclear ophthalmoplegia seen in some patients with multiple sclerosis are signs that correlate with the interruption of vestibular projections to the motor nuclei of III, IV, and VI via the MLF.

Hippocampal Connections

Selected afferent and efferent connections of the hippocampus (upper) and the mammillary body (lower) with emphasis on the circuit of Papez. The hippocampus receives input from, and projects to, diencephalic nuclei (especially the mammillary body via the postcommissural fornix), the septal region, and amygdala. The hippocampus receives cortical input from the superior and middle frontal gyri, superior temporal and cingulate gyri, precuneus, lateral occipital cortex, occipitotemporal gyri, and subcallosal cortical areas. The mammillary body is connected with the dorsal and ventral tegmental nuclei, anterior thalamic nucleus (via the mammillothalamic tract), septal nuclei, and through the mammillotegmental tract, to the tegmental pontine and reticulotegmental nuclei.

Neurotransmitters: Glutamate (+)-containing cells in the subiculum and Ammon’s horn project to the mammillary body, other hypothalamic centers, and the lateral septal nucleus through the fornix. Cholecystokinin (+) and somatostatin (−) are also found in hippocampal cells that project to septal nuclei and hypothalamic structures. The septal nuclei and the nucleus of the diagonal band give rise to cholinergic afferents to the hippocampus that travel in the fornix. In addition, a gamma-aminobutyric acid (−) septohippocampal projection originates from the medial septal nucleus. Enkephalin and glutamate containing hippocampal afferent fibers arise from the adjacent entorhinal cortex; the locus ceruleus gives origin to noradrenergic fibers to the dentate gyrus, Ammon’s horn, and subiculum; and serotoninergic fibers arise from the rostral raphe nuclei.

Clinical Correlations: Dysfunction associated with damage to the hippocampus is seen in patients with trauma to the temporal lobe, as a sequel to alcoholism, and as a result of neurodegenerative changes seen in the dementing diseases (such as Alzheimer disease and Pick disease). Bilateral injury to the hippocampus results in loss of recent memory (remote memory is unaffected), impaired ability to remember recent (new) events, and difficulty in turning a new experience (something just done or experienced) into a longer-term memory that can be retrieved at a later time. Also, memory that depends on visual, tactile, or auditory discrimination is noticeably affected. These represent visual agnosia, tactile agnosia, and auditory agnosia, respectively.

In the Korsakoff syndrome (amnestic confabulatory syndrome) there is memory loss, dementia, amnesia, and a tendency to give confabulated responses. This type of response is fluent but consists of a string of unrelated, or even made up, “memories” that never actually occurred or make no sense. This may lead to an incorrect conclusion that the patient is suffering from dementia. In addition to lesions in the hippocampus in these patients, the mammillary bodies and dorsomedial nucleus of the thalamus are noticeably affected. The Korsakoff syndrome (see also the Wernicke-Korsakoff syndrome) as seen in chronic alcoholics is largely owing to thiamine deficiency and can be treated with therapeutic doses of this vitamin.

Abbreviations

| AC    | Anterior commissure |

Amygdaloid Connections

The origin, course, and distribution of selected afferent and efferent connections of the amygdaloid nuclear complex in sagittal (upper) and coronal (lower) planes. The amygdala receives input from, and projects to, brainstem and forebrain centers via the stria terminalis and the ventral amygdalofugal pathway. Corticoamygdaloid and amygdalocortical fibers interconnect the basal and lateral amygdaloid nuclei with select cortical areas.

**Neurotransmitters:** Cells in the amygdaloid complex contain vasoactive intestinal polypeptide (VIP, +), neurotensin (NT), somatostatin (SOM, −), enkephalin (ENK, −), and substance P (SP, +). These neurons project, via the stria terminalis or the ventral amygdalofugal path, to the septal nuclei (VIP, NT), the bed nucleus of the stria terminalis (NT, ENK, SP), the hypothalamus (VIP, SOM, SP), the nucleus accumbens septi, and the caudate and putamen (NT). Serotoninergic amygdaloid fibers originate from the nucleus raphe dorsalis and the superior central nucleus, dopaminergic axons from the ventral tegmental area and the substantia nigra-pars compacta, and noradrenergic fibers from the locus ceruleus. Glutamate (+) is found in olfactory projections to the prepiriform cortex and the amygdaloid complex. Acetylcholine is present in afferents to the amygdala from the substantia innominata, as well as from the septal area. In patients with Alzheimer disease and the associated dementia, there is a marked loss of acetylcholine-containing neurons in the basal nucleus of the substantia innominata, in the cortex, and in the hippocampus.

**Clinical Correlations:** Dysfunctions related to damage to the amygdaloid complex are seen in patients with trauma to the temporal lobes, herpes simplex encephalitis, bilateral temporal lobe surgery to treat intractable epileptic activity, and in some CNS degenerative disorders (such as Alzheimer disease and Pick disease). The behavioral changes seen in individuals with amygdala lesions collectively form the Klüver-Bucy syndrome. In humans these changes/deficits are 1) hyperorality; 2) visual, tactile, and auditory agnosia; 3) placidity; 4) hyperphagia or other dietary manifestations; 5) an intense desire to explore the immediate environment (hypermetamorphosis), and 6) what is commonly called hypersexuality. These changes in sexual attitudes are usually in the form of comments, suggestions, and attempts to make a sexual contact (such as touching) rather than in actual intercourse or masturbation. These patients may also show aphasia, dementia, and amnesia.

**Abbreviations**

| AC | Anterior commissure |
| Amy | Amygdaloid nuclear complex |
| AmyCor | Amygdalocortical fibers |

Amygdaloid Connections

[Diagram showing various brain regions and connections, including Limbic System components like the Amygdala, Prefrontal Cortex, Cingulate Gyrus, and others.]
7–34 Blank master drawing for limbic pathways. This illustration is provided for self-evaluation of limbic pathways or connections, for the instructor to expand on aspects of these pathways not covered in the atlas, or both.
Anatomical–Clinical Correlations: Cerebral Angiogram, MRA, and MRV
Internal carotid angiogram (left lateral projection, arterial phase) showing the general patterns of the internal carotid, middle, and anterior cerebral arteries (A, B) and an image with especially good filling of the ophthalmic artery (B). The ophthalmic artery leaves the cerebral part of the internal carotid and enters the orbit via the optic canal. This vessel gives rise to the central artery of the retina, which is an important source of blood supply to the retina. Occlusion of the ophthalmic artery may result in blindness in the eye on that side. The terminal branches of the ophthalmic artery will anastomose with superficial vessels around the orbit. Compare with Figures 2-12 (page 19) and 2-25 (page 27).
Two internal carotid angiograms (left lateral projection, venous phase). Superficial and deep venous structures are clear in A, but B shows a particularly obvious vein of Trolard. The thalamostriate vein (A) at this location can also be called the superior thalamostriate vein. The junction of the superior thalamostriate vein with the internal cerebral vein is called the venous angle (A). The interventricular foramen is located immediately rostral to this point. Compare these images with the drawings of veins and sinuses in Figures 2-13 (page 19) and 2-28 (page 29).
8-3 Internal carotid angiogram (anterior–posterior projection, arterial phase). Note general distribution patterns of anterior and middle cerebral arteries and the location of lenticulostriate branches. The A1 segment of the anterior cerebral artery is located between the internal carotid bifurcation and the anterior communicating artery. The distal portion of the anterior cerebral artery (ACA) immediately rostral to the anterior communicating artery and inferior to the rostrum of the corpus callosum is the A2 segment (infracallosal). The portion of the ACA arching around the genu of the corpus callosum is the A3 segment (precallosal) and the A4 (supracallosal) and A5 (postcallosal) segments are located superior (above) the corpus callosum.

The M1 segment of the middle cerebral artery is located between the internal carotid bifurcation and the point at which this vessel branches into superior and inferior trunks on the insular cortex. As branches of the middle cerebral artery pass over the insular cortex they are designated as M2, as M3 when these branches are located on the inner surface of the frontal, parietal, and temporal opercula, and as M4 where they exit the lateral sulcus and fan out over the lateral aspect of the cerebral hemisphere. Compare with Figure 2-21 on page 25.
Internal carotid angiogram (anterior–posterior projection, venous phase). The patient’s head is tilted slightly; this shows the arching shapes of the superior and inferior sagittal sinuses to full advantage. Note the other venous structures in this image and compare with the arterial phase shown in Figure 8-3 on page 242 and the images in Figures 8-5 and 8-6 on pages 244 and 245. Also compare with Figure 2-28 on page 29.
Digital subtraction image of an internal carotid angiogram (anterior–posterior projection, venous phase). Image A is early in the venous phase (greater filling of cortical veins), whereas image B is later in the venous phase (greater filling of the sinuses and jugular vein). Both images are of the same patient.

The jugular bulb is a dilated portion of internal jugular vein (IJV) in the jugular fossa at the point where the sigmoid sinus is continuous with the IJV; this continuity is through the jugular foramen. The jugular foramen also contains the roots of cranial nerves IX, X, and XI, the continuation of inferior petrosal sinus with the IJV and several small arteries. Compare with Figures 2-16 (page 21) and 2-19 (page 23).
Magnetic resonance angiography (MRA) is a noninvasive method for imaging cerebral arteries, veins, and sinuses simultaneously. A 3-D phase contrast MRA (A) and an inverted video image window (B) of the same view show major vessels and sinuses from anterior to posterior. C shows the relative position of the major vessels and dural sinuses as imaged in A and B. The superior sagittal sinus, as seen in A and B, is usually continuous with the right transverse sinus at the confluence of sinuses.
8-7 A vertebral artery angiogram (left lateral projection, arterial phase) is shown in A, and the same view, but in a different patient, is shown in B, using digital subtraction methods. Note the characteristic orientation of the major vessels. Compare with Figure 2-21 on page 25.
A vertebral artery angiogram (anterior–posterior projection, arterial phase) is shown in A; the same view, but in a different patient, is shown in B, using digital subtraction methods. Even though the injection is into the left vertebral, there is bilateral filling of the vertebral arteries and of branches of the basilar artery. The thalamoperforating arteries are important branches of P1 that generally serve rostral portions of the diencephalon.

The root of the oculomotor (IIIrd) nerve, after exiting the inferior aspect of the midbrain, characteristically passes through the interpeduncular cistern and between the superior cerebellar and posterior cerebral arteries en route to its exit from the skull through the superior orbital fissure. In this position the IIIrd nerve may be damaged by large aneurysms that impinge on the nerve root. Compare with Figures 2-40 (page 39) and 2-41 (page 40).
MRA images arteries, veins, and sinuses simultaneously, based on the movement of fluid in these structures. These are inverted video images of 3-D phase contrast MRA images as viewed from the dorsal to ventral (A) and from the lateral aspect (B). The distal portion of the anterior cerebral artery (ACA) immediately rostral to the anterior communicating artery and inferior to the rostrum of the corpus callosum is the A2 segment (infracallosal). The portion of the ACA arching around the genu of the corpus callosum is the A3 segment (precallosal) and the A4 (supracallosal) and A5 (postcallosal) segments are located superior to (above) the corpus callosum. Compare these images with arteries and veins as depicted in Figures 2-18 and 2-19 (page 23), 2-21 (page 25), and 2-23 (page 27).
MRA images of the vessels at the base of the brain forming much of the cerebral arterial circle (of Willis) (A, B). Note the anterior, middle, and posterior cerebral arteries as they extend outward from the circle. The upper image is from a normal individual, and the lower image is from a patient with a vestibular schwannoma. Descriptions of the segments of the anterior, middle, and posterior cerebral arteries are found on pages 25 and 242.
8-11  Magnetic resonance venography (MRV) primarily demonstrates veins and venous sinuses although arteries (seen in A and B) will also sometimes be visualized. Many veins and venous sinuses can be seen in this lateral view (A) and in the anterior-posterior view (B). Note that the continuation of the superior sagittal sinus is most prominent into the right transverse sinus (B, compare with Figure 8-6 on page 245). Compare with Figures 2-13 (page 19), 2-16 (page 21), 2-19 (page 27), and 2-28 (page 29).
8–12 Blood supply to the choroid plexus of the lateral, third, and fourth ventricles. Those branches of the vertebrobasilar system and of the internal carotid artery and P2 segment of the posterior cerebral artery that supply the choroid plexus are accentuated by appearing in a darker red shade. In A, a representation of these vessels (origin, course, termination) is shown from the lateral aspect. Anterior, posterior medial, and posterior lateral choroidal arteries serve the plexuses of the lateral and third ventricles. The choroid plexus in the fourth ventricle and the clump of choroid plexus protruding out of the foramen of Luschka are served by posterior inferior and anterior inferior cerebellar arteries, respectively. In B, the origins of these branches from their main arterial trunks are shown. See also Figures 2-21 (page 25), 2-24 (page 27), and 2-35 (page 35).
Overview (A) of the arteries in the neck that serve the brain (internal carotid and vertebral) and of their main terminal branches (anterior cerebral artery and middle cerebral artery, vertebrobasilar system) as seen in an MRA (anterior-posterior view). In approximately 40–45% of individuals the left vertebral artery is larger, as seen here, and in about 5–10% of individuals one or the other of the vertebral arteries may be hypoplastic as seen here on the patient’s right. The MRI in B is a detailed view of the vertebrobasilar system from the point where the vertebral arteries exit the transverse foramen to where the basilar artery bifurcates into the posterior cerebral arteries. Compare this image with Figure 2-21 on page 25.

The vertebral artery (VA) is generally described as being composed of 4 segments sometimes designated as V₁ to V₄. The first segment (V₁) is between the VA origin from the subclavian artery and the entrance of VA into the first transverse foramen (usually C6); the second segment V₂ is that part of VA ascending through the transverse foramen of C6 to C2; the third segment (V₃) is between the exit of VA from the transverse foramen of the axis and the dura at the foramen magnum (this includes the loop of the VA that passes through the transverse foramen of C1/the atlas); the fourth segment (V₄) pierces the dura and joins its counterpart to form the basilar artery.
CHAPTER 9

Q & A’s: A Sampling of Study and Review Questions, Many in the USMLE Style, All With Explained Answers

D. E. Haines and J. A. Lancon

There are two essential goals of a student studying human neurobiology, or, for that matter, the student of any of the medical sciences. The first is to gain the knowledge base and diagnostic skills to become a competent health care professional. Addressing the medical needs of the patient with insight, skill, and compassion is paramount. The second is to successfully negotiate whatever examination procedures are used in a given setting. These may be standard class examinations, Subject National Board Examination (now used/required in many courses), the USMLE Step 1 Examination (required of all U.S. medical students), or simply the desire, on the part of the student, for self-assessment.

The questions in this chapter are prepared in two general styles. First, there are study or review questions that test general knowledge concerning the structure of the central nervous system. Many of these have a functional flavor. Second, there are single one best answer questions in the USMLE style that use a patient vignette approach in the stem. These questions have been carefully reviewed for clinical accuracy and relevance as used in these examples. At the end of each explained answer, page numbers appear in parentheses that specify where the correct answer, be it in a figure or in the text, may be found. In order to make this a fruitful learning exercise, some answers may contain additional relevant information to extend the educational process.

In general, the questions are organized by individual chapters, although chapters 1 and 2 and chapters 3 and 4 are combined. Reference to the page (or pages) containing the correct answer are usually to the chapter(s) from which the question originated. However, recognizing that neuroscience is dynamic and three-dimensional, some answers contain references to chapters other than that from which the question originated. This provides a greater level of integration by bringing a wider range of information to bear on a single question.

Correct diagnosis of the neurologically compromised patient not only requires integration of information contained in different chapters but may also require inclusion of concepts gained in other basic science courses. In this regard a few questions, and their answers, may include such additional basic concepts.

This is not an all-inclusive list of questions, but rather a sampling that covers a wide variety of neuroanatomical and clinically relevant points. There is certainly a much larger variety of questions that could be developed from the topics covered in this atlas. It is hoped that this sample will give the user a good idea of how basic neuroscience information correlates with a range of clinically relevant topics.
Review and Study Questions for Chapters 1 and 2

1. A 71-year-old man complains to his family physician that his face “feels funny.” The examination reveals numbness on his face and on the same side of his tongue. MRI shows a lesion in the cerebral cortex. This man’s lesion is most likely located in which of the following cortical regions?
   (A) Anterior paracentral
   (B) Lateral one-third of the postcentral
   (C) Lateral one-third of the precentral
   (D) Middle one-third of the postcentral
   (E) Posterior paracentral

2. A 41-year-old woman complains to her family physician about recurring episodes of sharp pain that seem to originate from around her mouth and cheek. The pain is so intense that she is unable to eat, brush her teeth, or apply make-up. Which of the following nerves is the most likely source of this pain?
   (A) Facial (VII)
   (B) Glossopharyngeal (IX)
   (C) Hypoglossal (XII)
   (D) Trigeminal (V)
   (E) Vagus (X)

3. The labyrinthine artery is an important source of blood supply to the inner ear. Which of the following arteries represents the major vessel from which this branch usually arises?
   (A) Anterior inferior cerebellar
   (B) Basilar
   (C) Posterior inferior cerebellar
   (D) Superior cerebellar
   (E) Vertebral

4. The quadrigeminal artery in a 20-year-old man is occluded by a fat embolus originating from a compound fracture of the humerus. Which of the following structures does this occluded vessel most directly affect?
   (A) Superior cerebellar peduncle
   (B) Mammillary bodies
   (C) Medial and lateral geniculate bodies
   (D) Pineal and habenula
   (E) Superior and inferior colliculi

5. What additional deficit could this patient also have?
   (A) Anosmia
   (B) Hemianopsia
   (C) Numbness on the face
   (D) Visual field deficits
   (E) Weakness of the tongue

6. In addition to the vestibulocochlear nerve, which of the following structures would most likely also be affected by the tumor in this man?
   (A) Anterior inferior cerebellar artery
   (B) Facial nerve
   (C) Glossopharyngeal nerve
   (D) Posterior inferior cerebellar artery
   (E) Vagus nerve

7. A 67-year-old man complains to his family physician of severe headaches. The examination reveals visual deficits in both eyes, and MRI shows a lesion in the cerebral cortex. Which of the following cortical structures represents the most likely location of this lesion?
   (A) Angular gyrus
   (B) Cingulate gyrus
   (C) Lingual gyrus
   (D) Parahippocampal gyrus
   (E) Precuneus

8. A sagittal MRI of a 23-year-old woman is located at, or immediately adjacent to, the midline. Which of the following spaces or structures would most likely be involved?
   (A) Cerebral aqueduct
   (B) Corpus callosum
   (C) Interpeduncular fossa
   (D) Interventricular foramen
   (E) Superior colliculus

9. A 20-year-old man is brought to the emergency department from the site of a motorcycle accident. He is unconscious and has a broken femur, humerus, and extensive facial injuries. Axial CT shows a white layer on the lateral aspect of the left hemisphere that is approximately 5 mm thick and extends for 12 cm. This observation most likely represents:
   (A) Epidural hemorrhage/hematoma
   (B) Parenchymatous hemorrhage in the cortex
   (C) Subarachnoid hemorrhage
   (D) Subdural hemorrhage/hematoma
   (E) Ventricular hemorrhage

10. Which of the following portions of the ventricular system does not contain choroid plexus?
    (A) Cerebral aqueduct
    (B) Fourth ventricle
    (C) Lateral ventricle
    (D) Interventricular foramen
    (E) Third ventricle

11. A 47-year-old man presents with an intense pain on his face arising from stimulation at the corner of his mouth. This is characteristic of trigeminal neuralgia (tic douloureux). MRI shows a vessel compressing the root of the trigeminal nerve. Which of the following vessels would most likely be involved?
    (A) Anterior inferior cerebellar artery
    (B) Basal vein (of Rosenthal)
    (C) Basilar artery
    (D) Posterior cerebral artery
    (E) Superior cerebellar artery

Questions 5 and 6 are based on the following patient.

A 63-year-old man has hearing loss, tinnitus (ringing or buzzing sounds in the ear), vertigo, and unsteady gait; all of these have developed over several years. MRI reveals a large tumor (3 cm in diameter) at the cerebellopontine angle, most likely a vestibular schwannoma (sometimes incorrectly called an acoustic neuroma).

5. What additional deficit could this patient also have?
   (A) Anosmia
   (B) Hemianopsia
   (C) Numbness on the face
   (D) Visual field deficits
   (E) Weakness of the tongue

6. In addition to the vestibulocochlear nerve, which of the following structures would most likely also be affected by the tumor in this man?
   (A) Anterior inferior cerebellar artery
   (B) Facial nerve
   (C) Glossopharyngeal nerve
   (D) Posterior inferior cerebellar artery
   (E) Vagus nerve
12. Which of the following cranial nerves contain the afferent and efferent limbs of the corneal reflex?
   O (A) II and III (optic and oculomotor)
   O (B) III, IV, VI (oculomotor, trochlear, abducens)
   O (C) V and VII (trigeminal, facial)
   O (D) VIII and IX (vestibulocochlear, glossopharyngeal)
   O (E) IX and X (glossopharyngeal, vagus)

13. A 73-year-old man is brought to the emergency department after being found in his garage in a state of confusion. CT shows an infarct involving much of the superior frontal gyrus. Which of the following vessels is most likely occluded in this patient?
   O (A) Angular artery
   O (B) Callosomarginal artery
   O (C) Lenticulostriate arteries
   O (D) Middle cerebral artery, M₄ segments
   O (E) Posterior cerebral artery, P₄ segments

14. The MRI of a 49-year-old woman shows a tumor located immediately superior to the corpus callosum. This lesion is most likely located in which of the following lobes?
   O (A) Frontal
   O (B) Limbic
   O (C) Occipital
   O (D) Parietal
   O (E) Temporal

15. A 69-year-old woman is brought to the emergency department. The daughter reports that her mother suddenly seemed to be unable to speak. The examination reveals that the woman has a nonfluent (Broca) aphasia. A sagittal MRI shows a lesion in which of the following gyri?
   O (A) Angular
   O (B) Inferior frontal
   O (C) Lateral one-third of the precentral
   O (D) Middle frontal
   O (E) Supramarginal

16. Which of the following Brodmann areas represents the primary somatosensory cortex?
   O (A) Areas 3, 1, 2
   O (B) Area 4
   O (C) Area 17
   O (D) Area 22
   O (E) Area 40

17. A 64-year-old man awakens with a profound weakness of his right hand. The man is transported by ambulance to a major medical center, a distance of 240 miles and taking several hours. About 2.5 hours after his arrival, an MRI shows a small lesion in the cerebral cortex. Which of the following gyri represents the most likely location of this lesion?
   O (A) Anterior paracentral
   O (B) Medial one-third of precentral
   O (C) Middle frontal
   O (D) Middle one-third of precentral
   O (E) Lateral one-third of precentral

18. A lumbar puncture, commonly called a “lumbar tap,” consists of a needle being inserted through an intervertebral space into the lumbar cistern to retrieve a sample of cerebrospinal fluid. Which of the following is the most likely level for the insertion of the needle?
   O (A) L₁–L₂
   O (B) L₂–L₃
   O (C) L₄–L₅
   O (D) S₁–S₂
   O (E) T₁₂–L₁

19. A 59-year-old man complains of persistent headache. An MRA (Magnetic Resonance Angiography) shows an aneurysm in the interpeduncular fossa (and cistern) arising from the basilar tip. Which of the following cranial nerves would be most directly affected by this aneurysm?
   O (A) Abducens (VI)
   O (B) Oculomotor (III)
   O (C) Optic (II)
   O (D) Trigeminal, V₁ (V)
   O (E) Trochlear (IV)

20. A 71-year-old man presents with a Broca (nonfluent) aphasia. MRI reveals a lesion in Brodmann area 44. As this lesion expands, due to edema, and impinges on the immediately adjacent cortical areas, which of the following deficits would most likely be seen?
   O (A) Loss of hearing in one ear
   O (B) Numbness and prickly sensation on the hand
   O (C) Visual field deficits in both eyes
   O (D) Weakness of facial muscles
   O (E) Weakness of the upper extremity

21. A 47-year-old woman presents with seizures and ill-defined neurologic complaints. The examination reveals a bruit on the lateral aspect of the head immediately rostral and superior to the ear. A CT shows a large arteriovenous malformation in the area of the lateral sulcus. The feeding artery(ies) is M₄ branches. Which of the following most likely represents the major draining vein?
   O (A) Inferior sagittal sinus
   O (B) Internal cerebral vein
   O (C) Ophthalmic vein
   O (D) Superficial middle cerebral vein
   O (E) Superior petrosal sinus

22. The collection of posterior and anterior roots that occupy the lumbar cistern are collectively known as which of the following?
   O (A) Cauda equina
   O (B) Conus medullaris
   O (C) Denticulate ligament
   O (D) Filum terminale externum
   O (E) Filum terminale internum

23. Which of the following Brodmann areas represents the primary somatomotor cortex?
   O (A) Areas 3, 1, 2
   O (B) Area 4
   O (C) Area 5
   O (D) Area 6
   O (E) Area 7
24. A 39-year-old woman complains of weakness in her right lower extremity. The history suggests that this deficit has developed slowly, perhaps over several years. MRI shows a meningioma imposes on the cerebral cortex. Which of the following gyri is most likely involved in this lesion?

- (A) Anterior paracentral
- (B) Lateral part of precentral
- (C) Medial part of precentral
- (D) Medial part of postcentral
- (E) Posterior paracentral

25. A 71-year-old woman presents with motor and sensory deficits affecting her face and upper extremity. CT shows a hemorrhage that is confined largely to the cortex and adjacent subcortical areas. Which of the following vessels/segments are most likely involved?

- (A) A1
- (B) M2
- (C) M3
- (D) M4
- (E) P4

26. A 22-year-old man is brought to the emergency department with a gunshot wound to the head. He is decorticate but soon becomes decerebrate. This change in status is due to uncal herniation. Which of the following most specifically describes the position of the uncus prior to herniation?

- (A) At the temporal lobe
- (B) Caudal aspect of the cingulate gyrus
- (C) Caudal aspect of the gyrus rectus
- (D) Medial edge of occipitotemporal gyri
- (E) Rostromedial aspect of the parahippocampal gyrus

27. A 73-year-old woman presents with visual deficits in both eyes. No other cranial nerve deficits or motor or sensory deficits are seen. CT shows a hemorrhage in the cerebral cortex. Which of the following vessels/segments is most likely involved in this hemorrhage?

- (A) A1
- (B) M3
- (C) M4
- (D) P2
- (E) P4

28. The CT of a 77-year-old man shows a calcified tuft of choroid plexus, the glomus choroideum. Which of the following represents the location of this part of the choroid plexus?

- (A) Anterior horn of the lateral ventricle
- (B) Atrium of the lateral ventricle
- (C) Body of the lateral ventricle
- (D) Caudal roof of the third ventricle
- (E) Temporal horn of the lateral ventricle

29. Which of the following represents the most common cause of blood in the subarachnoid space (subarachnoid hemorrhage)?

- (A) Bleeding from an arteriovenous malformation
- (B) Bleeding from a meningioma
- (C) Bleeding from a tumor
- (D) Rupture of an aneurysm
- (E) Trauma to the brain

30. The abducens nerve exits the brainstem at the pons-medulla junction generally in line with the preolivary sulcus and passes rostrally just lateral to, and in the same cistern as, the basilar artery. Which of the following cisterns contains the abducens nerve and basilar artery?

- (A) Ambient
- (B) Inferior cerebellopontine
- (C) Premedullary
- (D) Prepyramidal
- (E) Superior cerebellopontine

31. An 81-year-old woman is brought to the emergency department by her son with a complaint of weakness on the same side of her body and face. CT shows a hemorrhage in the territory of the lenticulostriate arteries. Which of the following represents the most likely origin of these vessels?

- (A) A1
- (B) M1
- (C) M2
- (D) P1
- (E) P2

32. The MRI of a 27-year-old woman shows a meningioma impinging on the gyrus rectus in axial and coronal MRI. This lesion is located on which of the following lobes of the cerebral hemisphere?

- (A) Frontal
- (B) Insular
- (C) Occipital
- (D) Parietal
- (E) Temporal

33. A 51-year-old man presents with visual field deficits in both eyes and a right-sided weakness of the upper and lower extremities. MRI shows a lesion in the optic tract that has spread into a structure located immediately adjacent to this tract. Based on its anatomical relationship, which of the following structures is most likely involved in a lesion spreading from the optic tract?

- (A) Left basilar pons
- (B) Left crus cerebri
- (C) Left pyramid
- (D) Right crus cerebri
- (E) Right optic nerve

34. A 19-year-old man presents with significant paralysis of movement in his left eye and a dilated pupil. No other deficits are seen. Suspecting some type of lesion on the root or along the intracranial course of the oculomotor (III) nerve, the neurologist orders an MRI. Which of the following describes the appearance of the subarachnoid and ventricular spaces in a T2-weighted image?

- (A) Black (hypointense)
- (B) Dark grey
- (C) Light grey
- (D) Medium grey
- (E) White (hyperintense)
35. A 49-year-old woman presents with ill-defined neurologic deficits that have persisted over several months. As part of the evaluation, the neurologist orders an MRI. Which of the following describes the appearance of CSF in the ventricular spaces, and consequently the outline and shape of the ventricles, in a T1-weighted image?

- (A) Black (hypointense)
- (B) Dark grey
- (C) Light grey
- (D) Medium grey
- (E) White (hyperintense)

36. A 71-year-old morbidly obese man is brought to the emergency department by his son. The son reports that the man complained of a sudden excruciating headache and then became stuporous. Suspecting a ruptured aneurysm the physician orders a CT. Which of the following describes the appearance of acute blood in the subarachnoid space in CT?

- (A) Black (hypodense)
- (B) Black to grey
- (C) Light grey
- (D) Medium grey
- (E) White (hyperdense)

37. Which of the following cranial nerves exits the brainstem via the preolivary sulcus?

- (A) Abducens (VI)
- (B) Facial (VII)
- (C) Hypoglossal (XII)
- (D) Vagus (X)
- (E) Trigeminal (V)

38. A 29-year-old woman becomes acutely ill with high fever, a stiff neck, and stupor. A lumbar puncture reveals cloudy cerebrospinal fluid from which organisms are cultured. Which of the following most frequently seen organisms in cases of adult bacterial meningitis?

- (A) Escherichia coli
- (B) Haemophilus influenzae
- (C) Herpes simplex
- (D) Listeria monocytogenes
- (E) Streptococcus pneumoniae

39. Which of the following cranial nerves exits the posterior (dorsal) aspect of the brainstem?

- (A) Abducens (VI)
- (B) Hypoglossal (XII)
- (C) Trigeminal (V)
- (D) Trochlear (IV)
- (E) Vestibulocochlear (VIII)

40. Which of the following cranial nerves passes between the posterior cerebral artery and the superior cerebellar artery as it exits the brainstem?

- (A) Abducens
- (B) Oculomotor
- (C) Optic
- (D) Trigeminal
- (E) Vestibulocochlear

41. The MRI of an 11-year-old boy shows a tumor in the pontine portion of the fourth ventricle. The rostral edge of which of the following structures represents the border between the medullary and pontine parts of the fourth ventricle?

- (A) Facial colliculus
- (B) Hypoglossal trigone
- (C) Medial eminence
- (D) Stria medullares
- (E) Vagal trigone

42. A 61-year-old man presents with a tremor and unsteady gait; these problems are on the same side of his body. Sagittal MRI shows a lesion in the anterior lobe of the cerebellum. Which of the following represents the fissure separating the anterior and posterior lobes of the cerebellum?

- (A) Horizontal fissure
- (B) Posterior superior fissure
- (C) Posterolateral fissure
- (D) Primary fissure
- (E) Secondary fissure

43. The MRI of a 49-year-old woman with a brain tumor shows tonsillar herniation. Based on its anatomical position, which of the following portions of the brainstem would be most adversely affected by tonsillar herniation?

- (A) Caudal midbrain
- (B) Caudal pons
- (C) Medulla
- (D) Rostral midbrain
- (E) Rostral pons

44. A 4-year-old boy is brought to the emergency department by his mother who explains that the boy fell off a porch onto a concrete sidewalk. The examination reveals that the boy has a parietal scalp laceration, is stuporous, and has reactive pupils. Suspecting that this boy may have a possible skull fracture with some type of intracranial bleeding, which of the following imaging tests would be most immediately (and appropriately) useful?

- (A) CT
- (B) MRI, gadolinium enhanced
- (C) MRI, T1-weighted
- (D) MRI, T2-weighted
- (E) PET (Positron Emission Tomography)

45. A sagittal MRI of a 52-year-old man clearly shows a small tumor in the area of the long and short gyri. These gyri are characteristic found in which of the following lobes?

- (A) Frontal
- (B) Insular
- (C) Limbic
- (D) Occipital
- (E) Parietal

46. A lesion involving the root of which of the following nerves would most likely have an effect on the gag reflex?

- (A) Accessory
- (B) Facial
- (C) Glossopharyngeal
- (D) Hypoglossal
- (E) Trigeminal
Answers for Chapters 1 and 2

1. Answer B: Nummness on the face, resulting from a lesion in the cerebral cortex, indicates a lesion in the lateral one-third of the postcentral gyrus (face area of the somatosensory cortex). The anterior paracentral gyrus and the precentral gyrus are somatomotor areas of the cerebral cortex. The upper extremity is represented in the middle one-third of the postcentral gyrus and the lower extremity is represented in the posterior paracentral gyrus. (p. 15)

2. Answer D: Tic douloureux (trigeminal neuralgia) is a lancinating pain that originates from the territories of the trigeminal nerve, primarily its V2 or V3 territories. The trigger zone is frequently around the corner of the mouth. There is a geniculate nerve, primarily its V2 or V3 territories. The trigger zone is frequently around the corner of the mouth. There is a geniculate nerve, primarily its V2 or V3 territories. The trigger zone is frequently around the corner of the mouth. (p. 25)

3. Answer A: In most cases (85–100%), the labyrinthine artery, also called the internal auditory artery, originates from the anterior inferior cerebellar artery. It enters the internal acoustic meatus, serves bone and dura of the canal, the nerves of the canal, and vestibular and cochlear structures. In a few cases (15% or less), this artery originates from the basilar artery. None of the other choices gives rise to vessels that serve the inner ear. (p. 25, 27)

4. Answer E: The quadrigeminal artery is the primary blood supply to the superior and inferior colliculi; this vessel originates from P1. The geniculate bodies receive their blood supply from the thalamogeniculate arteries, and the pineal and habenula from the posterior medial choroidal artery. The superior cerebellar peduncle receives its blood supply via the medial branch of the superior cerebellar artery, and branches of the cerebral circle (of Willis) serve the mammillary bodies. (p. 25, 35)

5. Answer C: Vestibular schwannomas larger than 2.0 cm in diameter may impinge on the root of the trigeminal nerve and cause numbness on the same side of the face. Although the other deficits listed are not seen in these patients, diplopia (involvement of oculomotor, abducens or trochlear nerves, singularly or in combination) may be present, but in fewer than 10% of these individuals. (p. 42)

6. Answer B: The internal acoustic meatus contains the vestibulocochlear nerve, the facial nerve, and the labyrinthine artery, a branch of the anterior inferior cerebellar artery. A vestibular schwannoma located in the meatus would likely affect the facial nerve and result in facial weakness. The vagus and glossopharyngeal nerves exit the skull via the jugular foramen (along with the accessory nerve). The cerebellar arteries originate within the skull and distribute to structures within the skull. (p. 42)

7. Answer C: The lingual gyrus is the lower bank of the calcarine sulcus; the upper (cuneus) and lower banks of this sulcus are the location of the primary visual cortex. The precuneus is the medial aspect of the parietal lobe, and the angular gyrus is a portion of the inferior parietal lobule on the lateral aspect of the hemisphere. The cingulate and parahippocampal gyri are located on the medial aspect of the hemisphere and are parts of the limbic lobe. (p. 13–15, 28)

8. Answer A: The cerebral aqueduct is about 1.5–2.0 mm in diameter, and connects the third ventricle with the fourth ventricle. When this part of the ventricular system appears in a sagittal MRI, the plane of the scan is at the midline. Neither the interventricular foramen nor the superior colliculus are on the midline. Both the interpeduncular fossa and the corpus callosum are on the midline, but extend off the midline well beyond the width of the cerebral aqueduct. (p. 28–31, 49, 50, 52)

9. Answer D: Trauma may cause epidural hemorrhage, subdural hemorrhage, or subarachnoid hemorrhage. Acute subdural hemorrhage/hematoma will appear white in CT and will usually present as a comparatively thin but long defect. Epidural hemorrhage will usually be seen as a shorter but thicker lesion and may appear loculated (have some sort of internal structure). The structure (shape) of this lesion does not conform to hemorrhage into the substance of the brain (brain parenchyma), into the subarachnoid space (or cisterns), and certainly not to hemorrhage into the ventricles. (p. 46, 48, 51)

10. Answer A: The only portion of the ventricular system that does not contain choroid plexus is the cerebral aqueduct. The choroid plexus in the lateral ventricle is continuous from the inferior horn into the atrium and into the body of the ventricle, and through the interventricular foramen with the choroid plexus located along the roof of the third ventricle. There is a tuft of choroid plexus in the fourth ventricle, a small part of which extends into the lateral recess and through the lateral foramen (of Luschka) into the subarachnoid space at the cerebellomedullary angle. (p. 52–53)

11. Answer E: Branches of the superior cerebellar artery are most frequently involved in cases of trigeminal neuralgia that are presumably of vascular origin. The posterior cerebral artery and its larger branches serve the midbrain-diencephalic junction or join the medial surface of the hemisphere. The basilar artery serves the basilar pons and the anterior inferior cerebellar artery serves the caudal midbrain, inner ear, and the inferior surface of the cerebellar surface. The basal vein drains the medial portions of the hemisphere and passes through the ambient cistern to enter the great cerebral vein (of Galen). (p. 41)

12. Answer C: The afferent limb of the corneal reflex is via the ophthalmic division of the trigeminal nerve (V); the cell body of origin is in the trigeminal ganglion and the central terminations in the pars caudalis of the spinal trigeminal nucleus. The efferent limb originates in the motor nucleus of the facial nerve (VII) and distributes to the facial muscles around the eye. None of the other choices contains fibers related to the corneal reflex. (p. 42)

13. Answer B: The callosomarginal artery, a branch of the anterior cerebral artery, serves the medial aspect of the superior frontal gyrus and that portion of this gyrus on the superior and lateral aspects of the hemisphere. M4 segments of the middle cerebral artery serve the lateral aspects of the hemisphere; P4 segments of the posterior cerebral artery serve the medial aspects of the hemisphere caudal to the parietocipital sulcus, and the angular artery (an M4 branch) serves the angular gyrus of the inferior parietal lobule. The lenticulostriate arteries are branches of M1 that serve internal structures of the hemisphere. (p. 17, 29)

14. Answer B: The limbic lobe, consisting primarily of the cingulate gyrus and the parahippocampal gyrus, is located on the most
medial aspect of the hemisphere; the cingulate gyrus is located immediately adjacent to the corpus callosum. None of the other lobes of the cerebral cortex borders directly on the corpus callosum. (p. 13, 28)

15. Answer B: The inferior frontal gyrus consists of the pars orbitalis (Brodmann area 47), pars triangularis (area 45), and pars opercularis (area 44). A lesion located primarily in areas 44 and 45 in the dominant hemisphere will result in a nonfluent (Broca) aphasia. The supramarginal (area 40) and angular (area 39) gyri represent what is called the Wernicke area, and the middle frontal gyrus contains areas 6 and 8. The lateral one-third of the precentral gyrus is the face area of the somatomotor cortex. (p. 14)

16. Answer A: Areas 3, 1, 2 collectively represent the primary somatosensory cortex. Area 4 is the primary somatomotor cortex, area 17 the primary visual cortex, and area 22 the primary auditory cortex. Area 40 is in the supramarginal gyrus, a large part of which is called the Wernicke area. (p. 14)

17. Answer D: The body is represented in the somatomotor cortex (precentral gyrus, anterior paracentral gyrus) in the following pattern: the face in about the lateral one-third of the precentral gyrus above the lateral sulcus; the hand and upper extremity in about its middle third; and the trunk and hip in about its medial third. The lower extremity and foot are represented in the anterior paracentral gyrus. Caudal portions of the middle frontal gyrus are the location of the frontal eye field. (p. 15)

18. Answer C: The L4-L5 interspace is commonly used for a lumbar puncture. The L3-L4 space may also be used. Levels T12 to L2-L3 are too high. Because the caudal end of the spinal cord (the conus medullaris) may be as low as L2 in some individuals, levels T12-L1 to L2-L3 are not used, as this would most likely result in damage to the spinal cord. The S1-S2 vertebrae are fused so there is no intervertebral space through which a needle can pass. Furthermore, the dural sac ends at about S2. (p. 12)

19. Answer B: The oculomotor nerve (III) exits from the medial aspect of the midbrain into the interpeduncular fossa/cistern. It traverses this space, courses through the lateral wall of the cavernous sinus to eventually enter (along with the trochlear [IV] and abducens [VI] nerves) the superior orbital fissure. Cranial nerves IV, VI, and V1 (the ophthalmic portion of the trigeminal nerve), along with III, pass through the cavernous sinus. Cranial nerve II (optic) is quite rostral to the interpeduncular fossa. (p. 24, 30, 40)

20. Answer D: A lesion in area 44 (the pars opercularis) that spreads will affect the lower portions of the precentral gyrus in which the face is represented. This will result in weakness of facial muscles, accompanied by other cranial nerve deficits. The cortical areas for hearing and vision are far separated from area 44. Also, a lesion in the primary auditory cortex will not result in a hearing loss in one ear. The hand area of the sensory cortex and the upper extremity area of the motor cortex are not adjacent to Brodmann area 44. (p. 14)

21. Answer D: The superficial middle cerebral vein is located on the surface of the cerebral hemisphere in the immediate vicinity of the lateral sulcus and, of the choices, is the most likely candidate. The deep middle cerebral vein is located on the surface of the insular lobe. The inferior sagittal sinus primarily drains the medial aspect of the hemisphere immediately superior to the corpus callosum. The internal cerebral vein (to the great cerebral vein) drains the internal parts of the hemisphere; the ophthalmic vein connects the orbit with the cavernous sinus; and the superior petrosal sinus connects the cavernous sinus with the sigmoid sinus at its junction with the transverse sinus. (p. 19, 23, 29)

22. Answer A: As they descend in the dural sac from their origin from the spinal cord to their exit at their respective intervertebral foramen, the anterior and posterior roots form the cauda equina. The conus medullaris is the most caudal end of the spinal cord, and the filum terminale internum is the strand of pia that extends from the conus caudally to attach to the inner aspect of the dural sac at about S2. The denticulate ligament anchors the spinal cord laterally to the inner surface of the dural sac, and the filum terminale externum anchors the dural sac caudally to the inner aspect of the coccyx. (p. 12, 85, 87)

23. Answer B: The primary somatomotor cortex consists of the precentral gyrus and the anterior paracentral gyrus; area 4 is found in these structures. Areas 3, 1, and 2 are the primary somatosensory cortex; areas 5 and 7 make up the superior parietal lobule and the precuneus; and area 6 is located rostral to area 4. Portions of area 6 in the caudal region of the middle frontal gyrus are the frontal eye field. (p. 15)

24. Answer A: In this patient, the meningioma is located in the falk cerebri and is impinging on the anterior paracentral gyrus correlating with her motor deficit. The lower extremity is represented in the anterior paracentral gyrus (somatomotor) and in the posterior paracentral gyrus (somatosensory). The precentral gyrus contains the motor representation for the face (lateral part) and the trunk and hip (medial part). The postcentral gyrus is part of the somatosensory cortex. (p. 15)

25. Answer D: The M1 segments of the middle cerebral artery serve the lateral aspect of the cerebral hemisphere. The named M2 vessels that serve the pre- and postcentral gyri (hemorrhage into approximately the lower two-thirds of these gyri explain the motor and sensory deficits) are the precentral branches ( prerolandic), central branches (Rolandic branches), and anterior parietal branches. The M3 segment serves the insular cortex, and the M5 segment serves the inner surface of the frontal, parietal, and temporal opercula. The A1 segment serves hypothalamic structures, the subcallosal and septal areas, and adjacent structures. P1 serves the medial aspect of the occipital lobe (visual cortex). (p. 19, 29)

26. Answer E: The uncus is a small elevation at the rostral and medial aspect of the parahippocampal gyrus adjacent to the crus cerebri of the midbrain. In addition to the catastrophic effect of decerebration, herniation of the uncus may also affect corticospinal and corticonuclear (corticobulbar) fibers in the crus cerebri and the root of the oculomotor nerve. None of the other areas of the forebrain listed as choices is related to uncal herniation. (p. 20, 22)

27. Answer E: The P1 segments of the posterior cerebral artery consist of the parieto-occipital and calcareous branches; the latter being located in the calcareous sulcus and a primary blood supply to the primary visual cortex. M1 and M2 segments of the middle cerebral are located, respectively, on the inner aspect of the frontal, parietal, and temporal opercula and on the lateral aspect of the cere-
bral hemisphere. The P₂ segment of the posterior cerebral artery is located just distal to the posterior communicating–posterior cerebral intersection and gives rise to medial and lateral posterior choroidal and to thalamogeniculate arteries. The A₁ segment is located between the internal carotid and anterior communicating artery and gives rise to branches that serve anterior hypothalamic structures, septal areas, and the optic chiasm. (p. 21, 29)

28. **Answer B:** The glomus choroidiæ is found in the atrium of the lateral ventricle. This part of the choroid plexus is rostrally continuous with that in the body of the lateral ventricle and continuous anteroinferiorly with that in the temporal horn. The roof of the third ventricle has a small portion of choroid plexus that is continuous with that in the body of the ventricle via the interventricular foramen. The anterior horn contains no choroid plexus. (p. 52)

29. **Answer E:** Trauma is the most common cause of subarachnoid hemorrhage (SAH). The most common cause of spontaneous (also called nontraumatic) SAH is bleeding from a ruptured aneurysm (about 75% of all spontaneous cases). Bleeding from an arteriovenous malformation (AVM) is an infrequent cause of SAH (about 5% of cases), and bleeding from brain tumors into the subarachnoid space is rare. Meningiomas are usually slow-growing tumors that may have a rich vascular supply but rarely hemorrhage spontaneously. (p. 46)

30. **Answer D:** The prepontine cistern is located external to the basilar pons and contains the abducens nerve, basilar artery, origin of the anterior inferior cerebellar artery, and small perforating arteries and veins. The ambient cistern is located on the lateral aspect of the midbrain and contains the trochlear nerve and several major arteries. The premedullary cistern is located at the anterior surface of the medulla and contains the anterior spinal artery. The inferior cerebellopontine cistern contains the glossopharyngeal, vagus, and accessory nerves. The superior cerebellopontine cistern contains the trigeminal, facial, and vestibulocochlear nerves plus a short segment of the trochlear nerve. (p. 50, 51)

31. **Answer B:** Lenticulostratite arteries, also called the lateral striate arteries, originate from the M₁ segment of the middle cerebral artery and serve much of the lenticular nucleus and adjacent parts of the internal capsule. A₁ branches serve the anterior hypothalamus and optic chiasm, and M₂ branches serve the insular cortex. The P₁ and P₂ segments give rise to many small perforating branches and to the thalamoperforating and quadrigeminal arteries (P₁), medial and lateral posterior choroidal arteries, and the thalamogeniculate artery (P₂). (p. 25, 49, 242)

32. **Answer A:** The gyrus rectus is located on the inferior and medial aspect of the frontal lobe. It is separated from the orbital gyri by the olfactory sulcus in which the olfactory bulb and tract is located. None of the other lobes has a direct relationship to the gyrus rectus. (p. 20, 22)

33. **Answer B:** The optic tract lies immediately on the surface of the crus cerebri, a relationship frequently seen in MRI. The fact that this patient has a right-sided weakness of the extremities specifies that the lesion is in the left crus cerebri. The bilateral visual deficits correlate with damage to the left optic tract. Lesions of the left basilar pons and pyramid would result in a right-sided weakness but no visual deficits. A lesion in the right optic nerve would result in blindness in that eye but no weakness of the extremities. (p. 20, 26, 40, 220–221)

34. **Answer E:** Cerebrospinal fluid in the ventricles, and throughout the subarachnoid space, appears very white in T₁-weighted MRI images. Structures located in, or traversing the subarachnoid space (such as vessels or cranial nerve roots, including the oculomotor nerve) appear grey to black against a white background. (p. 46–47, 49, 51, 54)

35. **Answer A:** Cerebrospinal fluid, and other fluids, appear black in T₁-weighted MRI images. Consequently, the ventricles, and more obvious parts of the subarachnoid space, appear black. Changes in ventricular shape (i.e., enlargement, midline shift), or obliterated sulci, or even subarachnoid space, most likely represent a potentially serious clinical issue. (p. 2–4, 33 as one example)

36. **Answer E:** Patients who experience rupture of an intracranial aneurysm frequently complain of an intense, sudden headache (“the most horrible headache I have ever had”). Acute blood in the subarachnoid space will appear white to very white on CT. This will contrast with the medium grey of the brain and the black of cerebrospinal fluid (CSF) in the ventricles. The degree of white may vary somewhat, based on the relative concentration of blood, from very white (concentrated blood) to white (mostly blood, some CSF), to very light grey (mixture of blood and CSF). (p. 46–47, 51)

37. **Answer C:** The hypoglossal nerve exits the medulla via the preolivary sulcus of the medulla immediately (and laterally) adjacent to the pyramid. The abducens nerve exits in line with the preolivary sulcus, but, at the caudal edge of the pons, and the trigeminal nerve exits the lateral aspect of the pons. The vagus nerve exits the lateral aspect of the medulla via the postolivary sulcus, and the facial nerve in line with this sulcus, but at the pons-medulla junction. (p. 24, 44)

38. **Answer E:** Approximately one-half of cases of bacterial meningitis in adults is caused by *S. pneumoniae*. *E. coli* and *L. monocytogenes* are causative agents in neonates and children, although the latter (*L. monocytogenes*) is present in less than 10% of cases. While *H. influenzae* was a major cause of bacterial meningitis in children, the use of a vaccine has reduced this bacterium as a causative agent to well under 10% of cases. *H. simplex* is a virus. (p. 46)

39. **Answer D:** The trochlear nerve exits the posterior (dorsal) aspect of the brainstem just caudal to the inferior colliculus and passes around the lateral aspect of the midbrain in the ambient cistern, en route to its exit from the skull via the superior orbital fissure. The abducens nerve exits at the caudal edge of the pons in line with the preolivary fissure, and the hypoglossal exits from the medulla via this fissure. The trigeminal nerve exits the lateral aspect of the pons, and the vestibulocochlear nerve exits at the most lateral aspect of the pons-medulla junction. (p. 26, 33, 34)

40. **Answer B:** As it exits the anterior (ventral) surface of the midbrain, the oculomotor nerve passes between the superior cerebellar artery (which is caudal to the nerve root) and the P₁ segment of the posterior cerebral artery (which is rostral to the nerve root). The trigeminal root is adjacent to more distal portions of the superior cerebellar artery; the labyrinthine artery accompanies the vestibulocochlear nerve as it enters the internal acoustic meatus; and the ophthalmic artery accompanies the optic nerve along part of its extent. The abducens nerve passes rostrally adjacent to the basilar artery in the prepontine cistern. (p. 25, 39, 40)
41. Answer D: The rostral edge of the striae medullares (of the fourth ventricle) is regarded as the border between the pontine and medullary portions of the fourth ventricle. These fibers pass from the median fissure in the floor of the ventricle laterally into the lateral recess where they arch up into the cerebellum. The facial colliculus and median eminence are located in the floor of the pontine portion of the ventricle, and the vagal and hypoglossal trigones are found in the medial floor of the medullary portion of the fourth ventricle. (p. 34, 35, 36)

42. Answer D: The primary fissure is the deepest fissure in the cerebellum and it separates the anterior lobe from the posterior lobe and extends from the vermis to the lateral cerebellar margin. The posterolateral fissure is located between the flocculonodular lobe and the posterior lobe. The horizontal, secondary, and posterior superior fissures are all located within the posterior lobe. (p. 32, 33)

43. Answer C: The tonsil of the cerebellum is found on the caudal and inferior aspect of the cerebellar hemisphere, adjacent to the midline and immediately posterior (dorsal) to the medulla. The cisterna magna is located in this area. Sudden tonsillar herniation may compress the medulla and damage respiratory and cardiac centers resulting in sudden death. The tonsil herniates downward through the foramen magnum. Consequently, no other part of the brainstem is directly affected. (p. 32, 44)

44. Answer A: A CT is a fast method, does not require sedation of young patients, and shows bone fractures and acute intracranial blood in detail. MRI (T1- and T2-weighted) does not show acute blood or bone fracture to advantage, takes much longer to do, and may require sedation in a child. Enhanced MRI is uniquely useful for tumors, and PET is useful in identifying metabolic activity of brain tissue, not anatomic detail. (p. 4–6)

45. Answer B: The long and short gyri (gyri longi et breves) are components of the insular lobe. This lobe is located deep to the lateral sulcus, has a central sulcus that separates the short gyri (rostro to this sulcus) from the long gyri (caudal to this sulcus). The cortex of the insular lobe is separated from the adjacent frontal, parietal, and temporal opercula by the circular sulcus of the insula. None of the other lobes has gyri that are specifically named long and short gyri. (p. 13, 45, 36)

46. Answer C: The glossopharyngeal nerve contains the afferent limb of the gag reflex and, through its innervation of the stylopharyngeus muscle, is an important part of the efferent limb of this reflex. The nucleus ambiguus, the location of the motor neurons serving the stylopharyngeus, also contributes to the innervation of muscle served by the vagus nerve and, therefore, to the efferent limb of the gag reflex. The trigeminal and facial nerves participate in the afferent and efferent limbs (respectively) of the corneal reflex. The accessory nerve innervates the ipsilateral trapezius and sternocleidomastoid muscles, and the hypoglossal nerve innervates the ipsilateral genioglossus muscle. (p. 24, 43)

Review and Study Questions for Chapters 3 and 4

1. A 47-year-old woman presents with signs of increased intracranial pressure (vomiting, headache, lethargy). MRI shows a large tumor invading the head of the caudate nucleus, the rostral portion of the putamen and involving a fiber bundle located between these two structures. This fiber bundle is most likely the:
   - (A) anterior commissure
   - (B) anterior limb of the internal capsule
   - (C) column of the fornix
   - (D) external capsule
   - (E) posterior limb of the internal capsule

2. A 76-year-old woman is diagnosed as having “probable” Alzheimer’s disease based on a steady decline in cognitive function. It is likely that this woman has cell dropout in the nucleus accumbens. Which of the following most specifically describes the location of this cell group?
   - (A) At the junction of the caudate head and putamen
   - (B) At the junction of the pallidum and putamen
   - (C) At the junction of the pallidum and substantia nigra
   - (D) In the anterior wall of the temporal horn
   - (E) Internal to the uncus

3. Which of the following structures is located in the medial wall of the temporal horn of the lateral ventricle and, if severely damaged, may result in memory deficits?
   - (A) Amygdaloid complex
   - (B) Calcar avis
   - (C) Hippocampus
   - (D) Pulvinar
   - (E) Tail of the caudate

4. Which of the following represents the fibers that fan out from the internal capsule into the white matter of the hemisphere?
   - (A) Cingulum
   - (B) Corona radiata
   - (C) Genu of the corpus callosum
   - (D) Superior longitudinal fasciculus
   - (E) Uncinate fasciculus

5. The lamina of white matter located immediately internal to the cortex of the insula is the:
   - (A) Arcuate fasciculus
   - (B) External capsule
   - (C) Extreme capsule
   - (D) Internal capsule
   - (E) Tapetum

6. A 48-year-old man presents with a movement disorder (chorea) and mental deterioration. MRI shows the loss of a structure in the wall of the anterior horn of the lateral ventricle. Which of the following is most likely lost in this patient?
   - (A) Anterior thalamic nucleus
   - (B) Body of the caudate nucleus
   - (C) Column of the fornix
   - (D) Dorsomedial nucleus
   - (E) Head of the caudate nucleus
7. A 76-year-old man presents with a resting tremor, bradykinesia, and stooped posture. These observations suggest loss of a prominent population of cells in the brain. Which of the following structures is most likely affected in this patient?  
   - (A) Lateral cerebellar nucleus
   - (B) Locus ceruleus
   - (C) Red nucleus
   - (D) Substantia nigra
   - (E) Subthalamic nucleus

8. Which of the following represents the larger, more laterally located portion of the basal nuclei (also called the basal ganglia)?  
   - (A) Caudate nucleus
   - (B) Globus pallidus
   - (C) Putamen
   - (D) Subthalamic nucleus
   - (E) Substantia nigra

9. The MRI of a 59-year-old woman shows a large arteriovenous malformation (AVM) located between the lenticular nucleus and the dorsal thalamus. Based on its location, this AVM most likely involves which of the following structures?  
   - (A) Anterior limb of the internal capsule
   - (B) Crus cerebri
   - (C) External capsule
   - (D) Posterior limb of the internal capsule
   - (E) Retrolenticular limb of the internal capsule

10. A 29-year-old man is brought to the emergency department with a severe and persistent headache. MRI shows a large tumor of the pineal gland. Based on its location, this pineal lesion would most likely impinge on which of the following structures?  
    - (A) Anterior thalamic nucleus
    - (B) Body of the caudate nucleus
    - (C) Globus pallidus
    - (D) Pulvinar nucleus(i)
    - (E) Ventral posteromedial nucleus

11. The hippocampal commissure contains fibers from one hippocampal formation that cross the midline to distribute to targets on the opposite side of the hemisphere. Which of the following structures is directly adjacent to this commissure?  
    - (A) Body of the corpus callosum
    - (B) Genu of the corpus callosum
    - (C) Splenium of the corpus callosum
    - (D) Spiral fibers of the hippocampus
    - (E) Precommissural fornix

12. An 85-year-old woman is brought to the emergency department by her family because she suddenly became confused and lethargic. CT shows a hemorrhage into the medial and lateral geniculate bodies. Which of the following structures would also likely be involved in this lesion due to its apposition to the geniculate bodies?  
    - (A) Anterior thalamic nucleus
    - (B) Rostral dorsomedial nucleus
    - (C) Globus pallidus
    - (D) Pulvinar nucleus(i)
    - (E) Subthalamic nucleus

13. A 29-year-old woman presents with neurologic deficits that wax and wane over time suggestive of multiple sclerosis. MRI (especially T2-weighted) shows small, demyelinated areas at several locations in her brain, one of these being the mammillothalamic tract. Which of the following structures is most intimately associated with this tract?  
    - (A) Anterior thalamic nucleus
    - (B) Centromedian nucleus
    - (C) Dorsomedial nucleus
    - (D) Ventral anterior thalamic nucleus
    - (E) Ventral lateral thalamic nucleus

14. Which of the following structures is a primary target of the optic tract as it passes caudally from the optic chiasm?  
    - (A) Lateral geniculate nucleus
    - (B) Mammillary body
    - (C) Medial geniculate nucleus
    - (D) Pulvinar
    - (E) Ventral posterolateral nucleus

15. An 82-year-old man presents with a severe motor deficit (resting tremor) and dementia. The former correlates with degenerative changes in the putamen and globus pallidus and the latter with degenerative changes in the ventral striatum and ventral pallidum. Which of the following structures separates these two areas in the basal forebrain?  
    - (A) Anterior commissure
    - (B) Lamina terminalis
    - (C) Massa intermedia
    - (D) Posterior commissure
    - (E) Septum pellucidum

16. A 23-year-old man is brought to the emergency department by emergency medical personnel after an automobile collision. CT shows bilateral damage to the temporal pole and the uncus. Which of the following structures is also most likely damaged in this patient?  
    - (A) Amygdaloid complex
    - (B) Anterior thalamic nucleus
    - (C) Cingulum
    - (D) Gracile nucleus
    - (E) Hippocampal formation

17. The optic radiations are closely associated with which of the following spaces?  
    - (A) Anterior horn of the lateral ventricle
    - (B) Body of the lateral ventricle
    - (C) Cisterns adjacent to the midbrain
    - (D) Posterior horn of the lateral ventricle
    - (E) Third ventricle

18. A 31-year-old man presents with ill-defined neurologic complaints (persistently tired, headache, confusion). CT shows an arteriovenous malformation occupying most of the dorsomedial nucleus (DM) of the thalamus. Which of the following structures separates the DM from the lateral thalamic nuclei and encompasses the centromedial nucleus?  
    - (A) Ansa lenticularis
    - (B) External medullary lamina
    - (C) Internal medullary lamina
    - (D) Lamina terminalis
    - (E) Stria medullaris thalami
19. A 48-year-old woman presents with violent, flailing movements of her left upper extremity. CT shows a small hemorrhage in the subthalamic nucleus. Which of the following structures is located directly adjacent to the subthalamic nucleus?

- (A) Centromedian nucleus
- (B) Globus pallidus
- (C) Medial geniculate nucleus
- (D) Putamen
- (E) Substantia nigra

20. Which of the following structures is located immediately caudal to the anterior commissure and appears as a distinct black spot in a T2-weighted axial MRI?

- (A) Anterior limb of internal capsule
- (B) Column of the fornix
- (C) Crus of the fornix
- (D) Lenticular fasciculus
- (E) Mammillothalamic tract

**Answers for Chapters 3 and 4**

1. Answer B: The anterior limb of the internal capsule is insinuated between the head of the caudate nucleus and the rostral aspect of the lenticular nucleus, mostly the putamen. The posterior limb is between the lenticular nucleus and the thalamus; the column of the fornix is rostromedial to the interventricular foramen; and the anterior commissure traverses the midline at the level of the genu of the internal capsule. The external capsule is a thin sheet of white matter lateral to the lenticular nucleus and medial to the claustrum. (p. 64–65, 76–77)

2. Answer A: The nucleus accumbens is located in the rostral and basal forebrain at the point where the head of the caudate is continuous with the putamen. The amygdaloid nucleus is located internal to the uncus and in the anterior wall of the temporal horn. The pallidum (globus pallidus) and the substantia nigra do not have a continuum with the nucleus accumbens. (p. 64, 78)

3. Answer C: The hippocampal formation, commonly called the hippocampus, is located in the medial wall of the temporal (inferior) horn of the lateral ventricle. Damage to the hippocampus may result in memory problems. The amygdaloid complex is located in the rostral wall of the temporal horn, the tail of the caudate in its lateral wall, and the calcar avis (also called the calcarine spur, a ridge in the wall of the posterior horn indicating the depth of the calcarine sulcus) is in the medial wall of the posterior horn of the lateral ventricle. The pulvinar is part of the diencephalon. (p. 58, 68–71)

4. Answer B: The corona radiata (radiating crown) are those fibers of the internal capsule that fan out in all directions from its superior edge. These fibers contain a variety of fibers traveling to and from the cerebral cortex. The superior longitudinal and uncinate fasciculi are organized bundles of corticocortical fibers on the ipsilateral side, and the cingulum is a fiber bundle located internal to the cingulate cortex. The fibers of the genu of the corpus callosum contain corticocortical fibers that pass between the cerebral hemispheres. (p. 57, 65–69)

5. Answer C: The layer of white matter located internal to the insular cortex, and external to the claustrum, is the extreme capsule. The external capsule is found between the claustrum and the putamen, and the internal capsule is a large bundle of fibers located primarily between the lenticular nucleus on one side and the head of the caudate and the diencephalon on the other side. The tectum is located in the lateral wall of the posterior horn of the lateral ventricle. Arcuate fasciculi are small bundles of fibers passing between gyri. (p. 65, 67–68, 77)

6. Answer E: The large bulge in the lateral wall of the anterior horn of the lateral ventricle is the head of the caudate nucleus. The position of the interventricular foramen represents the point at which the head of the caudate becomes the body of the caudate. The dorsomedial nucleus borders on the third ventricle; the anterior thalamic nucleus is located at the rostral end of the diencephalon and is caudomedial to the interventricular foramen; and the column of the fornix is rostromedial to this foramen. (p. 64–65, 76)

7. Answer D: These deficits are characteristic of Parkinson’s disease and are directly correlated with loss of the dopamine (and melanin)-containing cells of the substantia nigra of the midbrain. The locus (nucleus) ceruleus, also called the nucleus pigmentosus pontis, also contains cells with melanin, but loss of these cells does not cause motor deficits. The other choices do not contain pigmented cells, but damage to these structures does cause a different series of motor deficits. (p. 68–69, 78)

8. Answer C: The putamen is the most lateral part of the basal nuclei; taken together, the putamen and the globus pallidus comprise the lenticular nucleus. The caudate nucleus is located between the head of the caudate and the putamen, while the retrolenticular limb is found caudal to the lenticular nucleus. The crus cerebri is on the inferolateral aspect of the midbrain. The external capsule is lateral to the putamen. (p. 67–69, 76–77)

9. Answer D: The posterior limb of the internal capsule, containing important cortical afferent and efferent fibers, is located between the lenticular nucleus and the dorsal thalamus. Damage to this structure may result in sensory and/or motor deficits on the opposite side of the body. The anterior limb is located between the head of the caudate and the putamen, while the retrolenticular limb is found caudal to the lenticular nucleus. The crus cerebri is on the inferolateral aspect of the midbrain. The external capsule is lateral to the putamen. (p. 67–69, 76–77)

10. Answer D: The pineal gland is located in the quadrigeminal cistern, superior to the colliculi, and between the pulvinar nuclei of the thalamus. At this location, the lesion would potentially involve the colliculi and pulvinar. The other thalamic nuclei are not adjacent to the pineal, the globus pallidus is lateral to the posterior limb of the internal capsule, and the body of the caudate is located in the lateral wall of the body of the lateral ventricle. (p. 71)

11. Answer C: The hippocampal commissure is located immediately inferior to the splenium of the corpus callosum; the crossing of these fibers takes place at this point. Other parts of the corpus callosum are not related to the hippocampal commissure, and the spiral fibers of the hippocampus are bundles within the hippocampal formation in the temporal lobe. Some of the fibers in the hippocampal commissure enter the precommissural fornix, but by no means all. (p. 72)
12. **Answer D:** The geniculate bodies are tucked-up under the caudal and inferior aspect of the pulvinar. The groove between the medial geniculate body and the pulvinar contains the brachium of the superior colliculus. The geniculate bodies and the pulvinar have a common blood supply from the thalamogeniculate artery, a branch of P₂. None of the other choices have a close apposition with the geniculate bodies. The anterior thalamic, rostral dorsal-medial, and subthalamic nuclei do not share a common blood supply with the pulvinar. (p. 58–59, 70)

13. **Answer A:** The mammillothalamic tract extends from the mammillary bodies to the anterior nucleus of the thalamus; the cells of origin are in the mammillary nuclei and the axons terminate in the anterior nucleus. This tract is frequently visible in axial T2-weighted MRI. The ventral anterior nucleus is laterally adjacent to the mammillothalamic tract, but does not receive input therefrom. The other choices are nuclei located more caudally in the diencephalon. (p. 67, 77)

14. **Answer A:** Many of the fibers contained in the optic tract terminate in the lateral geniculate nucleus. Some of these fibers bypass this nucleus to traverse the brachium of the superior colliculus and a few enter the suprachiasmatic nucleus. The medial geniculate nucleus receives input via the brachium of the inferior colliculus (auditory); the pulvinar has interconnections with the visual cortex and superior colliculus; and the ventral posterolateral nucleus receives input from the anterolateral system and the medicallemniscus. The mammillary body is located rostral to the interpeduncular fossa and medial to the optic tract. (p. 58, 59)

15. **Answer A:** The anterior commissure, as it passes laterally from the midline, separates the dorsal basal nuclei (putamen and globus pallidus) from the ventral striatum and ventral pallidum. The posterior commissure is located at the caudal aspect of the third ventricle just above the opening of the cerebral aqueduct, and the Massa intermedia bridges the third ventricle in about 80% of individuals. The rostral wall of the third ventricle is formed by the lamina terminalis and the septum pellucidum forms the medial wall of the anterior horn of the lateral ventricle. (p. 65, 152–153)

16. **Answer A:** The amygdaloid complex is located immediately internal to the uncus. Bilateral damage to rostral portions of the temporal lobe may include the amygdala and result in a constellation of deficits known as the Klüver-Bucy syndrome. The hippocampal formation is internal to the cortex of the parahippocampal gyrus, and the anterior thalamic nucleus is internal to the anterior thalamic tubercle. The cingulate gyrus overlies the longitudinally oriented fibers of the cingulum and the gracile tubercle is the external elevation formed by the gracile nucleus. (p. 58–59, 65–66, 78, 170)

17. **Answer D:** The optic radiations are located in the lateral wall of the posterior horn of the lateral ventricle as they pass through the retrolenticular limb of the internal capsule from the lateral geniculate nucleus to the primary visual cortex. A thin layer of white matter, the tapetum, separates the optic radiations from the wall of the ventricle. The cisterns at the midbrain on the basal aspect of the hemisphere contain the optic tract. The other ventricular spaces listed have no direct relationship to the optic radiations. (p. 71–72, 77, 138–141, 162)

18. **Answer C:** The internal medullary lamina is a vertically oriented sheet of fibers that extends from the rostral portion of the thalamus caudally to surround the centromedian nucleus; this nucleus is frequently referred to as “in” the internal medullary lamina due to its position. This lamina separates the dorsomedial nucleus from the laterally adjacent ventral anterior, ventral lateral, and ventral posterolateral nuclei. The external medullary lamina is located between the thalamus and the posterior limb of the internal capsule, and the lamina terminalis is the rostral wall of the third ventricle. The stria medullaris is a small bundle of fibers passing rostrocaudally along the upper medial edge of the thalamus from the general location of the interventricular foramen to the habenula, and the ansa lenticularis contains pallidothalamic fibers. (p. 68–69, 76, 144–149, 162)

19. **Answer E:** The subthalamic nucleus is separated from the substantia nigra by only a thin layer of myelinated fibers; these two structures are directly adjacent to each other. Damage to the subthalamic nucleus gives rise to hemiballistic movements (described in this question) while loss of cells in the substantia nigra results in the motor deficits seen in Parkinson’s disease. The putamen, globus pallidus, and the medial geniculate nuclei are all lateral to the internal capsule; the subthalamic nucleus is medial. The centromedial nucleus is separated from the subthalamic nucleus by other thalamic nuclei. (p. 68–69, 148–149)

20. **Answer B:** The column of the fornix is that portion of this fiber bundle that arches around the rostromedial end of the thalamus. As it does so, the column joins its counterpart on the opposite side and “leans against” the anterior commissure. The column of the fornix also signifies, in cross section or axial planes, the laterally adjacent interventricular foramen and genu of the internal capsule. The mammillothalamic tract is located caudal to the fornix, and the crus of the fornix is found along the midline superior to the thalamus. The anterior limb of the internal capsule is found between the head of the caudate nucleus and the lenticular nucleus (mainly the putamen). The lenticular fasciculus contains pallidothalamic fibers and traverses the posterior limb of the internal capsule en route to the dorsal thalamus. (p. 31, 77, 163–164)
2. A 54-year-old morbidly obese and hypertensive man is brought to the emergency department after experiencing sudden onset of weakness of his left upper and lower extremities. CT shows an infarcted area in the medulla. Damage to which of the following tracts or fiber bundles of the medulla would most likely explain this deficit?

- (A) Anterolateral system
- (B) Corticospinal fibers
- (C) Medial lemniscus
- (D) Rubrospinal tract
- (E) Vestibulospinal fibers

3. A 78-year-old healthy, active woman experiences a sudden weakness of her right upper extremity during an angiogram to determine the patency of her carotid bifurcation. The immediate examination reveals weakness of both extremities on the right and a partial loss of vision in both eyes (homonymous hemianopsia). These observations suggest an embolic stroke resulting in a lesion involving motor and visual structures. The infarcted area in CT points to the occlusion of one vessel. Which of the following vessels is most likely occluded?

- (A) Anterior cerebral artery
- (B) Anterolateral system
- (C) Medial lemniscus
- (D) Lenticulostriate branches (of M1)
- (E) Posterior cerebral artery (P3 and P4 segments)

4. A 69-year-old man is brought to the emergency department by his wife after complaining of a bad headache and becoming stuporous. CT shows a hemorrhage into the head of the caudate nucleus that has ruptured into the anterior horn of the lateral ventricle. This hemorrhage has most likely originated from which of the following vessels?

- (A) Anterior choroidal artery (branch of internal carotid)
- (B) Lenticulostriate branches (of M1)
- (C) Medial posterior choroidal artery (branch of P2)
- (D) Medial striate artery (branch of A2)
- (E) Thalamoperforating artery(ies)

5. Damage to which of the following tracts would correlate with weakness of the lower extremity in this man?

- (A) Left lateral corticospinal tract
- (B) Reticulospinal fibers on the right
- (C) Right lateral corticospinal tract
- (D) Right rubrospinal tract
- (E) Vestibulospinal fibers on the right

6. Which of the following represents the most likely level of damage to the spinal cord resulting from the fracture to the vertebral column in this man?

- (A) T6 on the left
- (B) T8 on the left
- (C) T8 on the right
- (D) T10 on the left
- (E) T10 on the right

7. The artery of Adamkiewicz is an especially large spinal medullary artery supplementing the arterial blood supply to the spinal cord. Which of the following represents the most consistent location of this vessel?

- (A) At C7–C8 on the left
- (B) At L5–S1 on the left
- (C) At L5–S1 on the right
- (D) At T6–T7 on the right
- (E) At T12–L1 on the left

8. The CT of a 73-year-old woman shows an infarcted area in the rostral portions of the dorsomedial nucleus, the anterior nucleus, and the ventral anterior nucleus. Which of the following arteries supply blood to this area of the brain?

- (A) Anterior choroidal
- (B) Lateral striate (lenticulostriate)
- (C) Medial striate
- (D) Thalamogeniculate
- (E) Thalamoperforating

9. Which of the following structures is insinuated between the external and extreme capsules and is functionally related to the insular cortex?

- (A) Claustrum
- (B) External medullary lamina
- (C) Lamina terminalis
- (D) Putamen
- (E) Stria terminalis

10. An 83-year-old man is brought to the emergency department by his daughter, who explains that her father started having “fits”. The examination reveals an alert, otherwise healthy, man who frequently has uncontrollable flailing movements of his left arm. Which of the following structures is most likely involved in this lesion?

- (A) Cerebellar cortex plus nuclei
- (B) Lenticular nucleus
- (C) Subthalamic nucleus
- (D) Ventral lateral nucleus
- (E) Ventral posterolateral nucleus

11. A 17-year-old girl presents with a bilateral loss of pain and thermal sensations at the base of the neck (C3 dermatome) and extending over the upper extremity and down to the level of the nipple (C4 to T4 dermatomes). MRI shows a cavitation in the spinal cord at these levels. Damage to which of the following structures would most likely explain this deficit?

- (A) Anterior white comissure
- (B) Left anterolateral system
- (C) Medial longitudinal fasciculus
- (D) Posterior columns
- (E) Right anterolateral system
12. Which of the following structures is located within the territory of the medulla that is served by the anterior spinal artery?

- (A) Anterolateral system
- (B) Gracile fasciculus
- (C) Medial lemniscus
- (D) Rubrospinal tract
- (E) Spinal trigeminal tract

13. A 59-year-old man complains to his family physician that he has trouble chewing. The examination reveals a weakness of masticatory muscles on the left side. Which of the following nuclei is specifically related to the deficit seen in this man?

- (A) Left facial motor
- (B) Left hypoglossal
- (C) Left trigeminal motor
- (D) Right facial motor
- (E) Right trigeminal motor

14. A 15-year-old boy with signs of increased intracranial pressure (stupor, vomiting, headache) is referred to a neurologist. The examination reveals a paralysis of upward gaze, and MRI shows a large tumor of the pineal gland. Damage to which of the following structures would be most specifically related to the deficit seen in this man?

- (A) Exit of the trochlear nerve
- (B) Inferior colliculus
- (C) Occlusion of the great cerebral vein
- (D) Posterior commissure
- (E) Superior colliculus

15. A 61-year-old man is brought to the emergency department after a fall from his garage roof. The examination reveals a hemiplegia on the left, a loss of vibratory sense on the left, and a loss of pain and thermal sensation on the right side involving the upper and lower extremities. These deficits are characteristically seen in which of the following syndromes?

- (A) Benedikt
- (B) Brown-Séquard
- (C) Claude
- (D) Wallenberg
- (E) Weber

16. Based on their relative locations in the spinal cord, which of the following tracts or fiber bundles would most likely be involved in a lesion located in the immediate vicinity of the lateral corticospinal tract?

- (A) Anterolateral system
- (B) Anterior spinocerebellar tract
- (C) Gracile fasciculus
- (D) Medial longitudinal fasciculus
- (E) Rubrospinal tract

17. A 92-year-old woman is brought to the emergency department by her caregiver. The woman had suddenly become drowsy and confused. The examination revealed no cranial nerve deficits and age-normal motor function, but a loss of pain, thermal, vibratory, and discriminative touch sensations on one side of the body excluding the head. CT shows a small infarcted area. Which of the following structures is the most likely location of this lesion?

- (A) Anterolateral system
- (B) Medial geniculate nucleus
- (C) Subthalamic nucleus
- (D) Ventral posterolateral nucleus
- (E) Ventral posteromedial nucleus

18. In its location immediately internal to the anterior spinocerebellar tract, which of the following fiber bundles would most likely be damaged in a lesion to this area of the spinal cord?

- (A) Anterolateral system
- (B) Anterior corticospinal tract
- (C) Anterior white commissure
- (D) Cuneate fasciculus
- (E) Lateral corticospinal tract

19. A 37-year-old man is brought to the emergency department with a severe head injury. Within a few hours he is decerebrate (upper and lower extremities extended) and comatose. The extension of his extremities indicates a dominant input to extensor motor neurons through vestibulospinal and reticulospinal fibers/tracts. Which of the following most specifically describes the position of these activated fibers within the spinal cord?

- (A) Anterolateral area (area of anterolateral system)
- (B) Posterolateral area (area of lateral corticospinal tract)
- (C) Posterior columns
- (D) Posterolateral (dorsolateral) tract
- (E) Intermediate zone

Question 20 and 21 are based on the following patient.

A 71-year-old woman presents to her family physician with the complaint that “food dribbles out of my mouth when I eat”. The examination reveals a unilateral weakness of muscles around the eye (palpebral fissure) and the opening of the mouth (oral fissure). She also has a loss of pain and thermal sensations on the opposite side of the body excluding the head. CT shows an infarcted area in the lateral portion of the pontine tegmentum.

20. Damage to which of the following nuclei would most likely explain the muscle weakness experienced by this woman?

- (A) Abducens
- (B) Arcuate
- (C) Facial motor
- (D) Hypoglossal
- (E) Trigeminal motor

21. The loss of pain and thermal sensations experienced by this woman would most likely correlate with a lesion involving which of the following structures?

- (A) Anterior (ventral) trigeminothalamic tract
- (B) Anterolateral system
- (C) Lateral lemniscus
- (D) Medial lemniscus
- (E) Spinal trigeminal tract
22. A 77-year-old woman is discovered slumped on the floor in the grocery store; emergency medical personnel transport her to a local hospital. The examination reveals a drowsy somewhat stuporous woman who is difficult to arouse. CT shows a large hemorrhage within the brain medial to the internal medullary lamina. Which of the following structures is most likely involved in this lesion?

- (A) Anterior thalamic nucleus
- (B) Dorsomedial nucleus
- (C) Globus pallidus
- (D) Ventral lateral and anterior nuclei
- (E) Ventral posterolateral nucleus

23. A 78-year-old man presents with deficits suggesting an occlusion of the posterior spinal artery at spinal cord levels C4-T2. Which of the following structures are in the territory served by this vessel at these levels?

- (A) Anterolateral system
- (B) Cuneate fasciculus
- (C) Gracile nucleus
- (D) Lateral corticospinal tract
- (E) Medial longitudinal fasciculus

24. Based partially on their embryological origin from a common group of cells, which of the following combinations of structures appear to be the same shade of grey in a T1-weighted MRI?

- (A) Dorsomedial nucleus and Globus pallidus
- (B) Globus pallidus and Caudate
- (C) Globus pallidus and Putamen
- (D) Putamen and Caudate nucleus
- (E) Putamen and Pulvinar

25. Which of the following portions of the trigeminal nuclear complex is found in lateral areas of the brainstem between the level of the obex and the spinal cord-medulla junction and is the source of trigeminothalamic fibers conveying pain and thermal information originating from the face and oral cavity?

- (A) Mesencephalic nucleus
- (B) Principal sensory nucleus
- (C) Spinal trigeminal nucleus, pars caudalis
- (D) Spinal trigeminal nucleus, pars interpolaris
- (E) Spinal trigeminal nucleus, pars oralis

26. Which of the following structures is located within the territory served by branches of the posterior inferior cerebellar artery (commonly called PICA by clinicians)?

- (A) Corticospinal fibers
- (B) Hypoglossal root
- (C) Medial lemniscus
- (D) Nucleus raphe magnus
- (E) Solitary nucleus

27. Space-occupying lesions within the posterior cranial fossa, or events that increase pressure within this infratentorial region, may result in herniation of a portion of the cerebellum through the foramen magnum. Which of the following parts of the cerebellum is most likely involved in this event?

- (A) Anterior lobe
- (B) Flocculus
- (C) Nodulus
- (D) Simple lobule
- (E) Tonsil

28. A 67-year-old woman is brought to the emergency department. She is stuporous and has signs that suggest a lesion in the brainstem; CT confirms this. Her right pupil is constricted (small) when compared with the left. Damage to which of the following tracts or fiber bundles in the pons or medulla would most likely explain this observation?

- (A) Anterolateral system
- (B) Hypothalamospinal fibers
- (C) Medial longitudinal fasciculus
- (D) Reticulospinal fibers
- (E) Vestibulospinal fibers

29. In addition to the medial and lateral geniculate nuclei, which of the following structures is also served by the thalamogeniculate tract, a branch of P2?

- (A) Anterior thalamic nucleus
- (B) Globus pallidus
- (C) Pulvinar nucleus
- (D) Substantia nigra
- (E) Ventral anterior thalamic nucleus

30. A 71-year-old man is brought to the emergency department by his wife. She explains that he suddenly became weak in his left lower extremity. She immediately rushed him to the hospital, a trip of about 20 minutes. The examination reveals an alert man who is obese and hypertensive. He has no cranial nerve deficits, is slightly weak on his left side, and has no sensory deficits. Within 2 hours the weakness has disappeared. An MRI obtained the following day shows no lesions. Which of the following most specifically describes this man’s medical experience?

- (A) Central cord syndrome
- (B) Small embolic stroke
- (C) Small hemorrhagic stroke
- (D) Syringobulbia
- (E) Transient ischemic attack

Questions 31 and 32 are based on the following patient.

A 41-year-old man is brought to the emergency department after an accident at a construction site. The examination reveals a weakness (hemiplegia) and a loss of vibratory sensation and discriminative touch all on the left lower extremity, and a loss of pain and thermal sensations on the right lower extremity. CT shows a fracture of the vertebral column adjacent to the T8 level of the spinal cord.

31. Damage to which of the following fiber bundles or tracts would most likely explain the loss of vibratory sensation in this man?

- (A) Anterolateral system on the right
- (B) Cuneate fasciculus on the left
- (C) Cuneate fasciculus on the right
- (D) Gracile fasciculus on the left
- (E) Gracile fasciculus on the right

32. The loss of pain and thermal sensation in this man reflects damage to which of the following fiber bundles or tracts?

- (A) Anterolateral system on the left
- (B) Anterolateral system on the right
- (C) Cuneate fasciculus on the left
- (D) Gracile fasciculus on the left
- (E) Posterior spinocerebellar tract on the left
33. Which of the following is the prominent population of melanin-containing cells located immediately internal to the crus cerebri? The loss of these cells may result in motor deficits.

- (A) Locus ceruleus
- (B) Pontine nuclei
- (C) Red nucleus
- (D) Reticular formation
- (E) Substantia nigra

34. Which of the following structures receives visceral sensory input and is located immediately inferior to the medial and spinal vestibular nuclei at medullary levels?

- (A) Cochlear nuclei
- (B) Inferior salivatory nucleus
- (C) Nucleus ambiguus
- (D) Spinal trigeminal nucleus
- (E) Solitary nucleus

35. Which of the following groups of visceromotor (autonomic) cell bodies is located lateral to the abducens nucleus, directly adjacent to the exiting fibers of the facial nerve, and sends its axons out of the brainstem via this cranial nerve?

- (A) Dorsal motor nucleus
- (B) Edinger-Westphal nucleus
- (C) Inferior salivatory nucleus
- (D) Intermediolateral cell column
- (E) Superior salivatory nucleus

36. A 56-year-old woman presents to her family physician with persistent headache and nausea. MRI shows a tumor in the fourth ventricle impinging on the facial colliculus. Which of the following nuclei is found immediately internal to this elevation?

- (A) Abducens
- (B) Facial
- (C) Hypoglossal
- (D) Trigeminal
- (E) Vestibular

39. Recognizing that this patient’s lesion involves the territory served by paramedian branches of the basilar artery, which of the following structures is also most likely included in the area of infarction?

- (A) Anterolateral system
- (B) Facial motor nucleus
- (C) Hypoglossal nucleus
- (D) Medial lemniscus
- (E) Spinal trigeminal tract

40. A 77-year-old man presents with a weakness of his right upper and lower extremities and he is unable to abduct his left eye on attempted gaze to the left. Which of the following most specifically describes this deficit?

- (A) Alternating hemianesthesia
- (B) Hemihypesthesia
- (C) Inferior alternating hemiplegia
- (D) Middle alternating hemiplegia
- (E) Superior alternating hemiplegia

41. In axial MRI which of the following structures is an important landmark that separates the third ventricle (rostral to this point) from the quadrigeminal cistern (caudal to this point)?

- (A) Lamina terminalis
- (B) Habenular nucleus
- (C) Massa intermedia
- (D) Pulvinar
- (E) Superior colliculus

42. A 77-year-old woman presents with deficits that suggest a lesion involving long tracts and a cranial nerve. CT shows an infarct in the region served by the penetrating branches of the basilar bifurcation. Which of the following structures is most likely located in this vascular territory?

- (A) Anterolateral system
- (B) Corticospinal fibers in pyramid
- (C) Gracile nucleus
- (D) Hypoglossal nucleus
- (E) Nucleus ambiguus

43. Damage to which of the following structures would most likely explain the man’s hoarse, gravely voice?

- (A) Facial nucleus
- (B) Gracile nucleus
- (C) Hypoglossal nucleus
- (D) Nucleus ambiguus
- (E) Spinal trigeminal nucleus

Questions 37 through 39 are based on the following patient.

An 88-year-old man is brought to the emergency department by his daughter. She indicates that he complained of weakness of his “arm” and “leg” (upper and lower extremities) on the right side and of “seeing two of everything” (double vision—diplopia). CT shows an infarcted area in the medial area of the pons at the pons-medulla junction. The infarcted area is consistent with the vascular territory served by paramedian branches of the basilar artery.

37. Weakness of the extremities on the right can be explained by damage to which of the following structures?

- (A) Corticospinal fibers on the left
- (B) Corticospinal fibers on the right
- (C) Middle cerebellar peduncle on the left
- (D) Rubrospinal fibers on the left
- (E) Rubrospinal fibers on the right

38. The diplopia (double vision) this man is having is most likely the result of damage to which of the following structures?

- (A) Abducens nerve root
- (B) Facial nerve root
- (C) Oculomotor nerve root
- (D) Optic nerve
- (E) Trochlear nerve or root

Questions 43 through 46 are based on the following patient.

A 69-year-old man is brought to the emergency department with the complaint of a sudden loss of sensation. The history reveals that the man is overweight, hypertensive, and does not regularly take medication. When the man speaks his voice is gravelly and hoarse. The examination further reveals a loss of pain and thermal sensations on the right side of his body and on the left side of his face. CT shows an infarcted area in the medulla.

43. Damage to which of the following structures would most likely explain the man’s hoarse, gravely voice?

- (A) Facial nucleus
- (B) Gracile nucleus
- (C) Hypoglossal nucleus
- (D) Nucleus ambiguus
- (E) Spinal trigeminal nucleus
44. Injury to which of the following structures in this man is most specifically related to the loss of pain and thermal sensations on the body below the neck?
- (A) Anterolateral system
- (B) Cuneate fasciculus
- (C) Gracile fasciculus
- (D) Medial lemniscus
- (E) Spinal trigeminal tract

45. Damage to which of the following structures would most specifically explain the loss of pain and thermal sensations on the man’s face?
- (A) Anterolateral system
- (B) Medial lemniscus
- (C) Medial longitudinal fasciculus
- (D) Solitary tract
- (E) Spinal trigeminal tract

46. The CT shows an infarcted area in the medulla in this man. Based on the deficits described, and the corresponding structures involved, which of the following vessels is most likely occluded?
- (A) Anterior spinal artery
- (B) Posterior spinal artery
- (C) Posterior inferior cerebellar artery
- (D) Anterior inferior cerebellar artery
- (E) Penetrating branches of the vertebral artery

47. A 77-year-old man presents with an ataxic gait. There are no other deficits. CT shows an infarcted area in the territory served by the posterior inferior cerebellar artery. Damage to which of the following structures would most likely explain the symptoms experienced by this man?
- (A) Anterolateral system
- (B) Corticospinal tract
- (C) Nucleus ambiguus
- (D) Restiform body
- (E) Vestibular nuclei

48. Which of the following cranial nerve nuclei is located in the anterior (ventral or inferior) and medial portion of the periaqueductal grey at the cross-sectional level of the superior colliculus?
- (A) Abducens
- (B) Mesencephalic
- (C) Oculomotor
- (D) Trigeminal motor
- (E) Trochlear

49. A 53-year-old woman presents with motor deficits that the examining neurologist describes as a superior alternating hemiplegia. Which of the following cranial nerve roots is most likely involved in this lesion?
- (A) Abducens
- (B) Hypoglossal
- (C) Oculomotor
- (D) Trigeminal
- (E) Trochlear

50. An 82-year-old woman presents to the emergency department with difficulty swallowing (dysphagia). Which of the following nuclei of the medulla contain motor neurons that innervate muscles involved in swallowing?
- (A) Dorsal motor vagal
- (B) Hypoglossal
- (C) Inferior salivatory
- (D) Medial vestibular
- (E) Nucleus ambiguus

Questions 51 through 53 are based on the following patient.

A 73-year-old man is brought to the emergency department after losing consciousness at his home. CT shows a hemorrhage into the right hemisphere. The man regains consciousness, but is not fully alert. After 3–4 days the man begins to rapidly deteriorate: his pupils are large (dilated) and respond slowly to light, eye movement becomes restricted, there is weakness in the extremities on the left side, and the man becomes comatose. Repeat CT shows an uncal herniation.

51. Based on its location, which of the following parts of the brainstem is most likely to be directly affected by uncal herniation, especially in the early stages?
- (A) Diencephalon/thalamus
- (B) Mesencephalon/midbrain
- (C) Myelencephalon/medulla
- (D) Pons and cerebellum
- (E) Pons only

52. Damage to corticospinal fibers in which of the following locations would most likely explain the weakness in his extremities?
- (A) Left basilar pons
- (B) Left crus cerebri
- (C) Right basilar pons
- (D) Right crus cerebri
- (E) Right posterior limb of the internal capsule

53. The dilated, and slowly responsive, pupils in this man are most likely explained by damage to fibers in which of the following?
- (A) Abducens nerve
- (B) Corticonuclear fibers in the crus
- (C) Oculomotor nerve
- (D) Optic nerve
- (E) Sympathetic fibers on cerebral vessels

54. The sagittal MRI of a 26-year-old man shows a dark shadow in the midbrain tegmentum on the midline at the cross-sectional level of the inferior colliculus. Which of the following structures does this dark area represent?
- (A) Central portions of the red nucleus
- (B) Compact and reticular parts of the substantia nigra
- (C) Decussation of the superior cerebellar peduncle
- (D) Decussation of trigeminothalamic fibers
- (E) Motor (pyramidal) decussation
55. The CT of a 39-year-old man with untreated hypertension shows a small hemorrhage in the brainstem. This lesion encompasses the brachium of the inferior colliculus and the brain substance immediately internal to this structure. Which of the following structures is also most likely involved in this lesion?

- (A) Anterolateral system
- (B) Central tegmental tract
- (C) Corticospinal fibers
- (D) Mesencephalic tract
- (E) Oculomotor nerve

56. A 69-year-old man complains of difficulty walking. The examination reveals no weakness, but does reveal a loss of discriminative touch and vibratory sense on the left lower extremity. MRI shows a small infarcted area in the midbrain. Which of the following structures is most likely involved in the infarcted area?

- (A) Anterolateral system
- (B) Corticospinal fibers
- (C) Lateral part of the medial lemniscus
- (D) Medial part of the medial lemniscus
- (E) Rubrospinal fibers

57. Which of the following nuclei containing visceromotor (autonomic) cell bodies is located immediately inferior to the medial vestibular nucleus, medial to the solitary tract and nucleus, and has axons that exit the brainstem on the glossopharyngeal nerve?

- (A) Dorsal motor nucleus
- (B) Edinger-Westphal nucleus
- (C) Inferior salivatory nucleus
- (D) Intermediolateral cell column
- (E) Superior salivatory nucleus

58. An 81-year-old woman is brought to the emergency department by her adult grandson. He explains that during dinner she slumped off of her chair, did not lose consciousness, but had trouble speaking. The examination reveals weakness of the upper and lower extremities on the left side of the tongue. MRI shows a small infarcted area in the medulla. Which of the following most specifically describes this deficit in this elderly patient?

- (A) Alternating hemianesthesia
- (B) Hemihypesthesia
- (C) Inferior alternating hemiplegia
- (D) Middle alternating hemiplegia
- (E) Superior alternating hemiplegia

Questions 59 and 60 are based on the following patient.

A 79-year-old woman is brought to the emergency department after a fall in her home from which she was unable to get up. The examination reveals a deviation of the tongue to the left on protrusion, a pronounced weakness of the right upper and lower extremities, and a loss of position and vibratory sense on the right side of the body below the neck. CT shows an infarcted area in the medulla.

59. Which of the following represents the best localizing sign in this patient?

- (A) Deviation of the tongue
- (B) Motor loss on lower extremity
- (C) Motor loss on upper extremity
- (D) Sensory loss on lower extremity
- (E) Sensory loss on upper extremity

60. Damage to which of the following tracts or fiber bundles would most likely give rise to the sensory deficits experienced by this patient?

- (A) Anterolateral system
- (B) Central tegmental tract
- (C) Medial longitudinal fasciculus
- (D) Solitary tract
- (E) Spinal trigeminal tract

61. The MRI of a 12-year-old boy reveals a cavity within the medulla. Which of the following terms most specifically describes this condition?

- (A) Brown-Séquard syndrome
- (B) Central cord syndrome
- (C) Hydromyelia
- (D) Syringobulbia
- (E) Syringomyelia

62. Which of the following cell groups within the white matter of the cerebellum characteristically appears as a long undulating line, looking somewhat like the principle oliveary nucleus in the medulla?

- (A) Dentate nucleus
- (B) Emboliform nucleus
- (C) Fastigial nucleus
- (D) Globose nucleus
- (E) Red nucleus

Answers for Chapter 5

1. Answer D: Although this patient initially presented with complete motor and sensory losses, some function had returned by 36 hours; in this case the lesion is classified as an incomplete lesion of the spinal cord. Patients with no return of function at 24 hours and no sacral sparing have suffered a lesion classified as complete and it is unlikely that they will recover useful neurologic function. In a central cord and a large syringomyelia there is sparing of posterior column sensations and in a hemisection the loss of motor function is unilateral. (p. 94–95)

2. Answer B: A medullary lesion that results in weakness of the extremities on one side indicates involvement of the corticospinal fibers located in the pyramid on the contralateral side; these fibers largely cross in the pyramidal (motor) decussation. Rubrospinal and vestibulospinal fibers influence the activity of spinal motor neurons, but isolated lesions of these fibers would not result in a unilateral weakness of upper and lower extremities. The anterolateral system and the medial lemniscus are sensory tracts. (p. 98–108, 110–111)

3. Answer B: The anterior choroidal artery serves the optic tract (homonymous hemianopsia) and the inferior portions of the posterior limb of the internal capsule (weakness of the extremities). The ophthalmic artery, via its central retinal branch, serves the retina; the anterior cerebral artery serves the lower extremity areas of the motor and sensory cortices; and distal segments of the posterior cerebral artery serve the medial temporal cortex and the visual cortex. The lateral posterior choroidal artery serves the choroid plexus in the lateral ventricle and some adjacent structures. (p. 21, 25, 29, 35, 158–159)
4. Answer D: The head of the caudate nucleus is located in the lateral wall of the anterior horn of the lateral ventricle and receives its blood supply from the medial striate artery (also called the artery of Heubner). This vessel also serves much of the anterior limb of the internal capsule. The lenticulostrate arteries serve a large part of the lenticular nucleus and portions of the surrounding internal capsule, and thalamoperforating arteries serve anterior portions of the dorsal thalamus. The anterior choroidal artery provides blood supply to inferior portions of the internal capsule, optic tract, and structures in the medial portions of the temporal lobe. The medial posterior choroidal artery serves choroid plexus in the lateral and third ventricles and adjacent areas of the lateral midbrain and caudomedial thalamus. (p. 154–158)

5. Answer C: In this patient the weakness of the right lower extremity is related to a lesion of lateral corticospinal tract fibers on the right side of the spinal cord. The left corticospinal tract serves the left side of the spinal cord and the left lower extremity. Rubrospinal, reticulospinal, and vestibulospinal fibers influence the activity of spinal motor neurons; however, the deficits related to corticospinal tract damage (significant weakness) will dominate over the lack of excitation to flexor or extensor motor neurons in the spinal cord via these tracts. (p. 86–88, 94)

6. Answer C: The loss of pain and thermal sensations beginning at the level of the umbilicus (T10 dermatome) on the left side results from damage to fibers of the anterolateral system at about the T8 level on the right. These fibers ascend 1 to 2 levels as they cross the midline. Damage at the T6 level would result in a loss beginning at the T8 level on the contralateral side and damage at the T10 level would result in a loss beginning at about the T12 level. (p. 88–89, 94)

7. Answer E: The artery of Adamkiewicz is usually located at the T12-L1 spinal cord levels and is more frequently (about 65% of the time) seen on the left side. The other cord levels listed may have small spinal medullary arteries but not the large diameter vessel characteristic of Adamkiewicz. (p. 94)

8. Answer E: The thalamoperforating arteries serve the more rostral portions of the dorsal thalamus. These vessels may originate as a single trunk or as several vessels from the P1 segment of the posterior portions of the dorsal thalamus. The artery of Adamkiewicz. (p. 94)

9. Answer A: The claustrum is the thin layer of grey matter that is located between the extreme and external capsules. It is generally regarded as being functionally related to the insular cortex. The external medullary lamina is found at the interface of the lateral portions of the thalamus with the internal capsule and the lamina terminalis is the thin structure forming the rostral wall of the third ventricle. The putamen is located medial to the external capsule and lateral to the globus pallidus and the stria terminalis is a fiber bundle in the groove between the body of the caudate nucleus and the dorsal thalamus. (p. 144–153, 162)

10. Answer C: Wild flailing movements of the extremities, especially the upper, are hemiballistic movements (hemiballismus); these are characteristic of a lesion in the subthalamic nucleus. Damage to the cerebellar cortex and nuclei and the lenticular nucleus will result in motor deficits, but these are usually described as involving tremor, ataxia, and related motor problems. The ventral lateral nucleus is a thalamic relay center for motor information and the ventral posterothalamic nucleus is a sensory relay nucleus. Lesions of these nuclei will result in motor (but not hemiballismus) and sensory deficits. (p. 146–149, 158)

11. Answer A: Fibers conveying pain and thermal sensations cross the midline in the anterior white commissure. Consequently, a lesion of this structure, as in syringomyelia, would result in a bilateral loss of these sensations, reflecting the levels of the syrinx. Damage to fibers of the anterolateral system results in a loss of these sensations on the contralateral side and the posterior columns convey proprioception, discriminative touch, and vibratory sense. The medial longitudinal fasciculus does not contain fibers conveying sensory input. (p. 90–91, 94)

12. Answer C: The anterior spinal artery serves the medial portion of the medulla, an area that encompasses the medial lemniscus, exciting roots of the hypoglossal nerve, and the corticospinal fibers in the pyramid. The anterolateral system, spinal trigeminal tract, and rubrospinal tract are in the territory of the posterior inferior cerebellar artery (commonly called PICA by clinicians). The posterior spinal artery in the caudal medulla and spinal cord serves the gracile fasciculus. (p. 110–111)

13. Answer C: The masticatory muscles receive their motor innervation via the motor neurons located in the trigeminal motor nucleus on the ipsilateral side; this excludes the right trigeminal nucleus. Facial motor neurons innervate the muscles of facial expression on the ipsilateral side and the hypoglossal nucleus innervates the ipsilateral side of the tongue. (p. 120–121, 124)

14. Answer E: A pineal tumor impinging on the superior colliculus may result in a paralysia of upward gaze (Parninaud syndrome). The inferior colliculus is related to the auditory system, trochlear fibers innervate the ipsilateral superior oblique muscle, and the posterior commissure contains fibers related to the pupillary light pathway. Occlusion of the great cerebral vein may cause serious neurologic deficits but not specifically a paralysia of upward gaze. (p. 136)

15. Answer B: Alternating sensory losses accompanied by a motor deficit on the same side as the loss of vibratory sensation are characteristics of the Brown-Séquard syndrome (also commonly called spinal cord hemisection). The Wallenberg syndrome is seen in lesions of the medulla, and the Benedikt, Claude, and Weber syndromes are seen in lesions of the midbrain. In these brainstem syndromes there are usually characteristic cranial nerve and long tract signs and symptoms. (p. 90–91, 94, 110, 113)

16. Answer E: The rubrospinal tract lies immediately anterior (ventral) to, and partially overlaps with, the lateral corticospinal tract. The anterolateral system is in the anterolateral area of the spinal cord and is spatially separated from the lateral corticospinal tract. The gracile fasciculus is in the posterior columns, the medial longitudinal fasciculus is in the ventral funiculus, and the anterior spinocerebellar tract is located on the anterolateral surface of the spinal cord. (p. 90–91, 94–95, 100)
17. **Answer D:** The ventral posterolateral nucleus of the thalamus receives the pathways (medial lemniscus and anterolateral system) that relay the information lost as a result of the lesion in this woman. The ventral posteromedial nucleus relays comparable information from the face and the medial geniculate nucleus is related to the auditory system. Lesions in the subthalamic nucleus result in hemiballismus. The anterolateral system relays pain and thermal sense; this is only part of the sensory deficits experienced by this woman. (p. 142, 158–159)

18. **Answer A:** The anterolateral system is located internal to the position of the anterior spino cerebellar tract; damage to this area of the spinal cord would most likely result in a loss of pain and thermal sensations on the contralateral side of the body below the lesion. The lateral corticospinal tract is located internal to the posterior spino cerebellar tract, the anterior white commissure and the anterior corticospinal tract are located in the anterior funiculus of the cord, and the cuneate fasciculus is in the posterior column medial to the posterior horn at upper thoracic and cervical levels. (p. 88–91, 95)

19. **Answer A:** Reticulospinal fibers (medial and lateral) and lateral vestibulospinal fibers are found predominately in the anterolateral area of the spinal cord; medial vestibulospinal fibers are located in the medial longitudinal fasciculus. In the decerebrate patient, the descending influence of rubrospinal fibers on spinal flexor motor neurons is removed, and descending influence on extensor motor neurons is predominant. The posterior columns, posterolateral area of the cord, and the posterolateral tract do not contain vestibulospinal or reticulospinal fibers. The intermediate zone, a part of the spinal cord grey matter, contains some of the terminals of these fibers but not the descending tracts in toto. (p. 86, 88, 90, 95)

20. **Answer C:** Weakness of the muscles of the face, particularly when upper and lower portions of the face are involved, indicate a lesion of either the facial motor nucleus or the exiting fibers of the facial nerve; both are located in the lateral pontine tegmentum at caudal levels. The hypoglossal nucleus innervates muscles of the tongue, the trigeminal nucleus innervates masticatory muscles, and the abducens nucleus innervates the lateral rectus muscle, all on the ipsilateral side. The arcuate nucleus is a group of cells located on the surface of the pyramid. (p.106, 116–120, 124)

21. **Answer B:** The fibers of the anterolateral system are located in the lateral portion of the pontine tegmentum anterior (ventral) to the facial motor nucleus; these fibers convey pain and thermal inputs. The spinal trigeminal tract and the anterior trigeminothalamic tract also convey pain and thermal input but from the ipsilateral and contralateral sides of the face, respectively. The lateral lemniscus is auditory in function and the median lemniscus conveys proprioception, vibratory sense, and discriminative touch. (p. 116–120, 124)

22. **Answer B:** The dorsomedial nucleus is located medial to the internal medullary lamina and, through its connections, one if its functions is to participate in arousal of the cerebral cortex. The other choices are in (anterior nucleus) or lateral to the internal medullary lamina, or, in the case of the globus pallidus, lateral to the internal capsule. (p. 144–149)

23. **Answer B:** Penetrating branches of the posterior spinal artery serve the posterior columns (gracile and cuneate fasciculi) of the spinal cord at all levels. Branches of the posterior spinal artery also serve the gracile nucleus, but this structure is in the medulla, not in the spinal cord. The lateral corticospinal tract and the anterolateral system are served by the arterial vasocorona on the surface of the cord and the internal branches of the anterior spinal artery. The medial longitudinal fasciculus is in the territory of the anterior spinal artery. (p. 95, 111)

24. **Answer D:** The putamen and the caudate nucleus originate from the same group of developing neurons, are collectively referred to as the neostriatum, and appear in the same shade of grey in a T1-weighted MRI. In general, the globus pallidus and pulvinar are distinctly lighter than the putamen and the dorsomedial nucleus frequently appears dark in a shade of grey distinctly different from that of the globus pallidus. (p. 151, 153, 155, 162)

25. **Answer C:** The pars caudalis portion of the spinal trigeminal nucleus is located in the lateral medulla adjacent to the spinal trigeminal tract in cross-sectional levels between the obex and the C1 level of the spinal cord. This portion of the spinal trigeminal nucleus is responsible for relaying pain and thermal information originating from the face and oral cavity on one side to the ventral posterior medullary nucleus on the contralateral side. The pars interpositus is found at levels between the obex and the rostral end of the hypoglossal nucleus and the pars oralis between the interpolaris and the principal sensory nucleus. The principal sensory nucleus is in the pons and the mesencephalic nucleus is in the midbrain. (p. 98–106, 120, 131)

26. **Answer E:** The solitary nucleus receives general visceral afferent (GVA) and special visceral afferent information (SVA, this input is taste) and is located in the region of the medulla served by posterior inferior cerebellar artery. All of the other choices are in the territory served by the anterior spinal artery. (p. 111)

27. **Answer E:** The tonsil of the cerebellum is located close to the midline and immediately above the medulla: its position relative to the cerebellum is caudal, medial, and inferior. Tonsillar herniation may compress the medulla, and if sudden, may result in death. The other portions of the cerebellum do not herniate. (p. 110, 123)

28. **Answer B:** In addition to other signs or symptoms, lesions in lateral areas of the brainstem may also interrupt hypothalamospinal fibers descending from the hypothalamus to the intermediolateral cell column in upper thoracic levels of the spinal cord. In this case the patient may present with a Horner syndrome, part of which is a small (constricted) pupil. In addition, the affected pupil may react slowly to reduced light. The anterolateral system conveys somatosensory input and fibers of the medial longitudinal fasciculus (originating from the medulla) are primarily descending to spinal cord levels. Reticulospinal and vestibulospinal tracts influence spinal motor neurons. (p. 124)

29. **Answer C:** The pulvinar, geniculate nuclei, ventral posteromedial and posterolateral nuclei, centromedian, and some other adjacent nuclei are served by the thalamogeniculate tract. The anterior and ventral anterior thalamic nuclei receive their blood supply from thalamoperforating arteries, the substantia nigra via branches of P1 and P2, and globus pallidus from the lenticulostriate branches of M1. (p. 140–141, 158–159)
30. **Answer**: The short-term loss of function, frequently involving a specific part of the body, is characteristic of a transient ischemic attack (commonly called a TIA). The follow-up MRI shows no lesion because there has been no permanent damage. TIAs are caused by a brief period of inadequate perfusion of a localized region of the nervous system; recovery is usually rapid and complete. However, TIAs, especially if repeated, may be indicative of an impending stroke. Hemorrhagic strokes frequently result in some type of permanent deficit, and the central cord syndrome has bilateral deficits. A small embolic stroke would be visible on the follow-up MRI, and in this patient would have resulted in a persistent deficit. Syringobulbia may include long tract signs as well as cranial nerve signs. (p. 158)

31. **Answer**: Damage to the gracile fasciculus on the left (at the T8 level this is the only part of the posterior columns present) accounts for the loss of vibratory sensation (and discriminative touch). Injury to the gracile fasciculus on the right would result in this type of deficit on the right side. The level of the cord damage is caudal to the cuneate fasciculi and the anterolateral system conveys pain and thermal sensations. (p. 86, 88, 90, 94)

32. **Answer**: The substantia nigra contains a large population of melanin-containing cells, located in the midbrain just internal to the crus cerebri, and the loss of these cells gives rise to the motor deficits characteristic of Parkinson disease. The neurotransmitter associated with these cells is dopamine. The reticular formation is in the core of the brainstem and the pontine nuclei are in the basilar pons; neither of these contain cells with melanin. The red nucleus is in the midbrain, but its reddish tone is related to a rich vascular supply, not to cells containing a pigment. (p. 128–133)

33. **Answer**: The superior salivatory nucleus lies adjacent to the quadrigeminal cistern. (p. 76, 138–143, 162)

34. **Answer**: The solitary nucleus is located immediately inferior (ventral) to the medial and spinal vestibular nuclei and is the only nucleus in the choices to receive a general visceral afferent (GVA) and special visceral afferent (SVA-taste) input. The inferior salivatory nucleus and the nucleus ambiguus are visceral motor (general visceral efferent [GVE] and special visceral efferent [SVE], respectively) and the spinal trigeminal and cochlear nuclei are sensory (general somatic afferent [GSA] and special somatic afferent [SSA], respectively). (p. 104, 106, 174–175)

35. **Answer**: The superior salivatory nucleus lies adjacent to the exiting fibers of the facial nerve in a position just lateral to the abducens nucleus in caudal levels of the pons. The preganglionic axons originating from these cells distribute on peripheral branches of the facial nerve. The dorsal motor and inferior salivatory nuclei are in the medulla and associated, respectively, with the vagus and glossopharyngeal nerves. The Edinger-Westphal nucleus is related to the oculomotor nucleus and the intermediolateral cell column is located primarily in thoracic levels of the spinal cord. (p. 116, 203)

36. **Answer**: The facial colliculus is an elevation in the floor of the fourth ventricle located medial to the sulcus limitans and formed by the underlying abducens nucleus and fibers (internal genu) originating from the facial nucleus. The vestibular area, indicating the position of the vestibular nuclei, is lateral to the sulcus limitans and the hypoglossal nucleus is internal to the hypoglossal trigone in the medial floor of the ventricle in the medulla. The trigeminal and facial nuclei are located in the pontine tegmentum and do not border on the ventricular space. (p. 34–36, 114–117)

37. **Answer**: In this case the weakness of the upper and lower extremities on the right reflects damage to corticospinal fibers on the left side of the basilar pons. A lesion of these fibers on the right side of the pons would produce a left-sided weakness. Rubrospinal fibers are not located in the territory of paramedian branches of the basilar artery. Also, lesions of rubrospinal fibers and of the middle cerebellar peduncle do not cause weakness but may cause other types of motor deficits. (p. 24, 116, 124, 190–191)

38. **Answer**: The exiting fibers of the abducens nerve (on the left) are in the territory of the paramedian branches of the basilar artery and are laterally adjacent to corticospinal fibers in the basilar pons. Diplopia may result from lesions of the oculomotor and trochlear nerves, but these structures are not in the domain of the paramedian basilar branches. A lesion of the optic nerve results in blindness in that eye and damage to the facial root does not affect eye movement but may cause a loss of view of the external world if the palpebral fissure is closed due to facial muscle weakness. (p. 24, 116, 124)

39. **Answer**: At caudal pontine levels most, if not all, of the mediallemniscus is located within the territory served by paramedian branches of the basilar artery. Penetrating branches of the anterior spinal artery serve the hypoglossal nucleus. The other choices are generally in the territories of short or long circumferential branches of the basilar artery. (p. 124–125)

40. **Answer**: Weakness of the extremities accompanied by paralysis of the lateral rectus muscle (innervated by the abducens nerve) on the contralateral side indicates a lesion in the caudal and medial pons involving the abducens nerve root and corticospinal fibers. This is a middle alternating hemiplegia. Inferior alternating hemiplegia specifies involvement of the hypoglossal root and the pyramid, and superior alternating hemiplegia indicates damage to the oculomotor root and the crus cerebri. Alternating (or alternate) hemiannelasia and hemihypesthesia are sensory losses. (p. 116, 124)

41. **Answer**: The prominent elevation formed on the caudal and medial wall of the third ventricle, at the general level of the posterior commissure, represents the location of the habenular nucleus. This is an excellent landmark to use in axial MRI when designating the separation between the third ventricle (rostral to this point on the midline) and the quadrigeminal cistern (caudal to this point). The pulvinar is lateral to the quadrigeminal cistern, the lamina terminalis forms the rostral wall of the third ventricle, and the massa intermedia bridges the space of the third ventricle. When present (in about 80% of patients) the Massa intermedia appears as a shadow in T2-weighted MRI bridging the third ventricle. The superior colliculus is a mesencephalic structure found in the quadrigeminal cistern. (p. 76, 138–143, 162)
42. Answer E: The red nucleus, exiting fibers of the oculomotor nerve, portions of the corticospinal fibers in the crus cerebri, and a number of other medially located structures are found in the territory of the penetrating branches of the basilar bifurcation. The paramedian branches of the basilar artery and the corticospinal fibers in the pyramid serve the abducens nerve by branches of the anterior spinal artery. The anterolateral system and the medial lemniscus are mainly, if not entirely, in the region of the midbrain served by branches of the quadrigeminal and posterior medial choroidal arteries. (p. 137)

43. Answer D: The vocalis muscle (this muscle is actually the medial portion of the thyroarytenoid muscle) is innervated, via the vagus nerve, by motor neurons located in the nucleus ambiguus. The gracile nucleus conveys sensory input from the body and the spinal trigeminal nucleus relays sensory input from the face. The hypoglossal nucleus is motor to the tongue and the facial nucleus is motor to the muscles of facial expression. (p. 100–106, 110)

44. Answer A: Fibers comprising the anterolateral system convey pain and thermal sensations from the body, excluding the face. These fibers are located in lateral portions of the medulla adjacent to the spinal trigeminal tract; this latter tract relays pain and thermal sensations from the face. The gracile and cuneate fasciculi convey proprioception, discriminative touch, and vibratory sense in the spinal cord and the medial lemniscus conveys same information from the medulla to the dorsal thalamus. (p. 100, 102, 104, 106, 110)

45. Answer E: The loss of pain and thermal sensations on one side of the face correlates with damage to the spinal trigeminal tract; in this case the loss is ipsilateral to the lesion. The anterolateral system relays pain and thermal sensations from the contralateral side of the body, the solitary tract conveys visceral sensory input (especially taste), and the medial lemniscus contains fibers relaying information related to position sense and discriminative touch. The medial longitudinal fasciculus does not contain sensory fibers. (p. 100–108, 110)

46. Answer C: The posterior inferior cerebellar artery (commonly called PICA by clinicians) serves the posterolateral portion of the medulla, which encompasses the anterolateral system, spinal trigeminal tract, and nucleus ambiguus. The anterior and medial areas of the medulla (containing the pyramid, medial lemniscus, and hypoglossal nucleus/nerve) are served by the anterior spinal artery and the anterolateral area of the medulla (the region of the olivary nuclei) is served by penetrating branches of the vertebral artery. The posterior spinal artery serves the posterior column nuclei in the medulla and the anterior inferior cerebellar artery (commonly called AICA) serves caudal portions of the pons and cerebellum. (p. 111)

47. Answer D: The restiform body is a large fiber bundle located in the posterolateral area of the medulla in the region served by posterior inferior cerebellar artery (PICA). This structure contains a variety of cerebellar afferent fibers including those of the posterior spinocerebellar tract. Damage to the vestibular nuclei will result in a tendency to fall to the ipsilateral side but will also produce diplopia (double vision) and nausea; symptoms not experienced by this patient. The anterolateral system is sensory, the nucleus ambiguus is motor to muscles of the throat (including the vocalis), and the corticospinal tract is not in the PICA territory. (p. 104, 106, 110–111)

48. Answer C: The oculomotor nucleus (containing general somatic efferent [GSE] cell bodies), along with the Edinger-Westphal (containing general visceral efferent [GVE] cell bodies) nucleus, is found in the most anterior and medial portion of the periaqueductal grey at the superior colliculus level. The trochlear nucleus is found at a comparable position, but at the cross-sectional level of the inferior colliculus. The mesencephalic nucleus is found in the lateral area of the periaqueductal grey, and the trigeminal and abducens nuclei are located in the pons. (p. 130–133, 201)

49. Answer C: A superior alternating (or alternate) hemiplegia is characterized by a loss of most eye movement (damage to oculomotor nerve fibers) on the ipsilateral side and weakness of the upper and lower extremities (damage to corticospinal fibers in the crus cerebri) on the contralateral side. The abducens nerve is the cranial nerve involved in a middle alternating hemiplegia and the hypoglossal is that nerve involved in an inferior alternating hemiplegia. The trigeminal nerve innervates the muscles of mastication and the trochlear nerve innervates the superior oblique muscle. (p. 132, 136, 200)

50. Answer E: Motor neurons in the nucleus ambiguous innervate, primarily through the vagus nerve, the muscles of the throat that move a bolus of food from the oral cavity to the esophagus. The tongue, via the hypoglossal nucleus and nerve, may move food around in the mouth and toward the back of the oral cavity, but the actual act of swallowing is through the action of pharyngeal and laryngeal musculature. The dorsal motor vagal and inferior salivatory nuclei are both visceromotor (autonomic) nuclei, and the medial vestibular nucleus is involved in the regulation of eye movement and in balance and equilibrium. (p. 100–106, 110)

51. Answer B: The uncus is at the rostral and medial aspect of the parahippocampal gyrus, and, in this position, is directly adjacent to the anterolateral aspect of the midbrain. The diencephalon is rostral to this point and the medulla, the most caudal part of the brainstem, is located in the posterior fossa. Late stages of uncal herniation may, but not always, result in damage to the rostral pons; this is especially so if the patient becomes decerebrate. The cerebellum is not involved in uncal herniation. (p. 20, 22, 24, 38, 78, 136)

52. Answer D: Uncal herniation compresses the lateral portion of the brainstem, eventually resulting in compression of the corticospinal fibers in the crus cerebri. Weakness on the patient’s left side indicates damage to corticospinal fibers in the right crus. In situations of significant shift of the midbrain due to the herniation, the contralateral crus may also be damaged resulting in bilateral weakness. While all other choices contain corticospinal fibers, none of these areas are directly involved in uncal herniation. (p. 136)

53. Answer C: The root of the oculomotor nerve conveys GSE fibers to four of the six major extraocular muscles and GVE parasympathetic preganglionic fibers to the ciliary ganglion from which postganglionic fibers travel to the sphincter muscle of the iris. Pressure on the oculomotor root, as in uncal herniation, will usually compress the smaller diameter, and more superficially located GVE fibers first. Optic nerve damage results in blindness in that eye, injury to sympathetic fibers to the eye results in constriction of the pupil, and an abducens root injury results in an inability to abduct that eye. A lesion of corticonuclear fibers in the crus results primarily in motor deficits related to the facial, hypoglossal, and accessory nerves. (p. 136, 201, 221)
54. Answer C: The decussation of the superior cerebellar peduncle is a prominent fiber bundle located in the tegmentum of the midbrain directly on the midline at the level of the inferior colliculus. This bundle is made up of cerebellar efferent fibers. The red nucleus is located in the midbrain tegmentum, but not on the midline. Decussating trigeminothalamic fibers are found in the medulla and do not form a visible structure on the midline. The motor decussation is a compact bundle on the midline, but it is in the medulla, not the midbrain. The main parts of the substantia nigra are in the midbrain, are seen in sagittal MRI, but they are definitely not on the midline. (p. 128, 163, 211)

55. Answer A: The anterolateral system is located just internal to the brachium of the inferior colliculus in the lateral portions of the midbrain tegmentum. This tract conveys pain and thermal sensations from the contralateral side of the body excluding the face. Corticospinal fibers are located in the crus cerebri, the mesencephalic tract at the lateral edge of the periaqueductal (central) grey, and the central tegmental tract is, as its name indicates, in the central part of the tegmentum. Oculomotor fibers within the midbrain leave the nucleus, arch through the tegmentum, and exit on the medial surface of the basis pedunculi into the interpeduncular cistern. (p. 128–131)

56. Answer C: Fibers conveying discriminative touch, vibratory sensations, and proprioception are located in the lateral lemniscus; those from the contralateral upper extremity are medial while those from the contralateral lower extremity are lateral. This man has difficulty walking due to a lesion of fibers conveying position sense from the lower extremity, not due to a lesion influencing descending fibers passing to spinal motor neurons. Fibers of the anterolateral system convey pain and thermal sensation. Rubrospinal and corticospinal are motor in function; however this man has no weakness. (p. 126–132, 178–179)

57. Answer C: The inferior salivatory nucleus is located in the rostral medulla, medial to the solitary tract and nuclei and inferior to the medial vestibular nucleus. Preganglionic axons that originate from these cells distribute on branches of the glossopharyngeal nerve. The dorsal motor nucleus is in the medulla, its axons travel on the vagus nerve. The superior salivatory nucleus is in the caudal pons and is associated with the facial nerve. Cells of the Edinger-Westphal nucleus are associated with the oculomotor nucleus of the midbrain and the intermediolateral cell column is located primarily in thoracic levels of the spinal cord. (p. 106, 203)

58. Answer C: Weakness of the extremities accompanied by paralysis of muscles on the contralateral side of the tongue (seen as a deviation of the tongue to that side on protrusion) indicates a lesion in the medulla involving the corticospinal fibers in the pyramid and the exiting hypoglossal roots. This is an inferior alternating hemiplegia. Middle alternating hemiplegia refers to a lesion of the pontine corticospinal fibers and the root of the abducens nerve, and superior alternating hemiplegia specifies damage to the oculomotor root and crus cerebri. Alternating (alternate) hemianesthesia and hemihypesthesia are sensory losses. (p. 102, 110)

59. Answer A: The deviation of the tongue to the left on attempted protrusion is the best localizing sign in this woman. This is especially the case when the deviation of the tongue is seen in concert with the motor and sensory losses described for this patient. This clearly indicates a lesion in the medial medulla encompassing the corticospinal fibers, medial lemniscus, and exiting fibers on the hypoglossal nerve. Motor and sensory losses, without the cranial nerve sign, could suggest a lesion at several different levels of the neuraxis. (p. 83, 110–111)

60. Answer B: All of the sensory deficits seen in this woman reflect a lesion in the medial lemniscus, which is located in the medial medulla in the territory of the anterior spinal artery. The anterolateral system and the spinal trigeminal tract convey pain and thermal sensations from the body (sans face) and face, respectively. The solitary tract is made up of the central processes of visceral sensory fibers and the medial longitudinal fasciculus at this level contains descending fibers that influence spinal motor neurons. (p. 100–108, 110–111)

61. Answer D: Syringobulbia is a cavitation within the medulla. A cavitation in this location may communicate with a cavity in cervical levels of the spinal cord (syringomyelia). Hydromyelia refers to a cavity of the spinal cord that is lined with ependymal cells. The central cord and Brown-Séquard syndromes are lesions of the spinal cord that give rise to characteristic motor and sensory losses. (p. 110)

62. Answer A: The dentate nucleus appears as a long thin undulating line within the white matter core of the cerebellar hemisphere. It is frequently described as having the three-dimensional shape of a crumpled bag with its hilus (the opening of the bag) directed rostromedially. The other cerebellar nuclei (fastigial, globose, emboliform) are small clumps of cells, and the red nucleus is found in the midbrain, not in the cerebellum. (p. 112–115)

Review and Study Questions for Chapter 6

1. The MRI of a 66-year-old man shows a tumor 2.0 cm in diameter located in the lateral wall of the atrium of the lateral ventricle. Which of the following structures does this lesion most likely damage?
   - (A) Corticonuclear (corticobulbar) fibers
   - (B) Corticospinal fibers
   - (C) Optic radiations
   - (D) Pulvinar nucleus
   - (E) Splenium of the corpus callosum

2. Which of the following structures is clearly seen in coronal and axial brain slices, and in many MRIs, in planes extending from the midline laterally through the basal nuclei?
   - (A) Anterior commissure
   - (B) Column of the fornix
   - (C) Genu of the internal capsule
   - (D) Optic chiasm
   - (E) Posterior commissure
3. The MRI of a 49-year-old woman with movement and personality disorders and with cognitive dysfunction shows a large anterior horn of the lateral ventricle. The attending physician suspects that her disease has resulted in loss of brain tissue in the lateral wall of the anterior horn. A loss of which of the following structures would result in this portion of the ventricular system being enlarged?  
(A) Body of the caudate nucleus  
(B) Head of the caudate nucleus  
(C) Lenticular nucleus  
(D) Pulvinar nucleus (i)  
(E) Septum pellucidum and fornix

4. The axial MRI of a 54-year-old man shows an arteriovenous malformation located between the thalamus and the lenticular nucleus. Which of the following structures is probably most affected by this malformation?  
(A) Anterior commissure  
(B) Anterior limb of the internal capsule  
(C) Extreme capsule  
(D) Retrolenticular limb of the internal capsule  
(E) Posterior limb of the internal capsule

5. In a sagittal MRI, and in a sagittal brain slice, both taken just off the midline (2–4 mm), which of the following structures would be clearly evident immediately caudal to the anterior commissure?  
(A) Column of the fornix  
(B) Lamina terminalis  
(C) Mammillothalamic tract  
(D) Optic chiasm  
(E) Precommissural fornix

6. The coronal MRI of a 15-year-old boy shows a 2.0 cm-diameter tumor in the rostral tip of the temporal (inferior) horn of the lateral ventricle. It is possibly arising from the choroid plexus in this area of the ventricle. In addition to the hippocampus, this tumor is most likely impinging on which of the following structures?  
(A) Amygdaloid nucleus  
(B) Body of the caudate nucleus  
(C) Hypothalamus  
(D) Optic radiations  
(E) Putamen

7. Which of the following structures is located immediately internal to the crus cerebri and appears as a dark shade of grey (hypointense) in a sagittal T1-weighted MRI?  
(A) Brachium of the inferior colliculus  
(B) Periaqueductal grey  
(C) Pretectal area  
(D) Red nucleus  
(E) Substantia nigra

8. An 81-year-old man is brought to the emergency department following a fall while walking in the park. The examination reveals mild confusion and memory loss, but no obvious motor or sensory deficits. MRI shows an old infarct in the territory of the thalamus served by the thalamoperforating artery. Which of the following nuclei is most likely involved in this lesion?  
(A) Centromedian  
(B) Medial geniculate  
(C) Ventral anterior  
(D) Ventral posterolateral  
(E) Ventral posteros medial

9. Which of the following nuclei is located within the internal medullary lamina and may be visible in an axial MRI in either T1- or T2-weighted images?  
(A) Centromedian  
(B) Dorsomedial  
(C) Pulvinar  
(D) Ventral anterior  
(E) Ventral lateral

10. The sagittal MRI of a 23-year-old woman shows a mass in the right interventricular foramen (possibly a colloid cyst); the right lateral ventricle is enlarged. Based on its location, this mass is most likely impinging on which of the following structures?  
(A) Anterior nucleus of thalamus  
(B) Posterior limb of internal capsule  
(C) Habenular nucleus  
(D) Head of caudate nucleus  
(E) Lamina terminalis

11. The sagittal MRI of a 42-year-old woman taken adjacent to the midline shows a round structure immediately rostral to the interpeduncular fossa on the inferior surface of the hemisphere. Which of the following most likely represents this elevation?  
(A) Anterior commissure  
(B) Basilar pons  
(C) Lamina terminalis  
(D) Mammillary body  
(E) Optic chiasm

12. Which of the following structures is located immediately inferior to the pulvinar, and, in the sagittal plane (MRI or brain section), forms a distinct elevation immediately adjacent to the lateral aspect of the crus cerebri?  
(A) Mammillary nuclei  
(B) Medial geniculate nucleus  
(C) Optic tract  
(D) Subthalamic nucleus  
(E) Uncus

---

**Answers for Chapter 6**

1. Answer C: The optic radiations are located in the lateral wall of the atrium of the lateral ventricle, represent projections from the lateral geniculate nucleus to the calcine cortex, pass through the retrolenticular limb of the internal capsule, and are separated from the ventricular space by a thin layer of fibers called the tapetum. The pulvinar and splenium are located rostomedial and medial, respectively, to the atrium. Corticogenous and corticospinal fibers are found in the genu, and the posterior limb of the internal capsule within the hemisphere. (p. 76, 77, 138, 162)

2. Answer A: The anterior commissure is a mediolaterally oriented bundle of fibers that crosses the midline and extends laterally, immediately inferior to the basal nuclei. In sagittal section, or in a sagittal MRI, this bundle can be followed into planes of the hemisphere that include the most lateral portions of the thalamus and the lenticular nucleus. The column of the fornix and optic chiasm are located immediately adjacent to the midline. The posterior commissure is located at the caudal aspect of the third ventricle and immediately
superior to the opening of the cerebral aqueduct. The genu of the internal capsule is medial to the lenticular nucleus and rostroventral to the anterior nucleus of the thalamus. (p. 163, 165, 167, 169, 171)

3. Answer B: The head of the caudate nucleus forms a prominent bulge in the lateral wall of the anterior horn of the lateral ventricle. In Huntington’s disease, this elevation disappears, and the wall of the ventricle may become concave laterally; the result being an enlarged anterior horn (hydrocephalus ex vacuo). The body of the caudate is located in the lateral wall of the body of the lateral ventricle. The lenticular nucleus lies within the hemisphere and does not border on any ventricular space. The septum and the fornix are located in the medial wall of the ventricle, and the pulvinar borders on the superior cistern. (p. 75, 76, 152–156, 162)

4. Answer E: The posterior limb of the internal capsule is located between the lenticular nucleus, which is lateral, and the thalamus, which is medial. This large fiber bundle contains thalamocortical projections related to motor and sensory function and descending corticospinal fibers. The anterior limb of the internal capsule is located between the head of the caudate and the lenticular nucleus, and the retrolenticular limb is found caudal to the lenticular nucleus. The anterior commissure is in the rostroventral portion of the hemisphere, and the extreme capsule is immediately internal to the insular cortex. (p. 162, 164, 166)

5. Answer A: The column of the fornix, commonly called the postcommissural fornix, lies caudal to, and against, the anterior commissure as it arches around the interventricular foramen and the anterior tubercle of the thalamus. The precommissural fornix is a diffuse bundle of fibers rostral to the anterior commissure, and the mammillothalamic tract is located between the mammillary body and the anterior nucleus of the thalamus. The lamina terminalis and the optic chiasm are anterior to the anterior commissure. (p. 163)

6. Answer A: The amygdaloid nucleus is in the rostral wall of the temporal horn of the lateral ventricle. In this position the amygdala is separated from the rostral tip of the hippocampus (the hippocampus occupies the medial and inferior wall of the temporal horn) by a narrow space of the ventricle. The optic radiations are in the lateral wall of the temporal horn, but are quite caudal to its rostral tip. The other choices do not have direct structural relationship to the rostral portions of the temporal horn. (p. 170, 171)

7. Answer E: The substantia nigra is located internal to the crus cerebri and, in T1-weighted MRI, appears a darker shade of grey (hypointense) than does the crus. The red nucleus and the periaqueductal grey are located in the midbrain, but do not border on the crus cerebri. The brachium of the inferior colliculus is found on the lateral surface of the midbrain, and the pretectal area is adjacent to the cerebral aqueduct at the midbrain-diencephalic junction. (p. 165, 167)

8. Answer C: The ventral anterior nucleus is located in the rostral portions of the thalamus, is in the territory of the thalamoperforating artery, and projects to large regions of the frontal lobe. An occlusion of the vessels serving this portion of the thalamus may result in a decreased level of alertness. The other choices are in caudal regions of the thalamus, are not in the territory served by the thalamoperforating artery, and, with the exception of the centromedian nucleus, do not relate to the cortex of the frontal lobe. (p. 159, 162, 164)

9. Answer A: The centromedian nucleus is found within the internal medullary lamina in a position just rostral to the pulvinar. The ventral anterior and ventral lateral nuclei are lateral to the internal medullary lamina, the dorsomedial nucleus is medial to this lamina, and the pulvinar is the large nucleus forming the caudal part of the dorsal thalamus. (p. 76, 142–143, 162, 164)

10. Answer A: The interventricular foramen is the space formed between the column of the fornix (located somewhat rostromedially) and the anterior nucleus of the thalamus (located somewhat caudolaterally). The anterior nucleus is located internal to the anterior tubercle of the thalamus. The head of the caudate is found in the lateral wall of the anterior horn of the lateral ventricle, and the posterior limb is located in the hemisphere between the thalamus and the lenticular nucleus. The lamina terminalis extends from the anterior commissure inferiority to the upper edge of the optic chiasm. The habenula is a small elevation in the caudal and medial wall of the third ventricle. (p. 76, 162, 164)

11. Answer D: The mammillary body forms an obvious elevation on the inferior aspect of the hemisphere rostral to the interpeduncular fossa/cistern; this small bulge is clearly evident in MRI. The optic chiasm and the basilar pons are both on the inferior aspect of the brain at the midline. The former is rostral to the infundibulum (and the mammillary body) and the latter is caudal to the interpeduncular fossa. The lamina terminalis forms the rostral end of the third ventricle and the anterior commissure is adjacent to the column of the fornix. (p. 31, 163, 170)

12. Answer B: The medial and lateral geniculate nuclei are located inferior to the pulvinar, and form elevations on the surface of the dorsal thalamus; the medial geniculate is adjacent to the lateral edge of the crus cerebri. The subthalamic nucleus is located internally, the mammillary nuclei (medial and lateral) are on the inferior aspect of the thalamus, and the uncus is on the medial portion on the temporal pole. The optic tract lies on the surface of the crus cerebri, but it does not form a distinct elevation on the brain surface inferior to the pulvinar; rather, it has a structural relationship to the lateral geniculate nucleus. (p. 26, 59, 169)

Review and Study Questions for Chapter 7

1. A 15-year-old boy is brought to the emergency department after an accident on his father’s farm. The examination reveals weakness of the left lower extremity, but no frank paralysis. There is a loss of pinprick sensation on the right side beginning at the T8 dermatome (about half way between the nipple and umbilicus), and dorsiflexion of the great toe in response to plantar stimulation. Based on this examination, which of the following represents the most likely approximate location of this lesion?
   - (A) T6 on the left side
   - (B) T6 on the right side
   - (C) T8 on the left side
   - (D) T8 on the right side
   - (E) T10 on the left side
2. A 47-year-old man is transported to the emergency department from the site of an automobile collision. The examination reveals a paralysis of both lower extremities. Which of the following most specifically identifies this clinical picture?
   - (A) Alternating hemiplegia
   - (B) Hemiplegia
   - (C) Monoplegia
   - (D) Quadriplegia
   - (E) Paraplegia

3. A 68-year-old woman presents with a complaint of difficulty swallowing. Which of the following most specifically identifies this condition in this patient?
   - (A) Dysarthria
   - (B) Dysmetria
   - (C) Dysphagia
   - (D) Dyspnea
   - (E) Dysdiadochokinesia

4. A 37-year-old man presents to his family physician with a complaint of pain on his face. The examination shows that gentle stimulation of the cheek and corner of the mouth precipitates a severe, sharp, lancinating pain. A consulting neurologist orders an MRI (T2-weighted), which reveals a vascular loop that appears to be pressing on the trigeminal root proximal to the ganglion. Which of the following vessels is most likely involved?
   - (A) Anterior inferior cerebellar artery
   - (B) Posterior cerebral artery
   - (C) Posterior inferior cerebellar artery
   - (D) Quadrigeminal artery
   - (E) Superior cerebellar artery

5. Which of the following brainstem structures receives input from the frontal eye field (in the caudal part of the middle frontal gyrus, areas 6 and 8) and is regarded as a vertical gaze center?
   - (A) Abducens nucleus
   - (B) Edinger-Westphal nucleus
   - (C) Oculomotor nucleus
   - (D) Paramedian pontine reticular formation (PPRF)
   - (E) Rostral interstitial nucleus of the medial longitudinal fasciculus (MLF)

6. A newborn girl baby is unable to suckle. The examination reveals that muscles around the oral cavity and of the cheek are poorly developed or absent. A failure in proper development of which of the following structures would most likely contribute to this problem for this baby?
   - (A) Head mesoderm
   - (B) Pharyngeal arch 1
   - (C) Pharyngeal arch 2
   - (D) Pharyngeal arch 3
   - (E) Pharyngeal arch 4

7. Which of the following neurotransmitters is associated with hypothalamic fibers that project to the cerebellar cortex (hypothalamocerebellar fibers)?
   - (A) Gamma aminobutyric acid
   - (B) Glutamate
   - (C) Histamine
   - (D) Noradrenalin
   - (E) Serotonin

Questions 8 through 9 are based on the following patient.

A 62-year-old woman presents with tremor and ataxia on the right side of the body excluding the head, and with a loss of most eye movement on the left; the woman’s eye is rotated slightly down and out at rest. The left pupil is dilated. There are no sensory losses on her face or body.

8. Based on the deficits seen in this woman, which of the following most likely represents the causative lesion?
   - (A) Cerebellum on the right
   - (B) Cerebellum on the left
   - (C) Midbrain on the left
   - (D) Midbrain on the right
   - (E) Rostral pons on the right

9. The dilated pupil in this woman is most likely a result of which of the following?
   - (A) Intact parasympathetic fibers on the left
   - (B) Intact parasympathetic fibers on the right
   - (C) Intact sympathetic fibers on the left
   - (D) Intact sympathetic fibers on the right
   - (E) Interrupted hypothalamospine fibers on the left

10. Which of the following nuclei are the primary target of cerebellar efferent fibers that arise in the dentate, emboliform, and globose nuclei on the left side?
   - (A) Ventral anterior nucleus on the right
   - (B) Ventral lateral nucleus on the left
   - (C) Ventral lateral nucleus on the right
   - (D) Ventral posterolateral nucleus on the left
   - (E) Ventral posterolateral nucleus on the right

11. A 22-year-old man presents to his family physician with motor deficits. The examination reveals that the man has jerky up-down movements of his upper extremities especially noticeable in his hands when his arms are extended. Which of the following most specifically designate this abnormal movement?
   - (A) Akinesia
   - (B) Asterixis
   - (C) Dystonia
   - (D) Intention tremor
   - (E) Resting tremor

12. A 59-year-old man is brought to his family physician by his wife. He complains of frequent and severe headaches. His wife states that he does not seem to understand what she is saying when she talks to him. The examination reveals that the man can speak fluently and clearly, can read notes written on paper, can hear noise, but has great difficulty understanding or interpreting sounds. MRI shows a tumor in the temporal lobe. This man is most likely suffering from which of the following?
   - (A) Agnosia
   - (B) Agraphia
   - (C) Alexia
   - (D) Aphasia
   - (E) Aphonia
13. A 47-year-old man is brought to the emergency department by local law enforcement personnel. The man is thin, undernourished, somnolent, and clearly intoxicated. Other indicators, such as a lack of personal hygiene, suggest that the man’s condition has been long-term. When the physician asks the man his name and where he lives the man give a nonsensical response. This man is most likely suffering from which of the following?  
   - (A) Broca aphasia  
   - (B) Klüver-Bucy syndrome  
   - (C) Korsakoff syndrome  
   - (D) Munchausen syndrome  
   - (E) Pick disease

Questions 14 through 15 are based on the following patient.

A 69-year-old man is diagnosed with dysarthria. The history reveals that the man has had this problem for several weeks. MRI shows an infarcted area in the brainstem on the right side.

14. Damage to which of the following structures would most likely result in this deficit?  
   - (A) Cuneate nucleus  
   - (B) Nucleus ambiguus  
   - (C) Solitary tract and nuclei  
   - (D) Spinal trigeminal tract  
   - (E) Vestibular nuclei

15. Assuming that the infarcted area in the brain of this man is the result of a vascular occlusion, which of the following arteries is most likely involved?  
   - (A) Anterior inferior cerebellar  
   - (B) Labyrinthine  
   - (C) Posterior inferior cerebellar  
   - (D) Posterior spinal  
   - (E) Superior cerebellar

16. Which of the following neurotransmitters is associated with the cells in the somatomotor cortex that project to the spinal cord as corticospinal fibers?  
   - (A) Acetylcholine  
   - (B) Dopamine  
   - (C) Gamma aminobutyric acid  
   - (D) Glutamate  
   - (E) Serotonin

17. A 77-year-old woman presents with a loss of pain and thermal sensations on the right side of her face and on the left side of her body. Which of the following most specifically describe this deficit in this woman?  
   - (A) Alternating hemianesthesia  
   - (B) Epidural anesthesia  
   - (C) Facial hemiplegia  
   - (D) Hemifacial spasm  
   - (E) Superior alternating hemiplegia

18. During a busy day in the emergency department, the neurology resident sees three patients with brainstem lesions. The first is an 83-year-old woman with a lesion in the territory of the midbrain served by the quadrigeminal and lateral posterior choroidal arteries. The second is a 68-year-old man with a posterior inferior cerebellar artery (lateral medullary or Wallenberg) syndrome. The third is a 47-year-old woman with a presumptive glioblastoma multiforme invading the mid- to lateral portions of the pontine tegmentum and adjacent portions of the middle cerebellar peduncle. Which of the following would most likely be seen in all three patients assuming a thorough neurologic examination?  
   - (A) Claude syndrome  
   - (B) Contralateral hemiplegia  
   - (C) Facial hemiplegia  
   - (D) Horner syndrome  
   - (E) Medial medullary syndrome

19. Which of the following structures serves as an important landmark in the placement of the intentional division of the spinal cord (myelotomy) in an anterolateral cordotomy?  
   - (A) Anterior median sulcus  
   - (B) Anterolateral sulcus  
   - (C) Denticulate ligament  
   - (D) Posterior intermediate sulcus  
   - (E) Posterolateral sulcus

20. A 17-year-old boy is brought to the emergency department from a high school football game. The examination reveals a loss of vibratory sensation and discriminative touch on the left lower extremity and to the level of the umbilicus. CT shows a vertebral fracture with bone displacement into the vertebral canal. Which of the following indicates the most likely level of damage to the spinal cord in this boy?  
   - (A) T7–8 on the left  
   - (B) T9–10 on the left  
   - (C) T12 on the left  
   - (D) T8–9 on the right  
   - (E) T10 on the right

21. During the neurologic examination of a 52-year-old man, the physician decides to test the gag reflex. Which of the following difficulties does this man have that would cause the physician to decide to test this particular reflex?  
   - (A) Dysgeusia  
   - (B) Dysmetria  
   - (C) Dysphagia  
   - (D) Dyspnea  
   - (E) Gustatory agnosia

22. A 57-year-old woman presents with the main complaint of difficulty speaking. The examination reveals that the woman’s tongue deviates to the right on attempted protrusion. When she says “Ah” her soft palate elevates slightly on the left and the uvula deviates to the same side. This combination of deficits would most likely indicate a small lesion in which of the following?  
   - (A) Crus cerebri on the right  
   - (B) Genu of the internal capsule on the left  
   - (C) Genu of the internal capsule on the right  
   - (D) Lateral medulla on the right  
   - (E) Medial medulla on the right
23. A 36-year-old-woman is diagnosed with myasthenia gravis. Which of the following deficits are seen first in about one-half of patients with this disease and is present in most at some time during its course?

- (A) Diplopia
- (B) Dysmetria
- (C) Lower extremity weakness
- (D) Tremor
- (E) Upper extremity weakness

Questions 24 through 26 are based on the following patient.

An 80-year-old woman is brought to the emergency department from an assisted care facility. The woman, who is in a wheelchair, complains of not feeling well, of numbness on her face, and of being hoarse, although she claims not to have a cold. The examination reveals a loss of pain and thermal sensations on the right side of her face and on the left side of her body. CT shows an infarcted area in the lateral portion of the medulla.

24. A lesion of which of the following structures in this woman would explain the loss of pain and thermal sensations on her body excluding the head?

- (A) Anterolateral system on the left
- (B) Anterolateral system on the right
- (C) Medial lemniscus on the left
- (D) Spinal trigeminal nucleus on the left
- (E) Spinal trigeminal tract on the left

25. The hoarseness in this woman is most likely due to which of the following?

- (A) Lesion of the facial nucleus
- (B) Lesion of the hypoglossal nucleus/nerve
- (C) Lesion of the nucleus ambiguous
- (D) Lesion of the spinal trigeminal tract
- (E) Lesion of the trigeminal nucleus

26. Assuming this woman suffered a vascular occlusion, which of the following vessels is most likely involved?

- (A) Anterior inferior cerebellar artery
- (B) Anterior spinal artery
- (C) Posterior inferior cerebellar artery
- (D) Posterior spinal artery
- (E) Superior cerebellar artery

27. In the course of a neurologic examination of a 23-year-old man, the physician places her index finger on the midline of the mandible and taps it with a percussion hammer stimulating the afferent limb of the jaw (jaw-jerk) reflex. Collateral fibers from which of the following brainstem nuclei enter the trigeminal motor nucleus to initiate the motor response?

- (A) Hypoglossal
- (B) Mesencephalic
- (C) Principal sensory
- (D) Spinal trigeminal, pars caudalis
- (E) Spinal trigeminal, pars interpolaris

28. A 45-year-old-man is brought to his family physician by his wife. The man’s main complaint is that he feels “real dizzy” and a little nauseated. The examination reveals that the man has a disease of his semicircular canals. While sitting still the man perceives that his body is actually moving around the room. Which of the following most specifically describes this condition?

- (A) Ataxia
- (B) Hysterical vertigo
- (C) Nystagmus
- (D) Objective vertigo
- (E) Subjective vertigo

Questions 29 and 30 are based on the following patient.

A 37-year-old-man is brought to the emergency department from the site of an automobile collision. He was unrestrained and, as a result, has extensive injuries to his face and head. CT shows numerous fractures of the facial bones and skull and blood in the rostral areas of the frontal lobes and in the rostral 3–4 cm of the temporal lobes, bilaterally. After several weeks of recovery the man is moved to a long-term care facility. His behavior is characterized by (1) difficulty recognizing objects in his mouth; (2) a propensity to place inappropriate objects in his mouth; (3) a tendency to eat excessively or to eat non-food items such as the leaves on the plant in his room; and (4) a tendency to touch his genitalia.

29. Which of the following most specifically describes this condition?

- (A) Aphagia
- (B) Dysphagia
- (C) Dyspnea
- (D) Hyperorality
- (E) Hyperphagia

30. Based on the totality of this man’s deficits he is most likely suffering from which of the following?

- (A) Klüver-Bucy syndrome
- (B) Korsakoff syndrome
- (C) Senile dementia
- (D) Wallenberg syndrome
- (E) Wernicke aphasia

31. A 31-year-old woman is examined by an otolaryngologist pursuant to her complaint of hearing difficulties. The physician places a tuning fork against the woman’s mastoid bone until she no longer perceives sound, then moves the prongs to her external ear where a faint sound is again heard. This maneuver is best described as:

- (A) A negative (abnormal) Rinne test
- (B) A normal Binet test
- (C) A normal Weber test
- (D) A positive (normal) Rinne test
- (E) Weber test localizing to the deaf side
32. A 64-year-old man is brought to a rural health clinic by a neighbor. The history reveals that the man is a recluse, lives by himself, and does not regularly visit a physician. The examination reveals that the man has difficulty walking, chorea and dystonia, and is suffering dementia. The neighbor believes that the man’s father died from a similar disease. A tentative diagnosis of Huntington’s disease is made. Absence of which of the following structures in an MRI of this man would be consistent with this diagnosis?

- (A) Anterior lobe of cerebellum
- (B) Head of the caudate
- (C) Lateral thalamic nuclei
- (D) Substantia nigra
- (E) Subthalamic nucleus

33. A 23-year-old man is brought to the emergency department from an accident at a construction site. CT shows a fracture of the left mastoid bone with total disruption of the stylomastoid foramen. Which of the following deficits would most likely be seen in this man?

- (A) Alternating hemianesthesia
- (B) Alternating hemiplegia
- (C) Central seven
- (D) Facial hemiplegia
- (E) Hemifacial spasm

34. Cell bodies located in which of the following ganglia of the head supply postganglionic fibers to the parotid gland?

- (A) Ciliary
- (B) Intramural
- (C) Otic
- (D) Pterygopalatine
- (E) Submandibular

Questions 35 and 36 are based on the following patient.

A 23-year-old man is brought to the emergency department from an accident on his BMX bicycle. The examination reveals that the boy has severe facial injuries. Craniofacial CT shows fracture of facial bones and probable crushing of the structures traversing the superior orbital fissure. Damage to which of the following structures passing through this fissure would result in diplopia when attempting to look down and in?

- (A) Abducens nerve
- (B) Oculomotor nerve
- (C) Ophthalmic nerve
- (D) Ophthalmic vein
- (E) Trochlear nerve

35. As this man recovers, which of the following deficits is most likely to be the most obvious in this man?

- (A) A bilateral sensory loss in the lower body
- (B) A loss of immediate and short-term memory
- (C) A loss of long-term (remote) memory
- (D) Dementia
- (E) Dysphagia and dysarthria

36. Assuming that this man has also sustained bilateral injury to the Meyer-Archambault loop, which of the following deficits would this man also most likely have?

- (A) Bitemporal hemianopsia
- (B) Bilateral inferior quadrantanopia
- (C) Bilateral superior quadrantanopia
- (D) Left superior quadrantanopia
- (E) Right superior quadrantanopia

37. A 59-year-old man, who is a family physician, confides in a neurology colleague that he believes he has early stage Parkinson’s disease. The neurologic examination reveals a slight resting tremor of the left hand, a slow gait, and a lack of the normal range of facial expression for this man. Which of the following is the most likely location of the degenerative changes at this stage of this physician’s disease?

- (A) Bilateral substantia nigra
- (B) Left globus pallidus
- (C) Left substantia nigra
- (D) Right globus pallidus
- (E) Right substantia nigra

38. A 14-year-old boy is brought to the emergency department after an accident on his BMX bicycle. The examination reveals that the boy has severe facial injuries. Craniofacial CT shows fracture of facial bones and probable crushing of the structures traversing the superior orbital fissure. Damage to which of the following structures passing through this fissure would result in diplopia when attempting to look down and in?

- (A) Abducens nerve
- (B) Oculomotor nerve
- (C) Ophthalmic nerve
- (D) Ophthalmic vein
- (E) Trochlear nerve

Questions 39 through 41 are based on the following patient.

A 67-year-old man is brought to the emergency department by his wife. She explains that he fell suddenly, could not get up, and complained of feeling sick. The examination revealed a left-sided weakness of the upper and lower extremities, a lack of most movement of the right eye, and a dilated pupil on the right. MRI shows an infarcted area in the brainstem.

39. The weakness of this man’s extremities is explained by damage to the axons of cell bodies that are located in which of the following regions of the brain?

- (A) Left somatomotor cortex
- (B) Right anterior paracentral gyrus
- (C) Right crus cerebri
- (D) Right precentral gyrus
- (E) Right somatomotor cortex

40. This man’s dilated pupil is due to damage to which of the following fiber populations?

- (A) Preganglionic fibers from the Edinger-Westphal nucleus
- (B) Preganglionic fibers from the inferior salivatory nucleus
- (C) Postganglionic fibers from the ciliary ganglion
- (D) Postganglionic fibers from the geniculate ganglion
- (E) Postganglionic fibers from the superior cervical ganglion

41. Which of the following descriptive phrases best describes the constellation of signs and symptoms seen in the man?

- (A) Alternating hemianesthesia
- (B) Brown-Séquard syndrome
- (C) Inferior alternating hemiplegia
- (D) Middle alternating hemiplegia
- (E) Superior alternating hemiplegia
42. Which of the following structures contains the cell bodies of fibers conveying taste information from the anterior two-thirds of the tongue?
   - (A) Ciliary ganglion
   - (B) Geniculate ganglion
   - (C) Superior ganglion of the vagus nerve
   - (D) Superior ganglion of the glossopharyngeal nerve
   - (E) Trigeminal ganglion

43. During a screening neurologic examination of a 39-year-old man, the physician taps the supraorbital ridge, stimulating the supraorbital nerve, and elicits a motor response. Which of the following most likely represents the motor response in this man?
   - (A) Constriction of the masticatory muscles
   - (B) Constriction of the orbicularis oculi muscle
   - (C) Constriction of the pupil
   - (D) Dilation of the pupil
   - (E) Horizental nystagmus

44. A 67-year-old man has a bilateral anterolateral cordotomy at T10 for intractable pelvic pain. Four months after this procedure the man begins to experience pain sensations. Which of the following would most likely explain this apparent recurrence of pain in this man?
   - (A) Activation of postsynaptic posterior column and spinocervicothalamic pathways
   - (B) Activation of recurrent corticospinal fibers
   - (C) Activation of spinoreticulotegmental-thalamocortical pathways
   - (D) Regeneration of anterolateral system fibers in the spinal cord
   - (E) Regeneration of anterolateral system fibers into the posterior column system

45. An 84-year-old woman presents to her physician with the complaint of difficulty walking. The examination reveals that the woman has an unsteady gait and tends to forcibly slap her feet to the floor as she walks. She has no other deficits. The physician concludes that the woman has sensory ataxia. Degenerative changes in which of the following would most likely explain this deficit?
   - (A) Anterolateral system fibers
   - (B) Corticospinal fibers
   - (C) Posterior column fibers
   - (D) Posterior root fibers
   - (E) Vestibulospinal and reticulospinal fibers

46. The facial sensory deficits experienced by this woman are explained by a lesion to the axons of cell bodies located in which of the following structures?
   - (A) Anterior trigeminothalamic fibers on the left
   - (B) Left trigeminal ganglion
   - (C) Principal sensory nucleus on the left
   - (D) Right trigeminal ganglion
   - (E) Spinal trigeminal nucleus on the right

47. The loss of pain and thermal sensations experienced by this woman on the right side of her body (excluding the face) is most likely the result of damage to which of the following structures?
   - (A) Anterolateral system fibers on the left
   - (B) Anterolateral system fibers on the right
   - (C) Anterior trigeminothalamic fibers on the left
   - (D) Medial lemniscus on the left
   - (E) Medial lemniscus on the right

48. Taking into account all the deficits experienced by this woman, which of the following characterizes the syndrome, and the side, in this patient?
   - (A) Benedikt syndrome on the left
   - (B) Lateral medullary syndrome on the left
   - (C) Lateral medullary syndrome on the right
   - (D) Parinaud syndrome (bilateral)
   - (E) Weber syndrome on the right

49. A 17-year-old boy from a poor rural community is diagnosed with hepatolenticular degeneration (Wilson’s disease). Which of the following is accumulating in certain tissues of his body and producing health problems?
   - (A) Arsenic
   - (B) Copper
   - (C) Lead
   - (D) Magnesium
   - (E) Mercury

50. Which of the following represents the location of the postganglionic fibers that influence the dilator pupillae muscle of the iris on the ipsilateral side?
   - (A) Ciliary ganglion
   - (B) Edinger-Westphal nucleus
   - (C) Hypothalamus
   - (D) Intermediolateral cell column
   - (E) Superior cervical ganglion

51. A 37-year-old man presents with vertigo, nystagmus, ataxia, and hearing loss in his right ear. MRI shows a tumor in the cerebellopontine angle. A biopsy specimen of this tumor indicates that this mass most likely originated from myelin-forming cells on the root of the vestibulocochlear nerve. Which of the following terms most correctly identifies this tumor?
   - (A) Acoustic neuroma
   - (B) Ependymoma
   - (C) Glioblastoma multiforme
   - (D) Meningioma
   - (E) Vestibular schwannoma

Questions 46 through 48 are based on the following patient.

A 70-year-old woman is brought to the emergency department by her daughter after becoming ill during a trip to the mall. The woman is conscious but lethargic, and she has trouble speaking and swallowing. The examination reveals a loss of pain and thermal sensation on the left side of the face and a hoarse gravelly voice (as if the woman has a sore throat). Movements of the extremities are normal for the woman’s age, but she has a loss of pain and thermal sensations on the right side of her body. The corneal reflex is absent on the left side. MRI shows an infarcted area in the brainstem.
52. An inherited (autosomal recessive) disorder may appear early in the teenage years. These patients have degenerative changes in the spinocerebellar tracts, posterior columns, corticospinal fibers, cerebellar cortex, and at select places in the brainstem. The symptoms of these patients may include ataxia, paralysis, dysarthria, and other clinical manifestations. This constellation of deficits is most characteristically seen in which of the following?  
- (A) Friedreich ataxia  
- (B) Huntington disease  
- (C) Olivopontocerebellar degeneration (atrophy)  
- (D) Parkinson disease  
- (E) Wallenberg syndrome

53. A 45-year-old man complains to his family physician that there seems to be something wrong with his mouth. The examination reveals a weakness of the masticatory muscles, a deviation of the jaw to the left on closure, and a sensory loss on the same side of the lower jaw. MRI shows a tumor, presumably a trigeminal schwannoma, in the foramen ovale. Compression of which of the following structures would most likely be the cause of the deficits experienced by this man?  
- (A) Maxillary and mandibular nerves and motor fibers on the left and the right  
- (B) Motor fibers and mandibular nerve on the left  
- (C) Motor fibers and mandibular nerve on the right  
- (D) Motor fibers and maxillary nerve on the left  
- (E) Motor fibers and maxillary nerve on the right

54. A 49-year-old man visits his ophthalmologist with what the man interprets as “trouble seeing”. The history reveals that the man had a sudden event a few days before in which he felt sick and was nauseated. The man said his trouble “seeing” started after this sudden sickness. The examination reveals a loss of abduction and adduction of the right eye and a loss of adduction of the left eye. MRI confirms an infarcted area in the caudal and medial pontine tegmentum. Which of the following most specifically identifies this man’s clinical problem?  
- (A) Horizontal gaze palsy  
- (B) Internuclear ophthalmoplegia  
- (C) One-and-a-half syndrome  
- (D) Parinaud syndrome  
- (E) Vertical gaze palsy

55. Collaterals of ascending anterior (ventral) trigeminothalamic fibers that contribute to the vomiting reflex would most likely project into which of the following brainstem structures?  
- (A) Dorsal motor vagal nucleus  
- (B) Facial nucleus  
- (C) Nucleus ambiguus  
- (D) Superior salivatory nucleus  
- (E) Trigeminal motor nucleus

56. The topographical arrangement of fibers in the medial lemniscus at mid-olivary levels is such that the sensory information being conveyed by those fibers located most anterior (ventral) in this bundle will eventually terminate in which of the following structures?  
- (A) Anterior paracentral gyrus  
- (B) Lateral one-third of the postcentral gyrus  
- (C) Medial one-third of the postcentral gyrus  
- (D) Middle one-third of the postcentral gyrus  
- (E) Posterior paracentral gyrus

57. An 11-year-old girl is brought to the family physician by her mother. The mother explains that the girl has been complaining that her hands and arms “feel funny”. In fact, the mother states that the girl cut her little finger, but did not realize it until she saw blood. The examination reveals a bilateral loss of pain and thermal sensation on the upper extremities and shoulder. Which of the following is the most likely cause of this deficit in this girl?  
- (A) Brown-Séquard syndrome  
- (B) Posterior inferior cerebellar artery syndrome  
- (C) Tabes dorsalis  
- (D) Syringobulbia  
- (E) Syringomyelia

58. A 57-year-old obese man is brought to the emergency department by his wife. The examination reveals that cranial nerve function is normal but the man has bilateral weakness of his lower extremities. He has no sensory deficits. MRI shows a small infarcted area in the general region of the cervical spinal cord-medulla junction. Which of the following represents the most likely location of this lesion?  
- (A) Caudal part of the pyramidal decussation  
- (B) Lateral corticospinal tract on the left  
- (C) Pyramids bilaterally  
- (D) Pyramid on the right  
- (E) Rostral part of the pyramidal decussation

Questions 59 through 61 are based on the following patient.  
A 34-year-old woman presents with the complaint of seeing “two of everything” (diplopia). The history reveals that the woman becomes tired during the workday to the point where she frequently must leave her workplace early. The woman said that her vision problems appeared first, and later she noticed that, when she drank, it would “go down the wrong pipe”. The examination reveals weakness of the ocular muscle, difficulty in swallowing (dysphagia), and mild weakness of the upper extremities. Sensation is normal. Further laboratory tests indicate that the woman has a neurotransmitter disease.

59. Based on the history and symptoms experienced by this woman, which of the following is the most likely cause of her medical condition?  
- (A) Amyotrophic lateral sclerosis  
- (B) Huntington disease  
- (C) Myasthenia gravis  
- (D) Multiple sclerosis  
- (E) Parkinson disease

60. Which of the following represents the most likely location of the neurotransmitter dysfunction in this woman?  
- (A) At the termination of corticospinal fibers  
- (B) At the termination of corticospinal fibers  
- (C) At the neuromuscular junction  
- (D) Within the basal nuclei  
- (E) Within the cerebellum

61. Which of the following represents the neurotransmitter most likely affected in this woman?  
- (A) Acetylcholine  
- (B) Dopamine  
- (C) Glutamate  
- (D) GABA  
- (E) Serotonin
62. A 39-year-old woman complains to her family physician that “sometimes I see two of everything, but not always”. The examination reveals that the woman can abduct both eyes and can adduct her left eye but cannot adduct her right eye. All other eye movement is normal. MRI shows a small lesion suggesting an area of de-myelination in the pons. Which of the following represents the most likely location of this lesion?

- (A) Left abducens nucleus
- (B) Left medial longitudinal fasciculus
- (C) Right abducens nucleus
- (D) Right medial longitudinal fasciculus
- (E) Right PPRF

63. A 20-year-old man is brought to the emergency department from the site of a motorcycle accident. The examination reveals multiple head injuries and a broken humerus. Cranial CT shows a basal skull fracture extending through the jugular foramen. Assuming that the nerve or nerves that traverse this opening are damaged, which of the following deficits would most likely be seen in this man?

- (A) Deviation of the tongue to the injured side on protrusion
- (B) Diplopia and ptosis
- (C) Drooping and difficulty elevating the shoulder
- (D) Drooping of the face on the ipsilateral side
- (E) Loss of the efferent limb of the corneal reflex

64. A 17-year-old boy is brought to the pediatrician by his mother. The examination reveals that the boy has rigidity, athetoid movements (athetosis), and difficulty speaking. His ophthalmologist reports that the boy has a greenish-brown ring at the corneoscleral margin. This boy is most likely suffering from which of the following?

- (A) Huntington disease
- (B) Parkinson disease
- (C) Pick disease
- (D) Sydenham chorea
- (E) Wilson disease

65. A 32-year-old woman complains to her gynecologist that her breasts are tender and a white fluid issues from her nipples. The examination reveals that the woman is not pregnant (she had her ovaries removed at age 28 resultant to a diagnosis of ovarian cancer), that a milky substance can be expressed from her nipples, and that she has a visual field deficit. MRI shows a tumor impinging on the midline portion of the optic chiasm. Based on the position of this tumor which of the following visual deficits would most likely be seen in this woman?

- (A) Bitemporal hemianopsia
- (B) Left homonymous hemianopsia
- (C) Left superior quadrantanopia
- (D) Right homonymous hemianopsia
- (E) Right superior quadrantanopia

66. Which of the following portions of the cerebellum have a close structural and functional relationship with the vestibular apparatus and the vestibular nuclei?

- (A) Dentate nucleus and interposed nuclei
- (B) Dentate nucleus only
- (C) Fastigial nucleus and flocculonodular lobe
- (D) Hemisphere of the posterior lobe
- (E) Interposed nuclei and hemisphere of the anterior lobe

67. A 17-year-old boy presents with the major complaint that he is having trouble playing baseball on the high school varsity team. The examination reveals a healthy, well-nurtured, athletic boy with normal motor and sensory function. The visual examination reveals a superior right quadrantanopsia. MRI shows a small lesion in a position consistent with the visual field loss. Which of the following represents the most likely location of the lesion in this boy?

- (A) Crossing fibers in the optic chiasm
- (B) Lower portions of the optic radiations in the left temporal lobe
- (C) Lower portions of the optic radiations in the right temporal lobe
- (D) Upper portions of the optic radiations in the left parietal lobe
- (E) Upper portions of the optic radiations in the right parietal lobe

68. A 68-year-old man is brought to the emergency department by his daughter. She explains that he unexpectedly began to have sudden movements of his left “arm”. The examination reveals a slender man with hypertension and with periodic, uncontrollable flailing movements of his left upper extremity suggestive of hemiballismus. Assuming this to result from a vascular occlusion, MRI would most likely show an infarction in which of the following structures?

- (A) Left substantia nigra
- (B) Left subthalamic nucleus
- (C) Right motor cortex
- (D) Right substantia nigra
- (E) Right subthalamic nucleus

Questions 69 through 72 are based on the following patient.

A 67-year-old man visits his family physician with the complaint that he is not able to “do things like I used to”. The examination reveals that the man is not able to perform rapid alternating movements with his left upper extremity, and is not able to touch his left index finger to his nose because of a tremor that worsens as the finger approaches the nose. He is able to do these movements on the right. When he walks, he is unsteady with a tendency to fall to the left. He has no sensory deficits.

69. Which of the following terms specifically designates the inability of this man to perform rapid alternating movements?

- (A) Dysarthria
- (B) Dysdiadochokinesia
- (C) Dysmetria
- (D) Intention tremor
- (E) Resting tremor

70. Which of the following terms specifically designates this man’s inability to touch his nose with his index finger?

- (A) Dysmetria
- (B) Intention tremor
- (C) Rebound phenomenon
- (D) Resting tremor
- (E) Static tremor
71. The MRI of this man shows an infarcted area in the brain. Based on the deficits this man is experiencing, which of the following represents the most likely location of this lesion?

- (A) Basal nuclei on the left side
- (B) Basal nuclei on the right side
- (C) Cerebellar cortex and nuclei on the left side
- (D) Cerebellar cortex and nuclei on the right side
- (E) Midbrain on the right side

72. Assuming this lesion to be the result of the occlusion of an artery, which of the following is the most likely candidate?

- (A) Left anterior inferior cerebellar artery
- (B) Left superior cerebellar artery
- (C) Lenticulostriate arteries on the left
- (D) Right anterior inferior cerebellar artery
- (E) Right superior cerebellar artery

73. A 61-year-old woman complains to her family physician that the muscles of her face sometimes twitch. The examination reveals that the woman has irregular and intermittent contractions of facial muscles; sometimes these are painful. MRI shows an aberrant loop of an artery that appears to be compressing the facial nerve root. Which of the following is most likely the offending vessel in this case?

- (A) Anterior inferior cerebellar artery
- (B) Anterior spinal artery
- (C) Posterior inferior cerebellar artery
- (D) Posterior spinal artery
- (E) Superior cerebellar artery

74. An 81-year-old man presents with a loss of pain, thermal sensations, and proprioception on the right side of his body excluding his head. CT shows a comparatively small infarct representing the territory of one vessel. Based on the positions and relationships of the pathways conveying the sensations lost in this man, which of the following represents the most likely location of this lesion?

- (A) Caudal pons
- (B) Midbrain
- (C) Mid-medulla
- (D) Rostral medulla
- (E) Upper cervical spinal cord

75. The MRI of a 70-year-old man shows an infarcted area in the medulla on a mid-olivary level on the left. This correlates with a loss of position sense from the man’s upper right extremity. Which of the following represents the location of the cell bodies of origin of those fibers damaged in this patient in the medulla?

- (A) Cuneate nucleus on the left
- (B) Cuneate nucleus on the right
- (C) Gracile nucleus on the left
- (D) Gracile nucleus on the right
- (E) Posterior root ganglia on the left

76. A 39-year-old woman presents with sustained and oscillating muscle contractions that have twisted her trunk and extremities into unusual and abnormal postures. This woman is most likely suffering from which of the following?

- (A) Dysarthria
- (B) Dysmetria
- (C) Dysphagia
- (D) Dysphonia
- (E) Dystonia

77. A 21-year-old man is brought to the emergency department from the scene of an automobile collision. He has a compound fracture of the humerus, a fractured tibia, various cuts and bruises, and significant facial trauma. Cranial CT shows fractures of the bones of the face and orbit on the left, and a total collapse of the optic canal on that side with probable transection of the optic nerve. Following an initial recovery period, which of the following would most likely be seen during an ophthalmologic examination?

- (A) A loss of both the direct and consensual pupillary response when the light is shown in the right eye
- (B) A loss of only the consensual pupillary response when the light is shown in the right eye
- (C) A loss of the direct but not the consensual pupillary response when a light is shown in the left eye
- (D) Direct and consensual pupillary responses are intact when light is shown in the right eye
- (E) Direct and consensual pupillary responses are intact when light is shown in the right eye

78. A 27-year-old man presents with athetosis (athetoid movements), rigidity, and dysarthria. He also has a flapping tremor. The man has an obvious greenish-brown ring at the corneoscleral margin. A tentative diagnosis of advanced Wilson disease is made. MRI showing which of the following would provide further, if not conclusive evidence, of this disease?

- (A) Atrophy of gyri of the frontal and temporal lobes
- (B) Degeneration and cavitation of the putamen
- (C) Lacunae in the thalamus and internal capsule
- (D) Loss of cells in the substantia nigra
- (E) Loss of the caudate nucleus

79. A 77-year-old man complains to his family physician that he is having trouble picking up his coffee cup, shaving with a safety razor, and picking up the checkers when playing with his grandson. The examination reveals that the man is unable to control the distance, power, or accuracy of a movement as the movement is taking place. He undershoots or overshoots that target. Which of the following most specifically describes this condition?

- (A) Bradykinesia
- (B) Dysarthria
- (C) Dysdiadochokinesia
- (D) Dysmetria
- (E) Dysphagia

Questions 80 through 82 are based on the following patient.

A 70-year-old woman is brought to the emergency department by members of the volunteer fire department of a small town. She primarily complains of weakness. The examination reveals a hemiplegia involving the left upper and lower extremities, sensory losses (pain, thermal sensations, and proprioception) on the left side of the body and
face, and a visual deficit in both eyes. MRI shows an area of infarction consistent with the territory served by the anterior choroidal artery.

80. Which of the following visual deficits is seen in this woman?
- (A) Left homonymous hemianopsia
- (B) Left nasal hemianopsia
- (C) Left superior quadrantanopia
- (D) Right homonymous hemianopsia
- (E) Right superior quadrantanopia

81. Which of the following most specifically identifies the pattern of sensory deficits experienced by this woman?
- (A) Alternating hemianesthesia
- (B) Hemianesthesia
- (C) Paresthesia
- (D) Sensory level
- (E) Superior alternating hemiplegia

82. The weakness of the extremities in this woman is most likely due to damage to which of the following?
- (A) Corticospinal fibers on the left
- (B) Corticospinal fibers on the right
- (C) Somatomotor cortex on the right
- (D) Thalamocortical fibers to motor cortex on the right
- (E) Thalamocortical fibers to sensory cortex on the right

83. A 16-year-old boy is brought to the family physician by his mother. The mother explains that her son is having trouble in school even though he is a hard worker and is well behaved. The examination reveals that the boy has a sensorineural hearing loss in his right ear. He has no other deficits. Which of the following represents the most likely location of the lesion in this boy?
- (A) Auditory cortex
- (B) Cochlea
- (C) External ear
- (D) Inferior colliculus
- (E) Middle ear

84. Which of the following laminae of the lateral geniculate nucleus receive input from the contralateral retina?
- (A) 1, 2
- (B) 1, 3, 5
- (C) 1, 4, 6
- (D) 2, 3, 5
- (E) 3, 4, 5, 6

85. A 12-year-old girl is brought to the pediatrician by her mother who explains that the girl has started to “act funny.” The history reveals that the girl was treated for a hemolytic streptococcus infection 4 weeks before the appearance of her symptoms; the mother states that the girl has had this problem for 3 weeks. The examination reveals a well-nurtured girl with brisk, flowing, and irregular movements of her face, neck, and upper extremities. This girl is most likely suffering from which of the following?
- (A) Huntington disease
- (B) Parkinson disease
- (C) Senile chorea
- (D) Sydenham chorea
- (E) Weber syndrome

1. Answer A: The combination of weakness on one side (corticospinal involvement) and a loss of pain sensation on the opposite side specifies components of a Brown-Séquard syndrome. The motor loss is ipsilateral to the damage and the sensory loss is contralateral; second order fibers conveying pain information cross in the anterior white commissure ascending one to two spinal segments in the process. In this patient, the lesion is on the left side at about the T6 level; this explains the loss of pain sensation on the right beginning at the T8 dermatome level. Lesions at T8 or T10 would result in a loss of pain sensation beginning, respectively, at dermatome levels T10 or T12 on the contralateral side. (p. 180–181)

2. Answer E: The paralysis of both lower extremities is paraplegia. Monoplegia specifies paralysis of one extremity, hemiplegia of both extremities on the same side, and quadriplegia of all four extremities. An alternating hemiplegia is the combination of a motor cranial nerve deficit on one side and a hemiplegia on the contralateral side; this is a brainstem lesion not a spinal cord lesion. (p. 190–193)

3. Answer C: While the causes of swallowing difficulties may be central or peripheral (and multiple), this particular problem is called dysphagia. Dysmetria is an inability to control the distance or power of a movement and is commonly seen in cerebellar disease. Dystarthis is difficulty in speaking, and dyspnea is a difficulty in breathing; the latter is usually associated with diseases of the lungs or heart. Dysdiadochokinies, an inability to perform rapid alternating movements, is seen most commonly in cerebellar disease. (p. 190, 202)

4. Answer E: One possible cause of trigeminal neuralgia (tic douloureux) is compression of the trigeminal root by the superior cerebellar artery or its main branches; surgical relocation of the aberrant vessel (neurovascular decompression) relieves the symptoms. Hemifacial spasm may be caused by compression of the facial nerve by the anterior inferior cerebellar artery (commonly called AICA). The other choices do not cause trigeminal neuralgia and are not a principal cause of cranial nerve dysfunction via root compression. (p. 41, 184–185)

5. Answer E: The rostral interstitial nucleus of the medial longitudinal fasciculus receives cortical input from the frontal eye field on the ipsilateral side and projects to the ipsilateral (heavy) and contralateral (light) oculomotor and trochlear nuclei. This nucleus is regarded as the vertical gaze center. The paramedian pontine reticular formation is the horizontal gaze center. The oculomotor and abducens nuclei do not receive direct input from the frontal eye field and the Edinger-Westphal is a visceromotor nucleus containing preganglionic parasympathetic cell bodies. (p. 192–193)

6. Answer C: The absence of, or the aberrant development of, muscle around the oral cavity and over the cheek (muscles of facial expression, innervated by the facial [VII] nerve) indicate a failure of proper differentiation of the second (2nd) pharyngeal arch. Arch 2 also gives rise to the stapedius, buccinator, stylohyoid, platysma, and posterior belly of the digastric. Mesoderm of the head outside of the pharyngeal arches gives rise to the extraocular muscles and muscles of the tongue. The muscles of mastication
Q & A's: A Sampling of Study and Review Questions with Explained Answers

(plus the tensor tympani, tensor veli palati, mylohyoid, anterior belly of the digastric) arise from arch 1, the stylopharyngeus from arch 3, and striated muscles of the pharynx, larynx, and upper esophagus from arch 4. (p. 202–203)

7. Answer C: Hypothalamocerebellar fibers that project to the cerebellar nuclei and cortex contain histamine, GABA is found in several neurons that are located in the cerebellar cortex, and in Purkinje cells glutamate is found in many pontocerebellar fibers and in granule cells of the cerebellar cortex; noradrenaline is found in cereulocerebellar fibers. Serotonin is found in cells of the reticular formation and in some raphe cells that project to the cerebellum. (p. 206–207)

8. Answer C: The best localizing sign in this patient is the paucity of eye movement and dilated pupil on the left; this indicates a lesion of the midbrain on the left at the level of the exiting oculomotor fibers. The red nucleus is found at the same level and, more importantly, immediately lateral to the red nucleus is a compact bundle of cerebellothalamic fibers. The ataxia and tremor are related primarily to damage to these cerebellar efferent fibers. The motor deficit is contralateral to the lesion because the corticospinal fibers, through which the deficit is expressed, cross at the motor (pyramidal) decussation. Lesions at the other choices would not result in a paucity of eye movement and are, therefore, not potential candidates. (p. 132–133, 208–211)

9. Answer C: The lesion on the exiting oculomotor fibers (on the left) damages the preganglionic fibers from the Edinger–Westphal nucleus and removes their influence on the pupil. Consequently, the intact postganglionic sympathetic fibers from the ipsilateral superiority cervical ganglion predominate, and the pupil dilates. Choices on the right are on the incorrect side. Damage to hypothalamospinal fibers would remove sympathetic influence at the intermediolateral cell column, and the pupil would constrict (parasympathetic domination). (p. 200–201, 208–211, 220–221)

10. Answer C: Cerebellar efferent fibers exit the cerebellum via the superior cerebellar peduncle, cross in its decussation, and terminate primarily in the ventral lateral nucleus (VL). Consequently, the cerebellar nuclei on the left project to the right VL. The ventral anterior nucleus does not receive significant cerebellar input. While the ventral posterolateral nucleus receives a limited amount of cerebellar input, its major role is the relay of somatosensory information to the primary somatosensory cortex (postcentral gyrus). (p. 210–211)

11. Answer B: The jerking movements of the upper extremity (asteriskis) are also called a flapping tremor and are seen in patients with hepatoentereal degeneration (Wilson disease). Akinesia is lack of movement. Resting tremor is seen in patients with disease of the basal nuclei, such as Parkinson disease, and an intention tremor is a characteristic of patients with cerebellar lesions. Dystonia is the result of sustained muscle contractions that twist the extremities, trunk, and neck into distorted and abnormal postures. (p. 214–215)

12. Answer A: This man is unable to recognize or comprehend the meaning of sounds; although he is able to hear sounds, he is not able to put meaning to the sounds; this man is suffering from auditory agnosia. Agraphia is the inability to write in a person with no paralysis, and alexia is the inability to comprehend the meaning of written or printed words. Aphonia is a loss of the voice frequently due to disease of, or injury to, the larynx. Aphasia is seen in individuals with a lesion in the dominant hemisphere, and is manifest as an inability to comprehend the meaning of spoken, written, or various other types of input. (p. 226–227)

13. Answer C: The Korsakoff syndrome is a constellation of deficits including memory loss, confabulation, amnesia, and dementia that is seen in chronic alcoholics; the manifestations are related, in part, to excessive alcohol consumption and malnutrition. Therapeutic doses of thiamine are used to treat this disease. Broca aphasia (nonfluent or expressive aphasia) results from lesions in the dominant hemisphere. The Klüver–Bucy syndrome is related to bilateral lesions to the amygdaloid complex, and Pick disease is dementia related to atrophy of the frontal and temporal lobes. Munchausen syndrome is the fabrication or feigning of illness or disease to gain attention or control. (p. 232–233)

14. Answer B: Cell bodies in the nucleus ambiguous innervate muscles of the pharynx and larynx, including what is commonly called the vocalis muscle. A lesion of this nucleus is one cause of dysarthria. The solitary tract and nuclei are concerned with visceral afferent information including taste, and the spinal trigeminal tract is made the central processes of primary sensory fibers conveying general somatic afferent (GSA) information from the ipsilateral side of the face and oral cavity. Proprioceptive information from the ipsilateral upper extremity is transmitted via the cuneate nucleus; the vestibular nuclei are related to balance, equilibrium, and control of eye movement. (p. 202–203)

15. Answer C: The area of the brainstem that contains the nucleus ambiguous is served by branches of the posterior inferior cerebellar artery (PICA). Occlusion of this vessel usually gives rise to the PICA (lateral medullary or Wallenberg) syndrome. The anterior inferior cerebellar artery (AICA) serves the lateral and inferior cerebellar surface and the superior cerebellar artery serves the superior surface and much of the cerebellar nuclei. The labyrinthine artery, a branch of AICA, serves the inner ear. The posterior spinal artery serves the posterior columns and their nuclei. (p. 110–111, 202–203)

16. Answer D: Glutamate is found in many efferent fibers of the cerebral cortex including those of the corticospinal tract. Consequently, there are many glutaminergic terminals in the spinal cord. Acetylcholine is found at many central nervous system (CNS) sites and at the neuromuscular junction, and dopamine is found mainly in cells of the substantia nigra pars compacta and in their nigrostriatal terminals. Gamma aminobutyric acid (GAMA) is an inhibitory neurotransmitter and is found in many interneurons in the CNS. Serotonin is found in CNS areas such as the hypothalamus, basal nuclei, and the raphe nuclei. (p. 190)

17. Answer A: The loss of sensation on one side of the face and the opposite side of the body is an alternating hemianesthesia (also called an alternate hemianesthesia or a crossed hemianesthesia). Epidural anesthesia refers to anesthesia resultant to injection of an appropriate agent into the epidural space. The other choices are motor abnormalities. (p. 180–181, 186–187)

18. Answer D: Lesions in the lateral portions of the brainstem damage descending projections from the hypothalamus to the ipsilateral intermediolateral cell column at spinal levels T1–T4, these be-
ing the hypotalamospinal fibers. The result is Horner syndrome on the side ipsilateral to the lesion. Horner syndrome may also be seen following cervical spinal cord lesions. A contralateral hemi-
plegia is not seen in lesions in lateral areas of the brainstem. The other choices are syndromes or deficits specific to medial brain-
stem areas or to only a particular level. (p. 110, 124, 136,
220–221)

19. Answer C: The denticulate ligament is located on the lateral as-
pect of the spinal cord at a midpoint in the posterior–anterior ex-
tent of the spinal cord. The anterolateral system, the tract divided in the anterolateral cordotomy, is located in the anterolateral por-
tion of the spinal cord just inferior to the position of the denticu-
late ligament. The posterolateral sulcus is the entrance point for
sensory fibers of the posterior roots; the anterolateral sulcus is the
exit point for motor fibers of the anterior root; and the posterior
intermediate sulcus separates the gracile and cuneate fasciculi. The
anterior median sulcus is located on the anterior midline and con-
tains the anterior spinal artery. (p. 182–183)

20. Answer B: Damage to the gracile fasciculus on the left at T10,
the level of the umbilicus, will result in the deficits experienced by
this boy. The gracile fasciculus contains uncrossed ascending fibers
conveying vibratory sensation, discriminative touch, and proprio-
ception; consequently, the deficits will be seen beginning at the
level of the lesion and extending caudally on the same side. These
fibers are the central processes of primary sensory neurons whose
cell bodies are located in the ipsilateral posterior root ganglion.
The other choices are either on the wrong side (right) or at the
wrong level. (p. 178–179)

21. Answer C: The gag reflex is not regularly tested. However, in
patients with dysphagia (difficulty swallowing) or dysarthria (dif-

culty speaking), the gag reflex should be evaluated. Dysmetria is
a movement disorder associated with cerebellar lesions; dysgeusia
is the perception of an abnormal taste or of a tastant when there is
none; and dyspnea is difficulty breathing, usually associated with
disease of the lung or heart. Gustatory agnosia is the inability to recog-

22. Answer B: The combination of a deviation of the tongue to one
side (right) and the uvula to the opposite side (left) indicates a le-

23. Answer A: Deficits of eye movement (resulting in diplopia and
ptosis) are seen first in about 50% of all patients with myasthenia gravis and are eventually seen in approximately 85% of all patients

24. Answer B: The lesion in this woman is in the medulla, and the
sensory loss on the body (excluding the head) is on her left side; a

25. Answer C: The woman is hoarse because the lesion involves the
region of the medulla that contains the nucleus ambiguus. These
motor neurons serve, via the glossopharyngeal (IX) and vagus (X)
nerves, the muscles of the larynx and pharynx, including the me-
dial portion of the thyroarytenoid, also called the vocalis muscle.
Paralysis of the vocalis on one side will cause hoarseness of the
voice. Hypoglossal nucleus or nerve, or facial nucleus lesions may
cause difficulty with speech but not hoarseness. The spinal trigem-
inal tract conveys sensory input from the ipsilateral side of the
face. There are no historical or examination findings to support a
diagnosis of upper respiratory viral findings (cold or flu). (p.
180–181, 202–203)

26. Answer C: The posterior inferior cerebellar artery (PICA)
serves the lateral area of the medulla that contains the anterolat-
eral system, spinal trigeminal tract (loss of pain and thermal sen-
sations from the ipsilateral side of the face), and the nucleus am-
biguus. Many patients that present with a PICA (Wallenberg or
lateral medullary) syndrome also have involvement of the verte-
bral artery on that side. The posterior spinal artery serves the pos-
terior column nuclei in the medulla, and the anterior spinal artery
serves the pyramid, medial lemniscus, and exiting roots of the hy-
poglossal nerve. The anterior inferior cerebellar artery and the su-
perior cerebellar artery distribute to the pons and midbrain, re-

27. Answer B: The mesencephalic nucleus, a part of the trigeminal
complex, has peripheral processes attached to neuromuscular
spindles in the masticatory muscles, unipolar cell bodies in the ro-
stral pons and midbrain, and central collaterals that distribute bi-
laterally to the trigeminal motor nucleus. Through these connec-
tions, stretching of the spindle initiates a motor response. The
principal sensory and spinal trigeminal nuclei relay touch and
pain/thermal sensations respectively. The hypoglossal nucleus is
motor to the ipsilateral side of the tongue. (p. 184–185)

28. Answer E: The patient’s perception that his body is moving
around the room when he is actually sitting or laying still is sub-
jective vertigo. Objective vertigo is the perception, on the part of the
patient, that he is still and objects in the room are moving. As
its name clearly implies, hysterical vertigo is a psychosomatic dis-
order. Nystagmus is abnormal rhythmic movements of the eyes,
usually with fast and slow components. Ataxia is an inability to co-
ordinate muscle activity resulting in an unsteady gait or other uncoordinated movements. (p. 228–229)

29. **Answer E:** Excessive eating (gluttony), which may include a propensity to attempt to eat things not considered food items, is hyperphagia. Dysphagia is difficulty swallowing, and aphagia is the inability to eat. Hyperorality is the tendency to put items in the mouth or to appear to be examining objects by placing them in the oral cavity. Dyspnea is difficulty breathing. (p. 234–235)

30. **Answer A:** The constellation of deficits experienced by this man is characteristic of the Klüver-Bucy syndrome; this may be seen following bilateral damage to the temporal poles that includes the amygdaloid complex. The Korsakoff syndrome is seen, for example, in chronic alcoholics, and senile dementia is a loss of cognitive and intellectual function associated with neurodegenerative diseases of the elderly (such as Alzheimer). Wernicke (receptive or fluent) aphasia is seen in patients with a lesion in the area of the inferior parietal lobule, and the Wallenberg syndrome results from a lesion in the medulla characterized by alternating hemisensory losses and, depending on the extent of the damage, other deficits. (p. 234–235)

31. **Answer D:** Hearing a sound in the ipsilateral ear with the application of a tuning fork to the mastoid bone (actually the mastoid process of the temporal bone), and then hearing the sound again at the external ear by moving the prongs to the external ear after the sound disappears at the mastoid is a normal Rinne test. In a negative Rinne test, the sound is not heard at the external meatus after it has disappeared from touching the mastoid. In a normal Weber test, sound is heard equally in both ears with application of a tuning fork to the midline of the forehead. A localizing Weber test indicates that sound is heard in the normal ear, but not in the ear with disease or lesion. The Binet is an intelligence test. (p. 226–227)

32. **Answer B:** In Huntington disease, especially in advanced stages, there is a loss of the caudate nucleus and ex vacuo enlargement of the ventricles. The most obvious portion of the caudate missing in MRI coronal or axial planes is the head. The anterior lobe of the cerebellum is diminished in size in alcoholic cerebellar degeneration, but not so in Huntington disease. Lesions of the subthalamic nucleus result in hemiballismus, and degenerative changes in the substantia nigra result in the motor deficits seen in Parkinson disease. One of the main responsibilities of the lateral thalamic nuclei is to convey input to the somatomotor and somatosensory cortices. (p. 214–215)

33. **Answer D:** The paralysis of facial muscles on one side of the face (left in this case) with no paralysis of the extremities is a facial hemiplegia; this is also commonly known as Bell palsy or facial palsy. Hemifacial spasms are irregular contractions of the facial muscles, and a central seven refers to paralysis of muscles on the lower half of the face contralateral to a lesion in the genu of the internal capsule. Alternating hemiplegia describes a motor loss related to a cranial nerve on one side of the head and motor deficits of the extremities on the contralateral side of the body. A similar pattern of sensory losses is called an alternating hemianesthesia. (p. 202–203)

34. **Answer C:** The otic ganglion receives preganglionic parasympathetic fibers from the inferior salivatory nucleus (associated with the glossopharyngeal [IX] nerve) and sends postganglionic fibers to the parotid gland. The ciliary receives from the Edinger-Westphal nucleus and sends to the pupil; the pterygopalatine and submandibular receives from the superior salivatory nucleus (associated with the facial [VII] nerve) and sends, to the lacrimal, submandibular, and sublingual glands, respectively. Intramural ganglia are located in the gut and receive input from the dorsal motor vagal nucleus. (p. 202–203)

35. **Answer B:** Bilateral damage to the temporal lobes, as in an automobile collision, may result in damage to the hippocampus. While remote memory, the ability to recall events that happened years or decades ago, is intact, the man will have difficulty “re-memorizing” recent or immediate events. That is, he will find it difficult, if not impossible, to turn a new experience into longer-term memory (something that can be recalled in its proper context at a later time). Dysphagia (difficulty swallowing) and dysarthria (difficulty speaking) are deficits usually seen in brainstem lesions. Bilateral sensory losses of the lower portion of the body could be seen with bilateral damage to the posterior paracentral gyri (falcine meningioma) or to the anterior white commissure of the spinal cord. Dementia is a multiregional symptom that usually involves several areas of the brain, cortical as well as subcortical. (p. 232–233)

36. **Answer C:** The Meyer-Archambault loop is composed of optic radiation fibers that loop through the temporal lobe; these fibers, on each side, convey visual input from the contralateral superior quadrant of the visual field. Consequently, a bilateral lesion of these fibers results as a bilateral superior quadrantanopia. Bilateral inferior quadrantanopia is seen in bilateral lesions that would involve the superior portion of the optic radiations. Right or left superior quadrantanopia is seen in cases of unilateral damage to, respectively, the left or right Meyer-Archambault loop. A bitemporal hemianopsia results in a lesion of the optic chiasm. (p. 220, 223)

37. **Answer E:** Degenerative changes in the dopamine-containing cells of the substantia nigra pars compacta on the right side correlate with a left-sided tremor. The altered message through the lenticular nucleus and thalamus and on to the motor cortex on the side of the degenerative changes will result in tremor on the opposite (right) side via altered messages traveling down the corticospinal tract. The initial symptoms of Parkinson disease appear on one side in about 80% of patients and extend to bilateral involvement as the disease progresses. Bilateral changes in the substantia nigra correlate with bilateral deficits. The globus pallidus does not receive direct nigral input but rather input via a nigrostriatal-striatopallidal circuit. (p. 214–215)

38. **Answer E:** Damage to the trochlear nerve will cause diplopia on gaze inward and downward on the side of the injury. Abduccens damage will result in an inability to look laterally on the side of the lesion, and oculomotor injury will result in the loss of most eye movement on that side; the eye will be deviated slightly down and out. The ophthalmic nerve is sensory. (p. 200–201)

39. **Answer E:** The combination of eye movement disorders and a contralateral hemiplegia localizes this lesion to the midbrain on the side of the ocular deficits (right side). This also specifies that corticospinal fibers on the right (in the crus) are damaged, and places the location of the cells of origin for these fibers in the somatomotor cortex on the right side. The right crus contains the axons
of these fibers but not the neuronal cell bodies. The left somatomotor cortex influences the right extremities. The right precentral gyrus does not contain cells projecting to the left lumbosacral spinal cord (left lower extremity), and the right anterior paracentral gyrus does not contain the cells that project to the left cervical spinal cord (left upper extremity). (p. 15, 190–193)

40. Answer A: The lesion in this man is central (brainstem) and involves the IIIrd nerve. Consequently, the damage is to the preganglionic parasympathetic fibers in the root of the oculomotor (III) nerve; this removes the parasympathetic influence (pupil constriction) that originates from the Edinger-Westphal nucleus. Fibers from the superior cervical ganglion are intact, hence the dilated pupil. Fibers from the geniculate ganglion and inferior salivatory nucleus distribute on the facial (VII) and glossopharyngeal (IX) nerves respectively. Postganglionic fibers from the ciliary ganglion, while involved in this pathway, are not damaged in this lesion. (p. 200–201)

41. Answer E: The loss of most eye movement on one side (oculomotor nerve root involvement) coupled with a paralysis of the extremities on the contralateral side is a superior alternating hemiplegia (this is also Weber syndrome): superior because it is the most rostral of three; alternating because it is a cranial nerve on one side and the extremities on the other; and hemiplegia because one-half of the body below the head is involved. A middle alternating hemiplegia involves the abducens (VI) nerve root and adjacent corticospinal fibers, and an inferior alternating hemiplegia involves the hypoglossal (XII) nerve root and corticospinal fibers in the pyramidal tract. Alternating hemianesthesia is a sensory loss, and a Brown-Séquard syndrome results from a spinal cord lesion with no cranial nerve deficits. (p. 200–201)

42. Answer B: Taste fibers (special visceral afferent, SVA) that serve the anterior two-thirds of the tongue on the ipsilateral side are conveyed on the facial nerve and have their cell bodies of origin in the geniculate ganglion. The trigeminal ganglion contains cell bodies that convey general sensation (general somatic afferent, GSA), and the ciliary ganglion contains visceral motor cell bodies (general visceral efferent GVE, postganglionic, parasympathetic). The superior ganglion of the glossopharyngeal contains cell bodies for taste from the posterior one-third of the tongue, and the superior ganglion of the vagus nerve contains cell bodies for taste from the root of the tongue. (p. 187)

43. Answer B: Stimulation of the supraorbital nerve (Vth nerve, afferent limb of the supraorbital reflex) results in contraction of the orbicularis oculi muscle (VIIth nerve, efferent limb of the supraorbital reflex). Changes in pupil size relate to the third nerve, the pupillary light reflex, and the distribution of postganglionic fibers from the superior cervical ganglion. Contraction of mastiatory muscles is seen in the jaw-jerk reflex, and nystagmus usually results from cerebellum or brainstem lesions or disease of the vestibular apparatus. (p. 184–185, 202–203)

44. Answer A: Fibers in the postsynaptic posterior column and in the spinoocervicothalamic pathways are spared in an anterolateral cordotomy. These pathways originate from those laminae of the posterior horn that also contribute to the anterolateral system. It is possible that these pathways remold to transmit pain and thermal sensations in the absence of the normal anterolateral system (ALS) pathway. Regeneration to a functional state probably does not normally take place in the human nervous system; spinothalamic fibers are in the divided ALS; and corticospinal fibers function in the motor sphere. (p. 182–183)

45. Answer C: The ataxia seen in patients with lesions of posterior column fibers is due to the loss of proprioceptive input and the resultant inability of the patient to accurately judge the relative position of the extremity. Thus, the extremity is forcibly slapped to the floor partially in an attempt to “create” the missing input. Anterolateral system fibers convey pain and thermal sensations, and posterior root fibers convey these sensations plus those related to the posterior columns. Corticospinal, vestibulospinal, and reticulospinal fibers function in the motor sphere. (p. 178–179)

46. Answer B: The axons of cell bodies located in the left trigeminal ganglion collect inside the brainstem to form the spinal trigeminal tract on the left (this tract is made up of the central processes of primary sensory fibers on the trigeminal [V] nerve). A lesion of these fibers on the left side of the medulla will result in a loss of pain and thermal sensations on the left side of the face. Lesions of the right trigeminal ganglion, trigeminothalamic fibers on the left, and the right spinal trigeminal nucleus would all result in pain and thermal losses on the right side of the face. The principal sensory nucleus conveys touch information. (p. 184–185)

47. Answer A: Recognizing that this woman has a sensory loss on the left side of her face, damage to fibers of the anterolateral system on the left correlates with the loss of pain and thermal sensations on the right side of her body. These anterolateral system (ALS) fibers cross in the spinal cord within about two levels of where they enter. Lesions of ALS on the right would result in a left-sided deficit on the body. Damage to anterior trigeminothalamic fibers on the left would produce a corresponding right-sided deficit on the face. The medial lemniscus conveys vibratory, discriminative touch, and proprioceptive sensations. (p. 180–181, 184–185)

48. Answer B: This patient has a lateral medullary syndrome (also commonly called a posterior inferior cerebellar artery, or PICA syndrome) on the left; this correlates with the left-sided sensory loss on the face and right-sided sensory loss on the body. A lateral medullary lesion on the right would result in the same deficits, but on the opposite sides. The Parinaud, Weber, and Benedikt syndromes are all associated with lesions in the midbrain. (p. 180–181, 184–185, see also p. 136)

49. Answer B: Wilson disease (hepatolenticular degeneration) is an inherited error of copper metabolism. Plasma levels of copper are decreased; urinary levels are increased; and copper accumulates in the liver, lenticular nuclei, and kidneys. Wilson disease can be treated by reducing the level of dietary copper and administering a copper-chelating agent. Maintenance can be achieved by taking zinc, and treatment must be life-long. Ingestion of the other choices can cause serious illness and death. However, none of these is the causative agent in hepatolenticular degeneration. (p. 214–215)

50. Answer E: The dilator pupillae muscle of the iris is innervated by postganglionic sympathetic fibers whose cell bodies of origin are located in the ipsilateral superior cervical ganglion. Preganglionic sympathetic cell bodies are found in the intermediolateral cell column. Preganglionic parasympathetic cell bodies are found
in the Edinger-Westphal nucleus; axons of these cells terminate in the ciliary ganglion, which, in turn, innervates the sphincter pupillae muscle of the iris. The hypothalamus is the origin of hypothalamospinal fibers that project to the intermedialateral cell column. (p. 220–21)

51. Answer E: The deficits described for the man are consistent with a tumor on the root of the vestibulocochlear (VIII) nerve; these are correctly called a vestibular schwannoma because they arise from the Schwann cells on the root of the vestibular portion of the VIIIth nerve. Acoustic neuroma is an earlier, and now incorrect, designation for this lesion. Meningiomas arise primarily from the arachnoid layer, ependymomas from the cells lining the ventricular spaces, and a glioblastoma multiforme arises from astrocytes within the substance of the brain. (p. 228–229)

52. Answer A: This inherited disease is Friedreich ataxia; it initially appears in children in the age range of 8–15 years and has the characteristic deficits described. Huntington disease is inherited, but appears in adults; olivopontocerebellar atrophy is an autosomal dominant disease and gives rise to a different set of deficits. The cause of Parkinson disease is unclear, but it is probably not inherited; the Wallenberg syndrome is a brainstem lesion resulting from a vascular occlusion. (p. 204–205)

53. Answer B: A tumor in the foramen would damage the motor root of the trigeminal nerve and the mandibular root (sensory) of the Vth nerve. In this patient, the jaw deviates to the left and the sensory loss is on the left; this indicates that the tumor is on the left. The deviation of the jaw to the left is due to the action of the intact pterygoid muscles on the right (unlesioned side). Motor fibers on the trigeminal (V) nerve travel in association with the mandibular root and through the foramen ovale. Maxillary fibers are sensory for the upper jaw and cheek area of the face. (p. 202–203)

54. Answer C: The loss of abduction and adduction in one eye and of adduction in the opposite eye (the one-and-a-half syndrome) indicates a lesion in the area of the paramedian pontine reticular formation and abducens nucleus (in this case on the right side) and the adjacent medial longitudinal fasciculus (MLF). The lesion damages the ipsilateral abducens motor neurons, internuclear neurons passing to the contralateral MLF, and internuclear axons in the ipsilateral MLF coming from the contralateral abducens nucleus. Parinaud syndrome is a paralysis of upward gaze, and gaze palsies tend to be toward one side and may result from cortical lesions. Internuclear ophthalmoplegia is a deficit of medial gaze in one eye, assuming a one-sided lesion. (p. 192–193)

55. Answer A: Anterior trigeminothalamic collaterals that project into the dorsal motor nucleus of the vagus are an important link in the sneezing reflex, and the facial nucleus in the corneal reflex. Internuclear ophthalmoplegia is a deficit of medial gaze in one eye, assuming a one-sided lesion. (p. 192–193)

56. Answer E: The most anterior (ventral) portion of the medial lemniscus at mid-olivary levels contains second order fibers conveying discriminative touch, vibratory sense, and proprioception from the contralateral lower extremity. These axons will terminate in the lateral parts of the ventral posterolateral nucleus and, from there, be relayed to the posterior paracentral gyrus (the lower extremity area of the primary somatomotor cortex). The postcentral gyrus is the primary sensory cortex for the face (approximately the lateral one-third), upper extremity (middle one-third), and the trunk (medial). The anterior paracentral gyrus is the somatomotor cortex for the lower extremity. (p. 179–180)

57. Answer E: Syringomyelia is a cavitation in central areas of the spinal cord that results in damage to fibers conveying pain and thermal sensation as they cross the midline in the anterior white commissure. The loss is bilateral since fibers from both sides are damaged as they cross. Tabes dorsalis presents as posterior column deficits and lancinating pain; syringobulbia (cavitation within the brainstem) may have long tract signs and cranial nerve deficits; and PICA syndrome characteristically has alternating sensory losses (one side of face, opposite side of body). The Brown-Séquard syndrome has both sensory (anterolateral system and posterior column) and motor (corticospinal) deficits. (p. 180–181)

58. Answer A: There are basically only two areas where a relatively restricted lesion would result in weakness of both lower extremities. One is in caudal parts of the pyramidal decussation (damage to decussating corticospinal fibers traveling to the lumbar-sacral cord levels), and the other would be a lesion in the falx cerebri (such as a meningioma) damaging the lower extremity areas on the somatomotor cortex bilaterally. Decussating fibers in the rostral part of the pyramidal decussation terminate in cervical levels of the spinal cord. Damage to either the pyramid or the lateral corticospinal tract would result in a hemiplegia (pyramid-contra-lateral, lateral corticospinal tract-ipsilateral). Damage to the pyramids bilaterally would result in quadriplegia. (p. 190–191)

59. Answer C: The fatigability (progressive weakness), involvement of ocular muscles initially, followed by other muscle weakness, is characteristic of myasthenia gravis. Amyotrophic lateral sclerosis is an inherited disease that affects spinal and/or brainstem motor neurons and may result in upper or lower motor neuron symptoms; this disease is usually fatal within a few years. Multiple sclerosis is a demyelinating disease; Parkinson and Huntington diseases are neurodegenerative conditions that eventually have a dementia component. (p. 190, 202)

60. Answer C: The history and the combination of signs and symptoms seen in this woman indicate a probable diagnosis of myasthenia gravis and, consequently, a neurotransmitter disease at the neuromuscular junction. Damage to corticospinal and corticospinal terminals and to synaptic contacts within the basal nuclei and the cerebellum would result in motor deficits but not in the pattern seen in this woman. (p. 190, 202)

61. Answer A: The neurotransmitter at the neuromuscular junction is acetylcholine; a blockage of postsynaptic nicotinic acetylcholine receptors is the cause of the motor deficits characteristically seen in patients with myasthenia gravis. A loss of dopamine results in motor deficits that are not seen in this woman. Glutamate and GABA are found in many pathways involved in motor function but are not located at the neuromuscular junction. Serotonin is found in pathways related to the basal nuclei, raphe nuclei, and the hypothalamus. (p. 190, 202)
62. **Answer D:** A lesion in the medial longitudinal fasciculus (MLF) on the right interrupts axons of the interneurons that arise from the left abducens nucleus and pass to oculomotor motor neurons on the right innervating the medial rectus muscle (nuclear ophthalmoplegia). Damage to the abducens nucleus will indeed destroy these interneurons, but will also result in an inability to abduct the eye on the ipsilateral side. Injury to the MLF on the left would result in an inability to adduct the left eye, and a lesion in the PPRF would most likely produce a bilateral horizontal gaze palsy. (p. 192–193, 200–201)

63. **Answer C:** A fracture through the jugular foramen would potentially damage the glossopharyngeal (IX), vagus (X), and spinal accessory (XI) nerves. The major observable deficit would be a loss of the efferent limb of the gag reflex and a paralysis of the ipsilateral trapezius and sternocleidomastoid muscles. (drooping of the shoulder, difficulty elevating the shoulder especially against resistance, difficulty turning the head to the contralateral side). Involvement of facial muscles would suggest damage to the internal acoustic or stylomastoid foramina; this would also be the case for the efferent limb of the corneal reflex. Diplopia and ptosis would suggest injury to the superior orbital fissure, as all three nerves controlling ocular movement traverse this space. The hypoglossal nerve (which supplies muscles of the tongue) passes through the hypoglossal canal. (p. 200–201)

64. **Answer E:** The constellation of signs and symptoms experienced by this boy are characteristic of Wilson disease, also called hepatolenticular degeneration. These may include movement disorders, tremor, the Kayser-Fleischer ring at the corneoscleral margin, and eventual cirrhosis of the liver. Huntington and Parkinson diseases are predominately motor problems in the early stages and Pick disease is a degenerative disease of the cerebral cortex and cells of the fastigial nucleus project to the vestibular nuclei. (p. 208–211)

65. **Answer A:** A tumor impinging on the midline of the optic chiasm would damage crossing fibers from both eyes that are coming from the nasal retinas and would reflect a loss of all, or part of both temporal retinal fields. Between 60% and 70% of pituitary adenomas are prolactin-secreting tumors. Right or left homonymous hemianopsia (the nasal visual field of one eye and the temporal visual field of the other eye) are seen following lesions of, respectively, the left and right optic tracts. Quadrantanopsias result from lesions in the optic radiations. (p. 220–221)

66. **Answer C:** The flocculonodular lobe and the fastigial nucleus receive input from the vestibular apparatus (primary vestibulocerebellar fibers) and from the vestibular nuclei (secondary vestibulocerebellar fibers). In turn, the Purkinje cells of the flocculonodular cortex and cells of the fastigial nucleus project to the vestibular nuclei as cerebellar corticovestibular and cerebellar efferent fibers, respectively. While other areas of the cerebellar cortex may have a small projection to the vestibular nuclei, this is not significant compared to that of the flocculonodular lobe. (p. 228–229)

67. **Answer B:** Quadrantanopia, a loss of approximately one quarter (a quadrant) of the visual field, is seen in lesions in the optic radiations (geniculocalcarine radiations). The visual loss is in the visual field contralateral to the side of the lesion. Lesions in the lower portions of the radiations result in deficits in the contralateral superior quadrants, while lesions in the upper portions of the radiations result in deficits in the contralateral lower quadrants. Consequently, in this boy (with a superior right quadrantanopia), the lesion is in the lower portions of the optic radiations in the left temporal lobe (Meyer-Archambault loop). The lesion in the chiasm would result in a bitemporal hemianopsia. (p. 220–223)

68. **Answer E:** Hemiballismus is the result of a lesion largely confined to the subthalamic nucleus on the side contralateral to the deficit. These movements are violent, flinging, unpredictable, and uncontrollable. The abnormal movements are contralateral to the lesion because the expression of the lesion is through the corticospinal tract. Lesions in the left subthalamic nucleus would result in a right-sided problem. Damage in the motor cortex would be seen as a contralateral weakness, and cell loss in the substantia nigra would result in motor deficits characteristic of Parkinson disease (resting tremor, bradykinesia, stooped posture, festinating gait). (p. 216–217)

69. **Answer B:** The inability to perform a rapid alternating movement, such as pronating and supinating the hand on the knee, is dysdiadochokinesia. This is one of several cardinal signs of cerebellar disease or stroke. Dysmetria is an inability to judge power, distance, and accuracy during a movement, and dysarthria is difficulty speaking. A resting tremor is seen in diseases of the basal nuclei, and an intention tremor is seen in cerebellar lesions. (p. 208–211)

70. **Answer B:** The tremor that worsens as this man attempts to bring his index finger to his nose is called an intention tremor, sometimes referred to as a kinetic tremor. This type of tremor is one cardinal sign of cerebellar lesions. A resting tremor is seen in diseases of the basal nuclei and a static tremor (postural tremor) is seen in the trunk and extremities in a static position. Dysmetria is an inability to judge distance, power, or accuracy during a movement. The rebound phenomenon is an inability of agonist and antagonist muscles to rapidly adapt to changes in load. (p. 208–211)

71. **Answer C:** The signs and symptoms in this man clearly indicate a lesion in the cerebellum on the left side. The cerebellar nuclei on the left (lesion side) project to the contralateral thalamus (right) and from here to motor cortical areas (also right). The motor cortex projects, via the corticospinal tract and its decussation, back to the side of the body, excluding the head, on which the lesion is located (left cerebellum). The motor expression of the cerebellar deficit is through the corticospinal tract. The man’s left-sided deficits are not consistent with a right cerebellar lesion, and the deficits are not consistent with a midbrain lesion. Lesions of the basal nuclei would result in a different set of motor disorders. (p. 208–211)

72. **Answer B:** The superior cerebellar artery serves the cortex on the superior surface of the cerebellum and most of the cerebellar nuclei on the same side; in this case, it is the left artery. The anterior inferior cerebellar artery serves the cortex on the lateral inferior surface of the cerebellum and a small caudal tip of the dentate nucleus. A lesion that involves primarily the cerebellar cortex will not result in long-term deficits. A lesion that involves cortex plus nuclei or primarily nuclei, especially in an older patient (as in this
man), is likely to result in long-term deficits. The lenticulostriate arteries serve the basal nuclei. (p. 208–211)

73. Answer A: One cause of hemifacial spasm (intermittent and abnormal contractions of the facial muscles) is compression of the facial root by a loop of the anterior inferior cerebellar artery, or perhaps one of its larger branches. Aberrant loops of the superior cerebellar artery may compress the trigeminal root (trigeminal neuralgia), and the posterior inferior cerebellar artery serves the lateral medulla and medial regions of the cerebellum. The anterior and posterior spinal arteries serve areas of the medulla. (p. 202–203)

74. Answer B: The anterolateral system and the medial lemniscus are adjacent to each other in lateral portions of the midbrain and are served largely by the same vessel(s), these being penetrating branches of the quadrigeminal plate. This area may also receive some blood supply from the posterior choroidal arteries. Throughout the spinal cord, medulla, and into about the mid- to more rostral pons, these fiber bundles are spatially separated from each other and have separate blood supplies. (p. 137, 178–181)

75. Answer B: Fibers in the left medial lemniscus conveying position sense from the right upper extremity originate from cell bodies located in the right cuneate nucleus. These cuneate neurons give rise to axons that form the internucal arcuate fibers that arch towards the midline, cross, and collect to form the contralateral medial lemniscus. The left cuneate nucleus sends axons to the right medial lemniscus, and the gracile nucleus (right or left) conveys information from the lower extremity. Posterior root ganglia neurons project to the gracile or cuneate nuclei. (p. 178–179)

76. Answer E: Dystonia is a movement disorder characterized by abnormal, sometimes intermittent, but frequently sustained, contractions of the muscles of the trunk and extremities that force the body into a twisted posture. Dystonia may be seen in patients with diseases of the basal nuclei. Dysthria is the inability to judge the distance and trajectory of a movement. Dysnea is difficulty breathing; this may result from heart and/or lung disorders as well as from neurologic disorders. Dysphagia is difficulty swallowing, and dysarthria is difficulty speaking. (p. 124–215)

77. Answer E: Transection of the optic nerve (on the left in this man) eliminates the afferent limb of the pupillary light reflex, but the efferent limb, via the oculomotor nerve, is intact. Consequently, there is a loss of both the direct response (in the blind eye) and the consensual response (in the good eye) when light is shined in the blind eye, because the afferent limb is eliminated and no input is getting to the center from which the efferent limb originates. On the other hand, light shined into the good eye (right in this man) results in a direct pupillary response (in the good eye) and a consensual pupillary response in the blind eye because the efferent limb of this reflex is not damaged for the blind eye. Other combinations of responses may occur as a result of lesions in other portions of the nervous system. (p. 220–221)

78. Answer B: In addition to the motor deficits characteristic of this disease, MRI would reveal a spongy degeneration (with cavitations) of the lenticular nucleus most noticeable in the putamen. There may also be a spongy degeneration in areas of the cerebral cortex. Atrophy of frontal and temporal lobe gyri is seen in Pick disease; loss of nigral cells is characteristic of Parkinson disease; and loss of the caudate nucleus (especially noticeable as absence of its head) is seen in Huntington disease. Lacunae are usually seen in patients who have had small strokes. (p. 214–215)

79. Answer D: The inability of this man to control the distance, power, and accuracy of a movement is dysmetria; this is characteristically seen in cerebellar lesions. Dysphagia is difficulty swallowing, and dysarthria is difficulty speaking. The inability to perform rapid alternating movements is dysdiadochokinesia, and bradykinesia is a slowness to initiate movement. The latter is characteristic of individuals with disease of the basal nuclei. (p. 208–211)

80. Answer A: The territory served by the anterior choroidal artery includes the optic tract, inferior portions of the posterior limb of the internal capsule, thalamocortical radiations within the posterior limb, and structures in the temporal lobe. The left-sided deficits indicate a lesion on the right side. A lesion of the right optic tract results in a loss of vision in the opposite (left) visual fields; this being the temporal visual field of the left eye and the nasal visual field of the right eye (left homonymous hemianopsia). This constellation of deficits is known as the anterior choroidal artery syndrome. Quadrantanopia specifies a lesion in a portion of the optic radiations, and a nasal hemianopsia indicates a small lesion in the lateral aspect of the optic chiasm on one side. (p. 158–159, 220–223)

81. Answer B: This woman has sensory losses on the left side of her face and body that include pain/thermal sensations and the general category of proprioception (discriminative touch, vibratory and position sense); this is a hemianesthesia, a loss of sensation on one side of the body. This is a result of damage to thalamocortical fibers projecting from the ventral postero medial and ventral posterolateral thalamic nuclei to the somatosensory cortex. Alternating hemianesthesia refers to a sensory loss on one side of the face and on the contralateral side of the body. A sensory level is a characteristic of lesions in the spinal cord, and paresthesia refers to an abnormal spontaneous sensation not a loss. A superior alternating hemiplegia is a motor deficit. (p. 158–159, 178–181, 220–223)

82. Answer B: The corticospinal fibers traversing the inferior portions of the posterior limb of the internal capsule are damaged by an occlusion of the anterior choroidal artery; a left-sided deficit correlates with a lesion on the right side, especially when taking into consideration the concurrent visual loss. Damage to corticospinal fibers on the left would result in a right-sided deficit. The somatomotor cortex is not involved in the lesion. While thalamocortical fibers are certainly damaged in this lesion, the deficits related to corticospinal fiber involvement predominate. (p. 190–191)

83. Answer B: Sensorineural hearing loss, also called nerve deafness, results from lesions or diseases that involve the cochlea or the cochlear portion of the vestibulocochlear nerve. Obstructions of the external ear or diseases of the middle ear result in conductive deafness (conductive hearing loss). Lesions in the inferior colliculus, auditory cortex, or other areas within the brain may result in difficulty localizing, interpreting, or understanding sound but do not result in total deafness in one ear. (p. 226–227)

84. Answer C: Laminae 1, 4, and 6 receive input from the ganglion cells in the contralateral retina. Laminae 2, 3, and 5 receive an ipsilateral input; laminae 1 and 2 are the magnocellular layers of the
lateral geniculate nucleus; and laminae 3, 4, 5, and 6 are its parvocellular layers. (p. 222)

85. Answer D: Sydenham chorea is a disease of childhood thought to be an autoimmune disorder seen in children as a sequel to a hemolytic streptococcus infection. In most children the disease is self-limiting and the patient recovers with no permanent deficits. Huntington disease, Parkinson disease, and senile chorea present with motor deficits that partially resemble those seen in this girl but these are diseases of adults or the elderly. Weber syndrome (a superior alternating hemiplegia) is a motor deficit involving the oculomotor nerve on one side and the corticospinal tract on the opposite side. (p. 214–215)

Review and Study Questions for Chapter 8

1. Which of the following arteries is generally found in the area of the cingulate sulcus and has branches that serve the lower extremity areas of the somatomotor and somatosensory cortex?
   - (A) Callosomarginal
   - (B) Frontopolar
   - (C) Internal parietal
   - (D) Parietooccipital
   - (E) Pericallosal

2. A 44-year-old woman presents to her family physician with intermittent headache and the complaint that she can’t see in her left eye. The examination reveals that the woman is blind in her left eye. When a light is shined into her left eye there is no direct or consensual pupillary light reflex. Magnetic resonance angiography (MRA) shows a large aneurysm at the origin of the ophthalmic artery. Which of the following represents the usual point of origin of this vessel?
   - (A) Cavernous part of the internal carotid artery
   - (B) Cerebral part of the internal carotid artery
   - (C) First segment (A1) of the anterior cerebral artery
   - (D) First segment (M1) of the middle cerebral artery
   - (E) Petrous part of the internal carotid artery

3. The venous phase of an angiogram of a 52-year-old man suggests a small tumor at what the neuroradiologist refers to as the venous angle. Which of the following points most specifically describes the position of the venous angle?
   - (A) Where the internal cerebral vein meets the great cerebral vein
   - (B) Where the superficial middle cerebral vein meets the cavernous sinus
   - (C) Where the thalamostriate vein turns to form the internal cerebral vein
   - (D) Where the transverse sinus turns to form the sigmoid sinus
   - (E) Where the vein of Labbé meets the vein of Trolard

4. The superficial middle cerebral vein forms a direct anastomotic junction with which of the following venous structures on the lateral aspect of the cerebral hemisphere?
   - (A) Cavernous sinus
   - (B) Confluence of sinuses
   - (C) Superior sagittal sinus
   - (D) Transverse sinus
   - (E) Veins of Labbé and Trolard

5. The coronal MRI of a 69-year-old man reveals an infarcted area in the region of the cerebral hemisphere lateral to the internal capsule but internal to the insular cortex. A comparison of coronal and sagittal MRI suggests that the vessels involved are branches of the middle cerebral artery. Which of the following branches or segments of the middle cerebral artery are most likely involved in this man?
   - (A) Anterior and polar temporal branches
   - (B) Insular branches
   - (C) Lenticulostriate branches
   - (D) Opercular segment
   - (E) Uncal artery

6. The anterior and middle cerebral arteries are the terminal branches of which of the following vascular trunks?
   - (A) Basilar artery
   - (B) Cavernous part of the internal carotid
   - (C) Cerebral part of the internal carotid
   - (D) External carotid artery
   - (E) Petrous part of the internal carotid

7. The superior sagittal sinus, straight sinus, and transverse sinuses converge at which of the following landmarks?
   - (A) Clivus
   - (B) Confluens sinuum
   - (C) Great cerebral vein
   - (D) Jugular foramen
   - (E) Venous angle

8. A 47-year-old woman is brought to the emergency department by her husband. She has a severe headache, nausea, and is somnolent. The examination reveals that the woman is hypertensive and has papilledema. MRI shows evidence of cerebral edema, bilateral infarcted areas in the thalamus, and a large sinus thrombosis that is blocking the egress of blood through the vascular system. This thrombus is most likely located in which of the following venous structures?
   - (A) Inferior sagittal sinus
   - (B) Left sigmoid sinus
   - (C) Right transverse sinus
   - (D) Straight sinus
   - (E) Superior sagittal sinus
9. A 39-year-old man presents to his family physician with a complaint of difficulty swallowing. The history reveals that the man has had severe recurrent headaches over the last 5 days and suffered several bouts of vomiting. The examination confirms the difficulty swallowing, and reveals that the man’s voice is hoarse and gravely, and that he is unable to elevate his left shoulder against resistance. MRI shows a dural sinus thrombosis. Based on this man’s deficits, which of the following represents the most likely location of this thrombus?

- (A) Left cavernous sinus
- (B) Left jugular bulb
- (C) Left transverse sinus
- (D) Right jugular bulb
- (E) Straight sinus

10. Which of the following vessels forms a characteristic loop in the cisterna magna that is prominent on lateral angiograms and, in the process, supplies blood to the choroid plexus of the fourth ventricle?

- (A) Anterior inferior cerebellar artery
- (B) Posterior inferior cerebellar artery
- (C) Posterior spinal artery
- (D) Superior cerebellar artery
- (E) Vertebral artery

11. The MRI of a 42-year-old man shows a small tumor in the choroid plexus of the third ventricle. Angiogram and MRA suggest that this tumor contains numerous vascular loops. Which of the following represents the blood supply to this portion of the choroid plexus?

- (A) Anterior choroidal artery
- (B) Choroidal branches of AICA
- (C) Choroidal branches of PICA
- (D) Lateral posterior choroidal artery
- (E) Medial posterior choroidal artery

12. The angiogram of a 56-year-old woman shows an aneurysm originating from the lateral aspect of the basilar bifurcation and extending into the space between the posterior cerebral and superior cerebellar arteries. Based on the structure(s) located at this point, which of the following deficits would most likely be seen in this woman?

- (A) Constriction of the ipsilateral pupil
- (B) Inability to look down and out with the ipsilateral eye
- (C) Inability to look laterally with the ipsilateral eye
- (D) Inability to look up, down, or medially with the ipsilateral eye
- (E) Loss of pain and thermal sensation from the ipsilateral side of the face

13. The position of the posterior communicating artery, as frequently seen in MRA, is an important landmark that specifies the intersection of which of the following?

- (A) A1 and A2 segments
- (B) M1 and M2 segments
- (C) M2 and M3 segments
- (D) P1 and P2 segments
- (E) P2 and P3 segments

14. A 16-year-old boy with developmental delay has been followed since birth by a pediatric neurologist. A recent MRA is done in which major arteries and venous sinuses are visualized. It is concluded that the pattern of the boy’s venous sinuses is essentially normal. Which of the following describes the usual pattern of the superior sagittal sinus at the confluence of sinuses?

- (A) Always drains equally into the right and left transverse sinuses
- (B) Usually drains into the left transverse sinus
- (C) Always drains into the right transverse sinus
- (D) Usually drains into the left transverse sinus
- (E) Usually drains into the right transverse sinus

**Answers for Chapter 8**

1. Answer A: The callosomarginal artery lies generally in the region of the cingulate sulcus and gives rise to branches (paracentral branches) that distribute to the anterior and posterior paracentral gyri. The pericallosal artery is located immediately superior to the corpus callosum and the frontopolar artery serves the medial aspect of the frontal lobe. The internal parietal arteries are the terminal branches of the pericallosal artery; these vessels distribute to the medial portion of the parietal lobe, the precuneus. The parietooccipital artery is one of the terminal branches (part of P4) of the posterior cerebral artery. (p. 29, 240)

2. Answer B: In most instances (approximately 80–85%), the ophthalmic artery originates from the cerebral portion of the internal carotid artery just as this parent vessel leaves the cavernous sinus and passes through the dura. In a small percentage of cases the ophthalmic artery may originate from other locations on the internal carotid artery, including its cavernous portion. This vessel does not originate from the petrous portion of the internal carotid or from anterior or middle cerebral arteries. (p. 25, 240)

3. Answer C: The point at which the thalamostriate vein (also called the superior thalamostriate vein at this position) abruptly turns 180° to form the internal cerebral vein is called the venous angle. This angle is located immediately caudal to the position of the interventricular foramen and is, therefore, an important landmark. The thalamostriate vein is located in the groove between the thalamus and the caudate nucleus. At the superior aspect of the thalamus, this vein is the superior thalamostriate vein, and, on the inferior surface, it is called the inferior thalamostriate vein. None of the other choices is involved in the formation of the venous angle. (p. 241)

4. Answer E: The superficial middle cerebral vein is a comparatively obvious venous structure on the lateral surface of the hemisphere that communicates directly with the veins of Trolard (to the superior sagittal sinus) and Labbé (to the transverse sinus). The superficial middle cerebral vein also communicates with the cavernous sinus, but this sinus in not on the lateral aspect of the hemisphere as specified in the question. The other choices do not receive venous blood directly from the superficial middle cerebral vein. (p. 19, 241)

5. Answer C: The position of this lesion is in that portion of the hemisphere occupied by the lenticular nucleus; the lenticulostr-
6. Answer C: As the internal carotid artery exits the cavernous sinus, it becomes the cerebral part of the internal carotid and, after giving rise to three important small branches (ophthalmic, anterior choroidal, posterior communicating), bifurcates into the anterior and middle cerebral arteries. These two cerebral vessels are the terminal branches of the cerebral part of the internal carotid artery. In approximately 70–75% of specimens, the anterior cerebral artery is the smaller of these two terminal branches. None of the other choices gives rise to the anterior and middle cerebral arteries. (p. 242)

7. Answer B: The superior sagittal sinus, straight sinus, the two transverse, and the occipital sinus (when present) converge at the confluence of sinuses (confluens sinus), which is located internal to the external occipital protuberance. The venous angle is the junction of the thalamostriate and the internal cerebral veins, and the great cerebral vein (of Galen) receives the internal cerebral veins and several smaller veins including the basal vein (of Rosenthal) and empties into the straight sinus. The jugular foramen contains the transition from the sigmoid sinus to the internal jugular vein and the terminus of the inferior petrosal sinus. The clivus is composed mainly of the basal part of the occipital bone; this is the location of the basilar plexus. (p. 19, 23, 243–245)

8. Answer D: A key observation in this woman is the bilateral infarcted areas in the thalamus. The straight sinus receives venous flow from both internal cerebral veins; a blockage of flow through the straight sinus would adversely affect both thalami. Such a lesion would also cause potential damage to the medial temporal lobe due to the disruption of flow through the basal vein (of Rosenthal). None of the other choices receives venous drainage directly from the thalamus. (p. 29, 248, 250)

9. Answer B: The deficits experienced by this man (difficulty swallowing, hoarseness, inability to elevate the left shoulder against resistance) point to damage to the glossopharyngeal (IXth), vagus (Xth), and spinal accessory (XIth) nerves or to their roots. All three of these cranial nerves exit the jugular foramen along with the continuity of the sigmoid sinus with the internal jugular vein (jugular bulb or bulb of the jugular vein). In this case, the venous thrombosis is at the left jugular bulb and impinging on these three cranial nerve roots. Dural sinus thrombosis of the other choices may cause certain deficits, but not those experienced by this man. (p. 244, 250)

10. Answer B: The posterior inferior cerebellar artery (commonly called PICA) originates from the vertebral artery, courses around the lateral aspect of the medulla, loops sharply into the space of the cisterna magna (giving off small branches to the choroidplexus in the fourth ventricle), then joins the inferior and medial surface of the cerebellum. None of the other choices forms prominent vascular structures in the cisterna magna or serves the choroid plexus of the fourth ventricle. (p. 246)

11. Answer E: The medial posterior choroidal artery originates from the P2 segment of the posterior cerebral artery, arches around the midbrain, and enters the caudal end of the third ventricle. The anterior choroidal artery serves the choroid plexus in the temporal horn, and the lateral posterior choroidal artery serves the glosum choroideum and extends into the plexi of the temporal horn and the body of the ventricle. These patterns may be somewhat variable. Choroidal branches of anterior inferior cerebellar artery (AICA) serve the choroid plexus extending through the foramen of Luschka, and these branches from the posterior inferior cerebellar artery (PICA) serve the plexus within the fourth ventricle. (p. 251)

12. Answer D: The oculomotor nerve (III) is located between the posterior cerebral and superior cerebellar arteries and may be damaged by aneurysms at this location. Most eye movement would be lost (the trochlear (IV) and abducens (VI) nerves are intact) and the ipsilateral pupil would be dilated, not constricted. Sensation from the face is carried on the trigeminal nerve. Movement deficits related to injury to the IVth nerve (looking down and out) or the VIth nerve (looking laterally) are not affected. (p. 39, 40, 247, 252)

13. Answer D: The posterior communicating artery originates from the cerebral part of the internal carotid artery and courses caudally to join the posterior cerebral artery (PCA). The part of the PCA medial to this intersection is the P1 segment and the part of the PCA immediately lateral to this junction is the P2 segment. Important branches arise from both of these parts of the PCA. None of the other choices have any direct relationship to the points of origin of the posterior communicating artery. (p. 25, 247, 249)

14. Answer E: The drainage pattern of the superior sagittal sinus at the confluence of sinuses is variable, including about equal to both transverse sinuses or mainly to the right or to the left. However, the usual pattern is for the superior sagittal sinus to drain predominantly into the right transverse sinus. (p. 245)
